AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 1. SCRANTON, PA., AUGUST, 1891. WITH WHICH IS COMBINED THE MINING HERALD.

AN ELEMENTARY TREATISE ON THE PRINCIPLES OF COAL-MINING.

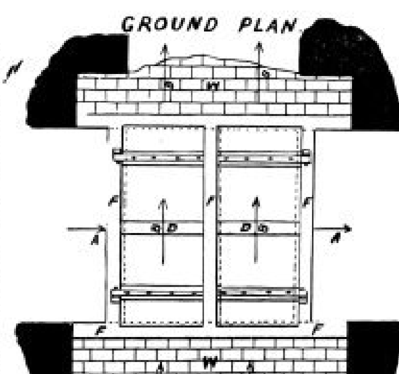
For the Use of Candidates for Mine-Foremen's Certificates, Mining Students, Mine-Foremen, Mine-Superintendents, Mining-Engineers, etc.

BY A. A. ATKINSON, DURHAM, ENG.

In the workings of a colliery it occasionally occurs that it is necessary a current of fresh or intake air may have to cross a current of return air, and it is requisite and essential that the two currents should not intermix with each other; and this passage is affected by means of an air-crossing, one current passing either above or below the other, but usually the return current is taken above the intake current, though not necessarily so. In case the crossing occurs in a main intake road where there is a considerable volume of fresh air going into the workings and where the crossing will probably have to last some considerable time, in some instances for a number of years, it is usual to put in a substantial air-crossing, and these are generally built with brick or stone side walls, with a brick arching built across from the side walls, the return air usually passing over the top of the arching. In case the seam is liable to a heavy thrust or pressure from the strata lying either immediately above or below the seam of coal, and from which the brick arching would be likely to suffer damage and become leaky, instead of the arching it may be of advantage to put on a wooden top for the crossing, as this is less liable to derangement by the pressure and likewise more easily remedied when it does become injured; besides occupying less height than the arching, and being cheaper also. The side walls are built of suitable thickness, say from 12 to 24 inches, according to the strength considered necessary, and the space between them being from say 6 to 10 or 12 fee. to suit the purposes for which the road is required, such as kind of haulage and size of airway needed. In case a brick arching is decided on, the two side walls are built up about 3 or 4 feet in height, commencing them on as solid a foundation as can conveniently be got. The arching may consist of 2, 3, or 4 courses of bricks according to the strength required. The nearer the shape of the arching is to a true semicircle, the stronger it will be.

Perhaps the best air-crossing considered from a point of strength is the "natural air-crossing," which is one made in the adjacent strata, as it may be a stone drift or tunnel driven from the seam and passing either above or below the intake airway. This is perhaps a costly method, but in case of an explosion occurring a considerable advantage would be likely to be derived from a natural crossing, as the force of the explosion might be insufficient to cause such damage as to allow fresh air to escape at this point into the return airway. Natural air-crossings are, however, very rarely made; it is much better to try and avoid explosions themselves, than think of counteracting their damages.

The wooden topped air-crossing is one that is much adopted, and consists of the two side walls, similar to those in an arched crossing but built somewhat higher, say 5, 6, or 7 feet in height. On the top of each of these walls a wooden beam or balk is built in, the beam being about 12 inches wide by 3 or 4 inches thick, and the length of it a little longer than the air-crossing is to be. Then cross-pieces of wood are laid from beam to beam, these cross-pieces generally being about 9″ or a foot wide, and 3″ thick; their joints may be tongued and grooved to make them air tight, or simply planed and laid close to each other with a thin lathe of wood nailed



over the joints on either the top or bottom side of them, or perhaps better on both sides, so as to make them as air tight as possible. The cross-pieces are spiked at both ends to the beams on which they rest, to keep them in position.

It is occasionally necessary to construct an air-crossing in a set of workings near the face and to last generally on such occasions for only a short time. This perhaps most frequently happens in working out the pillars of coal in a "Broken Flat or District." It is usual in such cases to construct the crossing wholly of wood and on a small scale, as compared with crossings over which large volumes of air have to pass and which have to stand in use for a much longer period. The ordinary ½″ brattice wood is used. The two sides are fitted up and nailed to props set for the purpose. Then the top is put on and the work finished by plastering up all the joints with hair lime. This in cases of thick seams may be done without taking down any roof-stone to allow the return-air to pass over the top of the crossing, but in case there is not sufficient height for this in the ordinary thickness of the seam, it may be necessary to take down some stone for the required height.

The three accompanying sketches show the plan of a valve air-crossing. It has been built with the hope that it may be of service in preventing the great delay, so frequently experienced at crossings, in attempting to restore the ventilation after explosions, which delays are, no doubt, the cause of a great many deaths. Perhaps the only more perfect crossing than this, is that formed by a drift overlapping the fresh air drift, or natural crossing; but it is not always convenient to have such crossings, as a strong roof to form them in is required.

In a few cases crossings have been formed by an old boiler, put together in segments, minus its ends.

FIRE-DAMP.

As carbureted hydrogen gas is the most important one met with in coal mines, it may be useful to give further particulars of it. It is well known to all concerned in mining, inasmuch as it is most frequently met with, and as having been a means of causing the loss of so many valuable lives. When found in any considerable quantity it constitutes perhaps the greatest danger the mining world can have to contend with. It is given off more or less freely by almost all coal seams, and also from the adjacent strata. It appears to be pent up in the small pores of the coal and stone, and when the working of them takes place the gas is liberated and becomes mixed with the surrounding atmosphere. From its lightness it finds its way to the roof of the workings, as it is lighter than air by almost one-half—1,000 cubic feet of fire-damp at 32° Fahr., and 30″ barometer, weighing 45·22 lbs., whilst the same quantity of air under the same conditions weighs 80·79 lbs. It has rather a pungent smell, some people resembling it to the smell of garlic. Fire-damp strictly speaking does not consist of this one gas (carbureted hydrogen), but others are intermixed with it, though perhaps only to a small extent. Carbureted hydrogen constituting over 90% of fire-damp, as will be seen from the following table:

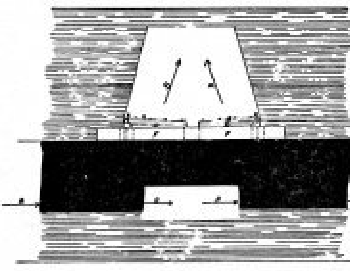
FIRE-DAMP ANALYSES.

Name of Colliery and Seam.	CH_4	N.	O.	CO_2.	H.	
Wallsend, from Pipe on Surface	92·8	6·9	·	0·3	·	= 100·00
Jarrow, Bensham Seam	81·1	14·2	0·6	2·1	·	= 100·00
Hebburn " "	86·0	12·3	·	1·7	·	= 100·00
Jarrow, Low Main Seam	79·7	14·3	3·0	2·0	0·3	= 99·30
Jarrow, Five Quarter Seam	93·4	4·9	·	1·7	·	= 100·00
Oakwellgate, " "	98·2	1·3	·	0·5	·	= 100·00
Hebburn, Seam 24 feet below Bensham	92·7	6·4	·	0·9	·	= 100·00

When met with this gas has to be diluted and so rendered harmless by a sufficient amount of fresh air. Sometimes it comes off as a blower without any previous warning, and some blowers have been known to render foul large areas of workings and large volumes of fresh air in a very short time; such force have they come away with sometimes from the seam of coal itself and at other times from the floor or roof stone. Then again in extracting the pillars of coal or in the "broken workings" large volumes of fire-damp are known to exist in the goaves or exhausted districts.

In detecting fire-damp the usual method is to use a locked safety-lamp, on the flame of which the presence of the gas can be seen: on nearing a place where it is thought likely for the gas to be, the flame of the lamp should be carefully lowered by pulling down the wick until a small light is attained and the lamp then slowly raised, at the same time keeping a careful watch on the flame. Should fire-damp be present it will quickly become known through its action on the flame, which will slightly rise in length as though something were drawing it upwards. If the wick of the lamp be further lowered to a very small light the gas may be seen to burn within the gauze with a blue flame and surrounding the flame of the lamp. It requires practice to become able to detect the gas, and every possible care should be taken that no harm befalls the lamp, and that no inexperienced person is allowed to go

END VIEW.



where gas is, by having every place known to contain it properly fenced off, in order that no unauthorized person may approach it. The consequences of an explosion of fire-damp are sometimes most terrible—and few people who have not had an experience of seeing the effects of one can form an idea of the results. The intensity of an explosion depends on many circumstances, such as the amount and composition of the gas present, nature of the workings—whether dry and dusty or damp, and if dry and dusty then the nature and amount of coal-dust may greatly intensify the explosion. Fire damp, when mixed with air, acts in a varying manner when ignited, according as the mixture of the gas and air varies. It has been discovered that when mixed with air in the proportion of one volume of fire-damp to 9½ volumes of air the mixture is at its most explosive point—as the quantity of air increases or decreases from this proportion so the explosive force or power diminishes; till at 5 volumes of air to one of gas it explodes but weakly, and similarly with 13 volumes of air to one of gas an explosion would only be slight. The force that is displayed by an explosion may be almost said to be incalculable, owing to a want of knowledge of the amount and chemical mixture of the explosive gas, though it may be worked out in theory, as is shown in the following, by a well known mining engineer:

1 lb. of CH_4 burning to CO_2 and H_2O gives off 23,550 units of heat. Suppose the initial temperature to be 62° Fahr. = 521° absolute.

1 lb. CH_4 = 12 oz. of C + 4 oz. of H.

12 oz. of C + 32 oz. of O = 2·75 lbs. CO_2.

4 oz. of H + 32 oz. of O = 2·25 lbs. H_2O.

And 64 oz. of O are contained in about 17 lbs. of air.

We have then, taking specific heat at constant volume,

CO_2 2·75	× ·1711 = ·470 units of heat to raise	2·75 lbs. of CO_2 one degree.			
H_2O 2·25	× ·364 = ·819	"	"	2·25 lbs. of H_2O	"
N 13	× ·1727 = 2·245	"	"	13 00 lbs. of N	"
18	3·534			18·00	

Then the degrees the mixture will be raised are

$$\frac{23550}{3 \cdot 534} = 6663^\circ \text{ Fahr.}$$

and the volume it will seek to attain $= \dfrac{521 + 6663}{521} = 13 \cdot 8$,

that is the steady pressure due to the explosion = 13·8 atmospheres; but to this must be added a considerably increased force due to shock, the amount of which can not be calculated. When it is remembered that 13·8 atmospheres are equal to 30,000 lbs. per square foot, whereas the force of a hurricane moving at the rate of 100 miles an hour is only 50 lbs. per square foot, some idea of the terrific force of an explosion may be realized.

When fire-damp is present in the air to the extent of only 2% in volume it just becomes detectable with an ordinary safety-lamp, and when present in greater proportion it is more easily detected. In some mixtures the flame of a safety-lamp is immediately extinguished. A more recently discovered method of examining the air in collieries by means of a safety-lamp burning alcohol enables a smaller quantity of fire-damp to be detected than with the ordinary safety-lamp. Perhaps a few words on this recent improvement may be pardoned. The new lamp consists essentially of an ordinary Davy lamp on a slightly enlarged scale, and instead of burning Colza oil is made to burn methylated spirits of wine, but preferably alcohol. A wick of a circular shape, and improved if made of silk, is employed and passed over a round tube, the height of which is regulated by means of a screw passing through the bottom of the lamp. A short conical chimney is placed round the flame, and the latter is so manipulated by the screw as not to appear above the top of this chimney when burning in pure air; but the top of the flame should be exactly level with the top of the chimney. After having carefully adjusted the flame in pure air, on taking the lamp into a mixture of fire-damp and air the spirit flame shows an elongated flame of light, a good deal larger than would be seen in the case of the ordinary vegetable or animal oils being used. The greatest possible care should be taken in treating this lamp and it ought never to be taken into a place where the atmosphere consists of anything even approaching a very explosive mixture. The inventor of the lamp—Herr Pieler—only intended it for use in the laboratory, to be used in connection with samples of air taken from the mine. The ordinary gauze of the lamp is protected by means of a thin iron shield covering the whole of the lamp and fitted with holes at the top and bottom, thus shielding the flame from the current. A small graduated glass window is fixed in the iron shield to enable the flame to be watched. The reservior of the lamp is filled with alcohol, care being taken not to overcharge it. On lighting the lamp it needs to have the flame adjusted most carefully "in a dark place," so that the top of it shall exactly reach the upper edge of the conical chimney. As much depends on this adjustment it requires considerable practice to become able to do it accurately. If the lamp becomes heated its accuracy cannot be depended on, and further it very quickly becomes dangerous. In an atmosphere with so small a volume as ¼ per cent. of fire-damp present, there is seen above the upper edge of the small conical chimney, a faint dun-colored light whose edges and tapered point are rendered indistinct by the reflection, and whose height is about 1½ inches.

Fire-damp, if breathed in an undiluted state, would soon cause death—and even in a strong mixture of it and air a curious sensation is at once felt by any one who enters into it; the head becomes light and the drums of the ears feel as though they were being tightened. The presence of this gas in mines is one of the reasons that has caused the ventilation of them to be one of the crucial points in their management.

The following will show the result as regards the gases in the case of an explosion of fire-damp and air:

Suppose there are 2 volumes of fire-damp or 2 CH_4.

C requires O_2 = 2 volumes of oxygen, forming 2 volumes CO_2

H_4 also requires O_2 = 2 volumes of oxygen, forming 4 volumes of H_2O.

And CH_4 therefore requires 4 volumes of oxygen.

But 1 volume of air contains ·21 volume of oxygen, and 19 volumes of air will be required for 4 volumes of oxygen, therefore 9½ volumes of air are required for 1 volume of CH_4.

The composition of after-damp, the resulting gases, is 1 volume CO_2 + 2 volumes H_2O (steam) + 7½ volumes N.

Of course the resulting after-damp will vary somewhat owing to the variation in the explosive mixture; all the marsh gas (CH_4) will be effected and its composition disturbed, and in all probability carbonic oxide (CO) is formed as a result of most explosions. It will be observed that none of the gases formed by an explosion are able to sustain life, and they are very poisonous, and many deaths occur owing to this circumstance; and one of the chief dangers the explorers have to contend with is the deadly after-damp.

The only effective method of dealing with fire-damp is to dilute it with air and so render it harmless, this being the only safe and reliable method; and every attention must be paid to the matter of ventilation in order to render it successful. In olden days it was a common practice, when the volume of fire-damp would be small and the quantity in a working place known, to set it on fire purposely and so get rid of it; or a man would take off his coat and dash it about among the gas a few minutes to disperse it—perhaps only to collect again in either case—but these means have long since been condemned and forbidden.

In order to drain goaves or old workings of fire-damp bore-holes from the surface as a means for an outlet have been suggested, but the cost of this method and the uncertainty of the bore-holes giving vent render them impracticable. In a very few instances the gas has been piped from a blower or a goaf to the upcast shaft or to the surface, but this likewise is found to be beyond the limit of utility. I have known gas piped from a blower underground, brought to the surface and utilized for raising steam in the boilers at a colliery. A tract of virgin ground might be drained possibly by bore-holes from an upper seam, but it is very seldom this is resorted to.

MEASUREMENT OF AIR-CURRENTS.

Three principal methods have been in common use to ascertain the amount of air traveling the different airways in mines, but two of them are now generally discarded.

First. Walking along a passage at the same rate as the passing air, noting the distance traveled in a certain time, and so computing the quantity of air passing.

This method is one of the old-fashioned ways of measuring the quantity of air, before the more improved method had been thought of. Any one will see that it can only be considered a rough and uncertain means and not at all satisfactory, so far as accuracy is concerned; and especially as compared with the efficiency that has been attained in the present day. The *modus operandi* was as follows: A length of airway of 100 or 200 yards was selected that was of as even and regular dimensions as could be chosen, the nearer the whole length of the selected portion was of a certain area the better; then a man with a burning open light, say a candle, walked the length of the selected portion, going with and at the same rate as the air-current, being guided in this by the flame of the candle which was held in such a manner as to be fully exposed to the current of air, and proceeding at such a rate as to keep the flame of the candle perfectly vertical and unswayed, either by the rate of his progress or by the traveling air; the time occupied in traveling the distance being noted in seconds by means of a watch. Then taking the average sectional area of the airway so walked over and multiplying it by its length and dividing by the average time occupied in walking, ascertained by a few trials, the result was taken as the quantity of air flying, generally expressed in so many cubic feet per minute; for instance:

Suppose the length of airway traveled to be 600 fee

Average sectional area of airway to be 40 square fee

Length of time occupied in traversing it to be minutes.

Then $\dfrac{600 \times 40}{3} = 8000$ cubic feet of air per minute.

The sectional area would be ascertained by measuring the passage at stated intervals of say 10 or 15 yards, and taking an average of all the measurements. Of course this method is open to many objections, and should not be practiced at the present day.

Second. The next way is that of ascertaining the velocity of the air by means of observing the rate at which particles travel that are held in suspension in the air. The general way of measuring the volume by this means was to select a portion of the air passage as in the latter case, of as even area as possible. Then to explode a small quantity of gun-powder at the starting point, and note how long the smoke given off was in reaching the other end of the selected portion of the gallery, and the quantity of air is calculated in the same manner as in the previous case. This method is still in practice to a certain extent, and in ascertaining the velocity and quantity of air in shafts is still the usual mode.

Third. The third and best means is effected by the anemometer; an instrument invented for the purpose.

The anemometers mostly used are constructed with vanes, which are made to revolve by the pressure of the passing air acting on their surface. They are somewhat delicate instruments and should be used with care. By mechanism the number of revolutions of the vanes is recorded on a dial marked on the face of the instrument. The experimenter stands in the airway, holding the anemometer in his hand and in such a position that it is fully exposed to the current of air. By means of a lever, something after the same style as is used in a stop-watch, he sets the mechanism in motion on receiving a signal from a person who is acting as time-keeper. The instrument is allowed to run for one, two, or three minutes, as may be determined on, and the points on the dial face are brought to a standstill at the end of the allotted time by means of the stop-lever. The number of revolutions made is read off, and with the sectional area of the airway at the point of measurement, we have the necessary figures for the calculation, as each revolution of the anemometer represents one lineal foot in the passage of the current of air. Take for instance the figures

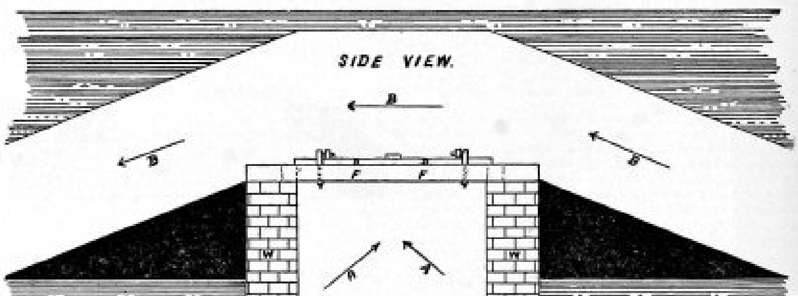
Sectional area 50 square feet.

No of revolutions of instrument in 2 minutes as 445.

Then $\dfrac{50 \times 445}{2} = 11{,}125$ cubic feet of air per minute.

It may be mentioned that in careful calculations some

SIDE VIEW.



other points have to be taken into consideration, such as correction of instrument for friction, atmospheric pressure and temperature of air, an allowance for the friction caused by the passage of the air through the mine, and an allowance for the presence of the measurer's body being in the airway.

The following rules are given by Professor Merivale for general use in measuring air-currents :

1. Use the recorded revolutions of the anemometer as correct ; do not bother with any formula (for friction).

2. Measure always at the same time of day, say noon, when the men are at dinner, the tubs at rest, the doors mostly likely shut, and the ventilation moving along its proper channels.

3. Always use the same places in the airways and see that they are as regular and straight as possible.

4. Take the record at several points, say at top, bottom, and center and the two sides, and use the average of these records for the velocity of the current.

A good idea is to have these rules printed in the book used for recording the results of measurements, and carried by the person whose duty it is to measure the air.

1. Sectional area is to be entered in the book at the time of each measurement ; height × width = area.

2. The person measuring must hold the anemometer at arm's length in front of his body, and keep the face of the instrument square on to the current of air and keep moving it slowly up and down and across the whole area of the passage.

3. The index figures of the instrument to be entered continuously.

4. Take the velocity for one minute and make complete entry.

5. Take the velocity for two minutes and divide by two, should the average be near that of the first reading, enter the average as the velocity.

For careful measurements in all cases add or subtract as the case requires, the correction due to the instrument for friction. This correction is necessary as the instruments do not record the actual velocity of the air, especially in feeble currents. A certain force of air is required in the starting of the instrument to overcome friction and put the anemometer in motion, the force varying with every separate instrument made ; some revolving in a current as slow as 30 feet a minute, but most of them require a velocity of 50 feet—though 40 feet is the accepted average required to start them. The formula of correction used for true velocities is

$$V = 0{\cdot}97 \times R + 40.$$

V = True velocity.

R = Recorded revolutions.

40 = Feet allowed to start instrument.

The following is an extract from an unpublished paper by T. J. Taylor, Esq., an eminent North Country mining engineer in his day :

1. Shallow coal seams have lost their fire-damp by its escape to the day. It is replaced in those beds by water and carbonic acid gas.

2. In mines which are deeper than those of the first head, the communication with the day is more intricate and difficult. Nevertheless in them also, the gas continued to escape so long as its tension much exceeded that of the atmosphere, and what remains is that of feeble expansive power which indicates exhaustion to a point that just balances the atmosphere. Here is situated the region of common blowers, the study of which has, by an inadequate generalization, deceived us into a belief that the state of the barometer has a good deal to do with explosions ; whereas no more in reality is established by the circumstance of a coincidence between its fluctuations and the issue of fire-damp than this, that the original supply of gas is in such situations very nearly spent off by the system of natural drainage alluded to.

Under this second head are to be ranked the masses of liberated gas in goaves and old workings, as well as the common blowers of fire-damp and stythe. It may be added, that in connection with the first and second heads, barometric observations are very useful ; but to the third, and really dangerous category, they are inapplicable.

3. In the next gradation of depth we have the fire-damp of great tension, the high pressure gas, as it may be called, distinctively from the little compressed gas of the second head. We are now at a depth where the dryness of the beds indicates them to be unreached by fissures from the day, and existent in a state that may be considered uninfluenced, as yet, by external causes of change. It is here, therefore, and not until we arrive here, that an opportunity occurs of studying the fire-damp in its more dangerous form. What we have previously ascertained is correct enough so far as it goes, but very imperfect; and, as already intimated, the cause of a generalization on the subject, which is far from being sufficiently comprehensive.

In these deep mines, so long as no more than the capillary issue goes on, the gas is yielded gradually, and is quite manageable; there is then no collected mass of it ; it is entangled in the cellular structure of the coal, and encounters too much resistance to escape at all freely. We have, however, seen, that even under these circumstances, a gradual and continuous issue takes place until the tension becomes very high, provided the gas issues into a confined receiver. And it evidently does not matter, in principle, whether such receiver be the artificial space of a mine barred up by water, or a natural cavity in that mine equally protected with the other from communication with the open atmosphere.

We may remark, however, that the tension is likely to be greater in the natural receiver than the artificial one, since the chances are that in an extensive mine-space, there may be some crevices through which the gas escapes as its tension increases.

It is scarcely necessary to say that natural cavities are to be found in mines ; they exist, in reality, both in roof and thill, above, below, and also in the beds of coal ; their formation, we must conclude, is due to those disturbances which have so much shaken the earth's strata, and they are most common in the neighborhood or along the line of faults, being precisely the situation where bags of foulness are most frequently met with.

It does not follow that every cavity will yield, on being reached, its stock of high-pressure gas ; on the contrary, the gas may be forced by its pressure through the cleavages of the coal as the workings approach it ; and when the cavity is reached, there may in this case be little or no gas given off ; sometimes a fissure or a fault may communicate at a distance with the cavity in which case the drainage is also gradual on account of the resistance which has to be overcome. But that the mine does contain in its cavities, and at its first opening, this high-pressure gas, is an obvious deduction from the premises. And whenever the intervening coal and strata accompanying it are compact enough to act as a dam, the gas will at length be reached and given off at this high rate of tension.

[TO BE CONTINUED.]

ABSTRACT OF A PAPER BY MR. RICHARD SUTCLIFFE, M. E.

(Proceedings Manchester Geological Society.)

Seeing that a number of colliery owners in different parts of the country proposed sinking new pits, most of which were intended to reach a very considerable depth, and therefore must occupy a long period of time before winning the coal, he began to study and enquire to see if there was no means of improving upon the slow method of sinking as at present prevails, and he came to the conclusion that it was quite easy to devise a more speedy, safe, and cheaper system by the adoption of machinery instead of hand labor, and by replacing the present practice of sinking in the middle of the pit, by what he thought to be a more rational mode of cutting-out and setting free the layers of strata all around the pit bottom in advance of the sinking. To accomplish this he had designed and patented a machine which could be worked by means of compressed air, electricity, or such other motive power as the user might decide to adopt, but he preferred the former (compressed air) on account of its cooling effects on the pit bottom, as well as its general utility in a mine. The machine consisted of a frame of steel or iron girders, firmly secured together with angle brackets at the center, and cross girders at one end to carry bearings, which took the driving shaft. Four shoes were fitted one at each end to the girders, and allowed to slide freely on the same to the ex ent of 2 or 3 ins., and having a flange at each side of the webs of the girders. Brackets were also secured to the sides of the girders near the ends, and these brackets contained two flanges each, between which flanges a nut was fitted, and worked by means of a ratchet, and in these flanges were suitable holes through which a screw passed, and was coupled to the shoe at each end of the girders. The air engines, or their equivalents, were fixed on the girders so as to gear into the cog wheel, which was keyed on the shaft, as was also the pinion, which meshed or geared into an annular rack and rotated it when the engines were set in motion. The size of the engine cylinders was about 8 in. by 12 in. An annular rack composed of four or more pieces for convenience in handling, and with which was cast a vertical flange or shroud about 2 ft. deep and 1 in. thick, to take girders and their strengthening stays. To the underside of the girders were secured four strong brackets, one at each end, fitted with journals which carried runners, upon which runners the annular rack traveled, carrying with it the whole of the under portion of the machine, a cutting barrel or cylinder composed of eight segmental steel castings, four of which were extended upwards to take slides which worked within the girders, and also the pistons of hydraulics. On the under end of the cutting barrel were cast tool boxes or sockets, to hold cutting tools, and on the internal side of the barrel were spirally-placed ribs at frequent intervals, which served to keep the annular channel clear of broken earth or *debris* by scooping out the material, and they also assisted to preserve the rotundity of the barrel by strengthening it. Also for the latter purpose an internal flange was placed at the top of these ribs, and four hydraulics for the purpose of regulating the feed and withdrawing the cutting barrel from the groove cut, or to lower the girders and their connections for a fresh cut. When the machine was being made ready for a cut, the girders were securely and firmly fixed in a horizontal position by pressing the shoes, which were packed with wood, to increased friction and absorb vibration, against the sides of the pit by means of the screws and nuts, care being taken that a small space was left between the annular ring in order that the weight might be lifted off the cutting pieces before starting the machine, and when working it should be allowed to feed as it cuts. When out to their full extent the shoes should be released from the pit sides and the upper portion allowed to descend, either by means of the hydraulics or the capstan rope, on which the whole machine might hang. Small flexible tubes were conveyed from a small plunger and fixed at the engine to the hydraulics, so as to be able to work them from the engine when desirable instead of by hand. The girders in this machine were arranged to allow two sinking buckets to pass, one on each side, but where it was desirable to have only one sinking rope near the center of the pit, the girders could be placed parallel and kept sufficiently apart. Assuming this machine to have twenty single and twenty double cutting pieces acting at the same time in the groove and making one revolution per minute in the pit bottom, it should cut at least 30 in. per hour in ordinary sinking stone, and with the stone set free all around layer after layer could be filed away without any powder. Sheet-iron shields were allowed to hang from the stationary girders to protect the workmen from the rotating portion of the machine. When it was necessary to cut a walling bed, special cutters were secured to the machine, and these cutters expanded outwardly as the cutting barrel descended from the annular rack. Mr. Sutcliffe next proceeded to describe his new method of sinking. In order to expedite the raising of the sinking material he used guide ropes, and in the following manner: Suspended on four guide ropes were two parallel beams of timber tied together at each end by iron plates, in which were fixed four set-screws, which pressed against the sides of the pit in order to steady the guide ropes and beams in their proper position. On these beams were secured flooring deals so as to cover the whole of the pit except the openings required for the sinking buckets, air pipes, etc., in order to facilitate working thereon and to afford additional protection to the sinkers underneath to that supplied by the special walling scaffold to be used in putting in the walling simultaneously with the sinking. For the walling or lining of the shaft he employed concrete, and to do so he placed on the flooring deals above referred to a temporary walling crib, composed of iron or steel, and made in four pieces or segments, which were connected together by four bolts or screws and nuts, with suitable brackets, as shown. The top of this temporary walling crib was placed on a level with the wall bed or annular step, and there expanded by the screws or bolts and nuts until made securely fast from pressure against the sides of the pit. When segments of wood were placed upon it in order to facilitate the closing of the next lift below to be afterwards put in underneath, a course of bricks, or blocks, with quick-setting cement, or a low course of rich concrete was next set partly resting on the annular step cut for walling bed, and partly on the temporary walling crib. On the inner side of the wood packing was next placed a circular course of casing composed of angle iron frames, lined with corrugated sheet iron having the undulations placed horizontally in eight segments of a height of 3 ft. bolted together and having a wood packing piece in one vertical joint to facilitate the withdrawal of the same. The freshly-made concrete was poured in behind this casing, taking care that it was properly placed and packed all round by a careful hand and suitable utensils, and when filled and packed to the top another course of casing was placed on the first and filled in at the back with concrete in like manner, and so on, placing course upon course and filling them with concrete at the back, until the bottom of the lift of lining or walling above is reached and closed up to. When the lift of walling to be put in was a long one, the annular steps might be cut at intervals of from eight to twelve yards, so as to distribute the weight of the walling on the surrounding strata for extra security, instead of allowing it to rest entirely on the material composing the lining of the pit. It would be at once seen that a short time sufficed to allow the withdrawal of the temporary walling crib, when it could be lowered with the guide ropes and reset for another lift of walling, leaving the corrugated casings above, secured by the undulations in the lining, until required for the fresh lift, when they could be brought down and reset at the same time as sinking proceeded. In conclusion, he might say he expected and believed that six yards per day of three shifts could be sunk and lined as safely and as easily as the amount now attained in ordinary sinking.

New Electric Mining Lamps.

At a meeting of the Inventor's Institute, held at Chancey Lane, London, Messrs. Charles N. Gawsentes and Walter L. Strong exhibited a new miner's electric lamp for which they claim the following advantages :

"Its weight does not exceed 3 lbs. 12 ozs.; it gives a regular and constant light for fourteen hours ; the cost of maintenance for a week's work, calculated at from 72 to 90 hours, does not exceed 5d., all charges included ; the cost of construction of each lamp does not exceed 5s.; the battery can be guaranteed to last for five years ; and the interior resistance does not undergo any alteration during that period. It is claimed that, whilst eliminating all sources of danger, whether by an explosion or fire, the new lamps give greater light, and that light is produced at a cheaper rate than the ordinary lamps in general use. The safety-lamp now used in the mines gives an illuminating power equal to $\frac{1}{15}$th of a candle. Supposing this power can be regularly maintained for twelve hours, the lamp will then have given a total light of $\frac{12}{15}$ths of a candle. The new electric lamp has an illuminating power estimated at three-fourths of a candle, consequently its total light in the same period is equal to eight candles ; that is, a light nine times greater in quantity and eleven times greater in effect upon the surface to be illuminated in consequence of the power of diffusion. The existing ordinary miners' lamps, giving $\frac{1}{15}$th candle power, cost 3½d. per week. The new electric lamp, giving nine times that light and offering every security, cost 5d. per week, thus showing a great economy over the ordinary lamp, and which to give an equal light would cost 3½ × 9 = 31½ pence."

At a recent meeting of the French Academy of Sciences a full description was presented of an accumulator miners' lamp. The lamp weighs 1,600 grammes complete (about 3½ lbs.) and is of about one c. p. It runs nominally for 12 hours with complete regularity, but its actual lighting power continues effective up to 14 or even 16 hours. Five hours suffices for the recharge, a current of one ampere and four volts being required. The lamp is furnished with an accumulator formed of two little cells of ebonite, each containing five plates three inches long and one and four-fifths inches wide. Two of these are positive plates of solid lead peroxide weighing about 180 grammes (about 6 ozs.) and having a capacity of seven ampere hours. The other three plates are of spongy lead. Frequent charge and discharge is found to rather improve the quality of the positive plates up to a certain limit, and there is very little tendency to disintegration. The exterior case of the lamp is of galvanized steel, and a space of about 2½ inches is reserved between this metallic case and the battery itself. This is provided with rubber cushions to avoid injury from shocks.

Forty-three mineral producing counties in Georgia, Alabama and Tennessee, in a convention of more than 100 delegates, held at Chattanooga, Tenn., have decided to make a tri-state exhibit at the World's Fair.

THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.*

BY W. S. GRESLEY, M. E.

[Written for the Colliery Engineer].

Figs. 27 and 27*a* will afford some general idea of the way in which a thick highly inclined coal bed is sometimes worked in France. Fig 27 is a cross profile of the seam and system, while Fig. 27*a* is a map or horizontal diagramatic view across a part of the workings about the middle of the profile Fig. 27. The seam is about 40 ft. thick, on a 20° pitch. The main openings are not made in the coal, but in the bottom rock or floor (a sandstone), Fig. 27 showing the gangways thus ⌂ ⌂ ⌂. These are driven about every 20 ft. apart vertically and the seam is crosscut to the top rock, roof or hanging wall about every 48 ft. and 20 ft. thick of coal worked out on a withdrawing method, in step-fashion to the floor, the gob being closely packed with refuse sent in from the surface or quarried in the mine as the mining out of the coal goes on. The packing material is conveyed into each section or lift through gravity planes. Usually three separate "lifts" or "heights" are in work at the same time, namely, the *highest* which will be nearly exhausted; the *middle* in full operation; and the *lowest* being opened up.

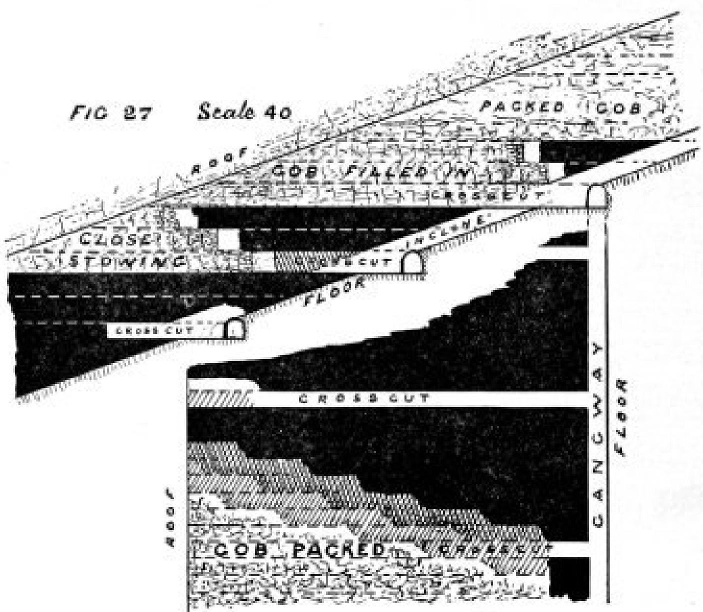


FIG 27 Scale 40

FIG 27 a Scale 40'

Without quite a number of profiles and different views it is impossible to fully illustrate this very instructive and interesting mining method. We hope to refer to it again at a future time. A modified form of this system (where the seam has two splits divided by by several yards of rock) is used at Blanzy, in France, each bench being about 51 ft. thick and the pitch 25° to 30°. Here, they drive galleries or gangways in the middle of each split 46 feet apart vertically (the height of each lift) and work crosscuts every 46 feet, off which are opened short horizontal forward ranges or stalls, taking 7½' high of coal in each cut or step. The excavations are well gobbed or stowed with sand, earth, clay, etc., taken into the mine.

Each pair of gangways serves two heights—one to the rise and one to the dip. The cars are manipulated in both by compressed air machinery, small engines being used for each series of working places. These either raise the empties and those containing the refuse for stowing to the higher working-places; or lower the refuse and hoist the fulls, if working to the dip. The engines being in the gangways. In gobbing the worked-out places, dry or pack-walls are first built along the face and then the rubbish thrown in behind. This procedure enables the props to be drawn where possible without letting down the overlying coal. Each working-place is practically a *cul de sac* (no air is circulated in it) but where gas is troublesome 12-inch galvanized pipe is carried in for main air course. The workings, even the stalls, are lighted by electricity. These modes of coal mining have, as it will be seen, no reference to the *natural* beds, benches, or stratification of the seams; the seam being worked out in *horizontal slices* no matter what pitch. [See dotted white lines Fig. 27.] By methods, not unlike the above, thick mineral veins or metalliferous deposits lying at various angles are mined; the ores of iron and copper in particular.

Figs. 28 and 28*a* are map and profile of some details of room and pillar working in flat seams. The coal is mined on the "face" or at right angles or nearly so with the direction of the "butt" entries. The Figs show the position of the track, where the props are stood; position of "breakthroughs" for air, rooms going forward, (an undercutting machine in one of them,) entry pillars and stumps left in or to be removed, a rib being drawn, and the fallen in gob.

Fig. 28*a* is taken through the second room from right. Two miners work in each room or on a rib, and will get from 4 to 8 tons, of 2,000 lbs. per shift, according to the nature of the seam and other circumstances. The yield per acre by this system will of course vary in different places, but may be put down a little over 1,100 tons per ft. thick on the average.

Fig. 29. Machines are here employed not only to undermine the face of the coal but also to drive the entries and start the rooms. The coal here may be flat or inclined. It is supposed to be worked nearly full "face," and the bulk of it got in kind of long walls, as are intended to be shown by the parallel dotted white and black lines. The main entries then are driven on the "end" and the productive, or branch entries, on the "face." The idea here is that all the entries are machine-driven, either by the *Stanley* or some other type. To work a room, a narrow heading is put through between the entries by machines, driven both ways if preferred, and a track laid right through. The full *length* of the room is then undercut, on one or both sides, and preferably by machines, and the coal broken out as in a Longwall face, taking one cut after another until the place is wide enough—until the roof becomes too weak to stand and must be allowed to cave. While one room is being worked in this way the next is being opened up, or in a less or more forward condition, and so on, advancing or retreating from or towards the openings, as circumstances suggest as the better way to work. One important feature of this method is that the traffic is all in one direction, because the empties go into a room at one end, are loaded and *pass on* out at the other. Ribs or pillars between the rooms ("Longwall rooms" would be a good term to use) are formed as thick as found necessary and may be drawn by using proper precautions in timbering, etc. In the Fig. five Longwall rooms are driven through, but in the first one only have long cuts been mined off the side of the opening heading. It is evident that facilities are afforded by this system for getting large quantities of coal in the best condition at a low cost and from a very small area of mine-workings open at one time. As to the speed of driving the headings, Stanley's machine (which cuts a circular core from 5 ft. to 7 ft. in diameter, or reduces to small the entire coal cut out) in clean coal will do from 35 to 45 lineal ft. a day, if not more

Up in the long cuts the undermining and breaking-out is done at night so that the loaders may work by day. Several hundred tons of coal may be sent out daily from each place.

Fig. 30. Profile of three "chambers" (rooms or breasts) with gangways, in a twin or split seam of Anthracite. The seams are beginning to pitch rapidly on the left, and, in order to make one gangway serve the two splits, chambers are worked one over another and the coal in the upper is put through a short "rock chute," to the gangway which is driven in the lower split.

It may be remarked here, that twin seams are usually worked as *one* until the "dividing rock" or "parting" exceeds 3 or 4 ft. when it answers best to work each split as a *separate* seam, the chambers and the pillars being formed one below or above the other, according to which split is worked first. And in working such seams it is usual to take the lower split first, going in with the bottom coal, dropping the dividing measure, and working the top coal backwards or retreating on the top of the fallen *debris*. Local conditions may, however, obtain so that when the bottom split has been worked (by chambers), the dividing slates fall *en masse* upon the floors of abandoned places, and the top split is then taken out advancing by working upon the top of fallen slate. We are of course speaking now of where the pitch is quite moderate—where the mine car goes to the face—a dip of not more than 12 degrees. Chambers so worked, and where the inclination of the seam is very regular and slight, may be carried in as much as 600 feet from gangway.

[TO BE CONTINUED.]

Labor Saving Records.

COKE MAKING.

In the Western Kentucky Coal Fields.

BY JNO. B. ATKINSON, EARLINGTON, KY.

[June, 1890, Meeting of the Engineering Association of the South.]

Most of the coals found in the Western Kentucky field are coking coals, and readily coke in the Bee-hive oven. The two most regular and valuable veins of coal so far developed in this field, B, and D, vary but little chemically and physically at the various openings in Hopkins, Ohio, Muhlenburgh, Webster, and Union Counties, while the lower veins vary much, both chemically and physically at the various openings in the above-named counties.

Vein B, after being crushed and thoroughly washed, averages 5·0 per cent. ash and 2·9 sulphur in the coal. Vein D, under same conditions, shows 6·0 per cent. ash and 2·5 sulphur.

The sulphur in all the coals in this field that causes trouble in the coke, is that which is chemically combined with the coal, and may be termed organic sulphur, and this cannot be separated by washing. The pyrites can be eliminated without great difficulty by washing.

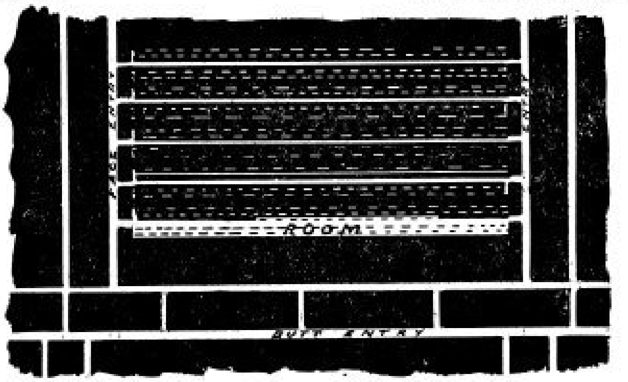

Fig 29 Scale 200

THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.

The coals of this field are different from ordinary coking coals, in the fact that the reduction of ash, after a certain condition is reached, does not reduce the sulphur.

Testing the lower veins, at one opening is found coal that will make coke with 7·572 per cent. ash, and 1·482 per cent. sulphur: while at another opening in the same vein, but a few hundred feet away, the coke made from the coal will show 8·893 per cent. ash, and 2·556 per cent. sulphur. Still another opening will show 18·542 per cent. ash, and 2·567 per cent. sulphur. The best results obtained from the lower veins showed in the coke 4·953 per cent. ash, and 1·168 per cent. sulphur. Could this limit of ash and sulphur be maintained, then would this field take a high position as a producer of coke equal to the best for metallurgical purposes, its nearness to great markets giving it great advantages. But the great uncertainty of the quality of the coal in these lower veins will possibly prevent any extended development for coking purposes, the good coal of to-day running into the very inferior coal of to-morrow.

During the year 1882, two Bee-hive ovens were built by the St. Bernard Coal Company for experimenting with the coals of the Western Kentucky fields. A crude system of washing the coals was used with fair results, physically, in the coke produced, but it was soon discovered that much of the sulphur of the coals was organic, and impossible to remove by washing. During 1887 twenty-one ovens were built, together with a washing plant and coke crusher. The idea was to convert the waste slack of the mines into crushed coke to be used in the place of Anthracite coal for base-burning stoves and heating furnaces. It was soon discovered that the coke was valuable for smelting silver and lead ores, for making steam, drying brick-kilns, where wood was formerly used, and for many other purposes, besides being crushed for domestic use. The coke made had a beautiful luster; very hard, but somewhat brittle, but with strength to bear any furnace burden. In 1888 twenty-two ovens were added to the former plant.

During the winter of 1887-88, the writer visited various coking and coal-washing plants in Europe, hoping to learn something in the way of desulphurizing coke. In Upper Silesia, Germany, coal-washing plants, made by Messrs. Simon and Luhrig, of Manchester and Dresden, were found perfect in operation and results—far superior to anything yet attempted in this country. All the sulphur, slate, and clay physically mixed with the coal were taken out, but no attempts were made anywhere to attack the organic sulphur, and nothing was learned as to how to make better coke in Western Kentucky in the way of desulphurizing it.

Much has been written of the value of steam as a desulphurizer of coke, and the writer learned of an effort made in England to do this, by admitting steam through the bottom of the oven and cooling the red-hot coke, instead of the usual way of wetting down with water. A visit was made to the place where the works were said to be, but the visit only demonstrated that the firm had failed financially and departed for parts unknown, leaving sulphur still a fixed fact in the coke. In all the researches of the writer this was the only practical attempt to desulphurize coke with steam. One of the ovens at Earlington was fitted with a system of perforated pipes under the tile floor, a perforation at each corner of the tile, the tile being twelve inches square. When the oven was burned and ready to be drawn, the pipes were connected with a boiler and the steam turned on. The coke cooled at the bottom first, the cooling process gradually reaching the top. Around the sides of the oven the coke was not reached by steam, and the water was turned on this coke. Samples of the coke cooled by steam showed 2·84 per cent. sulphur while samples of the coke cooled by water gave 2·9 per cent. sulphur. Practically no reduction of sulphur.

In another experiment the bottom of the oven was kept continually wet by means of perforated pipes, while the oven was burning. It was hoped that the steam from this moisture, when passing through the red-hot coke in its effort to escape, would be decomposed, and the hydrogen in passing, seize upon an atom of sulphur and take it out, while the oxygen was supposed to pick up a small piece of carbon at the same time, with resultant of less sulphur and more ash in the coke. But alas! the hydrogen either shirked its duty or the sulphur was too coy. The water disappeared, but the sulphur stayed in full force, and so far this effort was a failure.

In another experiment a portion of red-hot coke was cooled in the oven by steam through the hose, instead of water. Another portion of the coke was drawn red-hot and cooled in the air, while a third portion was cooled with water in the usual way with the following results:

Steam	2·485 % Sul.
Water	2·665 % Sul.
Air	2·780 % Sul.

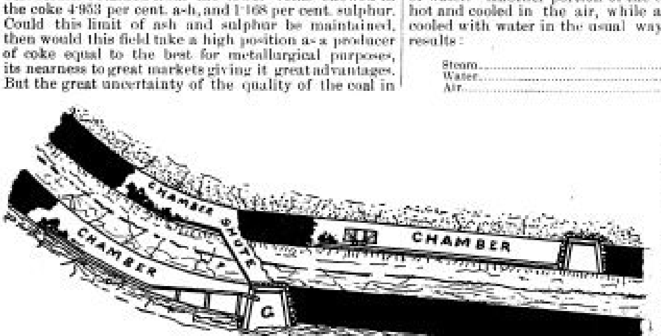

Fig 30 Scale 50'

THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.

In another experiment a solution of chloride of manganese was used to cool the coke, with no beneficial result.

After many experiments it has been determined that, by careful washing, a coke can be made from veins B and D, with an average ash of 12 per cent. and sulphur 2·3 to 2·6 per cent.

A new washing plant, now in operation at Earlington gives for the first examination of twelve ovens, the following analysis:

Moisture and volatile matter	1·351 %
Fixed carbon	86·021 %
Ash	12·628 %
Sulphur	2·523 %
Color of ash, reddish-brown	
True specific gravity	1·68
Apparent specific gravity	0·90
Per cent. of cells by volume	67·56
Weight per cubic foot	56·00

During the past summer, arrangements were made to test the coke in a blast furnace. The coke was used after charcoal, and 155 tons of pig-iron made. The ores were Tennessee brown ores, containing much silica and phosphorus. The coke used had lain upon the yard fully nine months, exposed to the weather.

It contained:

Moisture and volatile matter	2·746 %
Fixed carbon	82·578 %
Ash	14·656 %
Sulphur	2·787 %
Phosphorus	Trace.

This coke showed remarkable strength in the furnace and great heating and gaseous properties. The flux used was the Nashville lime rock, mixed with mud. It was a very wet time and the sweepings of the quarry were used, as it were, the furnace going out of blast immediately.

The foundryman selected three samples of pig-iron, at the writer's request, the best, the poorest, and intermediate.

Examination of these samples showed:

	No. 1.	No. 2.	No. 3.
Silicon	1·663	3·850	5·936
Sulphur	0·139	0·914	0·189
Phosphorus	1·246	1·238	1·441
Carbon	2·606	2·618	4·282

The coke is in part responsible for the sulphur in this pig, a quality of pig equal to much now made in the South and West, and the writer believes that, with the better coke of to-day, with good ores and a proper limestone, the sulphur can be largely reduced in the pig, and Western Kentucky take an important part in the wonderful progress of the South in making iron.

Coke made from unwashed slack of vein D gives:

Fixed carbon	79·94
Ash	20·06
Sulphur	3·54

Amongst other experiments, the slack coal, before coking has been treated to a strong solution of salt. Again, finely powdered fluor-spar has been intimately mixed with it, then layers of limestone alternately with layers of slack have been tried in the oven.

None of these experiments have reduced the sulphur in the coke. Up to this time coke has been made from slack coal only. The washing plant at Earlington is placed midway between the tipples of D and B veins. The slack is carried to this plant from either tipple and dumped into a common hopper and elevated to the sluice washer where it meets a stream of water. This sluice consists of two troughs, each 30 inches wide by 12 inches high, by 30 feet long at an inclination of 1 inch to 26 inches. One trough is used whilst the other is cleansed. Most of the pyrites, slate and clay, are deposited on the bottom of the sluice, the clean slack being carried to the lower end of the sluice by the water, where it passes over a screen into a Deshler jig washer, the water passing through the screen, and into the washer below the washer screen. This jig washer takes out the dirt that entered the washer with the slack, and the clean slack with the water passes into a trough and flows to the bins. Much fine slack is saved in this way. The continually increasing pile of washed slack in the bins acting as a partial filter, the water flowing off through perforated drainage pipes on the sides and in the floor of the bins. The bottom of the washing sluice is 48 feet above the railroad track on which the coke is loaded, this height being necessary to permit the washed product to flow into the storage bins, from which it is dumped through the floor of the bins into the charging larry. The waste from the sluice and jig washers is carried by water through troughs to the waste bank.

When run of mines coal is crushed and used, I should use only the jig washer. In a recent experiment with five tons of B coal crushed and washed the resultant coke showed:

Volatile matter	1·162
Fixed carbon	87·893
Ash	10·945
Metallic iron	2·222
Phosphorus	0·009
Sulphur	2·600

Analysis of the ash:

Silicon	4·437
Perox. iron	3·177
Alumina	2·405
Lime	0·391
Magnesia	0·142
Phosphoric acid	0·023

Some time ago I sent several barrels of B coal to Messrs. Simon and Luhrig, of Dresden, who washed and coked it. The resultant coke showed in one case:

Volatile matter	0·765
Fixed carbon	89·117
Ash	10·118
Sulphur	2·196

Another sample showed:

Volatile matter	1·090
Fixed carbon	88·546
Ash	10·364
Sulphur	2·196

Another sample showed:

Volatile matter	1·029
Fixed carbon	88·049
Ash	10·931
Sulphur	2·346

The fixed carbon and ash obtained from my best results at Earlington compare favorably with these obtained in Germany, but the sulphur is greater, due possibly to the fact that the German experiment was necessarily conducted with a small amount of coal.

In the recent experiment with run of mines coal from vein B, the coal was very carefully weighed before crushing and washing, and the resultant coke showed but 46·73 per cent. of the original weight of coal. The fixed carbon of vein B, being 49·50 per cent. this result shows a loss of 2·77 per cent. of coke as compared with the theoretical amount.

All the Western Kentucky coals are low in fixed carbon, not often exceeding 51 per cent. This is a matter of great importance to those who may attempt coke making in this field.

The coke used in making iron and many of the experiments heretofore referred to, was made from slack coal washed in the sluice washer only, being made before the present washing plant was built.

SAMPLING ORES WITHOUT USE OF MACHINERY.

BY WILLIAM GLENN, BALTIMORE, MD.

[Cleveland Meeting, June, 1891. American Institute of Mining Engineers.]

The taking of proper samples of crude ores seems to be less thoroughly understood, or less carefully practiced, than its importance requires. We all know how often we encounter the reports of very accurate assays and analyses, the weight of which, as evidence, wholly depends on the method of obtaining the sample, and is very probable *nil*, because there has been no proper sampling. Passages might be cited from technical books, and from current technical literature (all the work of writers whom we delight to honor) to show that even among high scientific authorities there is too little acquaintance with the practical art of the sampler. There is no metallurgical or chemical establishment which does not frequently receive samples truly representing nothing. They consist usually of bits of ore, or what not, selected because they are worse or better than the average of what they are meant to represent. And they are worthless, no matter who made the selection. Where conscious choice is permitted to enter into the operation, a fair sample will not result, unless by a miracle.

The work of sampling is often looked upon as within the realm of boys and of pensioners only. At least, though the manual labor be left to subordinates, the principles on which it is conducted and the safeguards with which it is surrounded are not unworthy of the study of experts; and experts should be ready to teach these principles and enforce them in practice. For exact sampling is the indispensable first step towards learning the value of any boxful, carload, or shipload of ore.

I propose to give a simple account of the method of sampling by hand, such as I have always pursued. There is nothing new about it. So far as I know, it is the immemorial old method, as old at least as Cornish copper mining. Perhaps my fellow members in the Institute may suggest improvements in it. If not, it will constitute a record in our *Transactions* to which laymen and beginners may be referred.

There are two principal processes to be considered: First, how to take the gross sample of the lot of ore; second, how to proceed with that sample. Really, there is no iron bound rule governing the first step; each may have a way of his own; yet most samplers proceed in much the same way. But once having the rough sample, there is no question as to what shall be done with it. It is to be worked down after the orthodox fashion. It must be broken and mixed and quartered until only a few ounces remain. The sampler bottles this residue; the chemist does the rest.

Assume that we have a rough sample, weighing a ton, of any ore with its gangue. Assume that by some manner of magic we can at once reduce the whole of it to dust. Evidently, if we could mix it long enough and well enough upon a clean, tight floor, it would finally become homogeneous. In that case, we could fill half a dozen small bottles from any part of the pile, and they would be fair samples. But the work would have to be admirably done; so well done that a single gramme taken from the pile would properly represent the entire ton of sample. Really this would entail a great deal of labor. And if the rough sample weighed 15 tons or more, as it would if taken from a shipload, the bare labor of mixing that quantity of dust until homogeneous is wearying even to think of. We cannot proceed upon the proposition that a final sample may be obtained in any such way. Yet upon a rock similar to this many are wrecked.

To take, for illustration, a definite case, let us assume that we have to sample a 10-ton pile of 10 per cent. copper ore, prepared for market. It will consist of masses generally the size of one's fist, but of all smaller masses and even of dust. We shall require for the work a clean, tight floor or pavement, an iron mortar and pestle, a shovel, a small hammer, a piece of iron for an anvil, and, lastly, a broom. Besides these we shall find convenient a wheelbarrow or a barrel or box of some kind.

For convenience and force I will put my description into the form of homely directions, such as I might give to my workman.

Begin by shoveling the pile roughly into the form of a flattened cone or a flattened pyramid; say we choose the pyramid. Now make a trench straight through the pile, cutting it into two nearly equal parts. And again by a trench (at right angles to the first) divide these halves into four nearly equal quarters. A part of the ore taken from these trenches will form the sample required. Proceed as follows:

Having the wheelbarrow ready, begin at the middle of any side of the made-up pile and cut the first trench. Cast the first shovelful to the right, the second to the left, the third into the wheelbarrow. Repeat this order of shoveling until the barrow is full, then empty it upon the well-swept floor intended to receive the sample. Continue in the same way until the trench has passed through the pile, when there will result two rather long and narrow piles. Begin the second trench, extending it across the middle of the two piles, casting the first shovelful right, the second left, the third into the barrow. Proceed in the same way as with the first trench. When done, you will have shoveled about 6,000 pounds of ore. As every third shovelful was thrown into the barrow, there will result about 2,000 pounds of sample upon the floor. That this is a fair sample of the original pile is based upon the assumption that each third shovelful thrown into the barrow was like the first and second ones cast into the piles. The hypothesis is reasonable and freely to be trusted.

Having the sample, proceed with it after the regulation method, as follows:

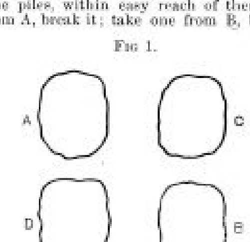
Spread it thinly upon the floor; now examine it. If there be any lumps which look larger than the general run, place the anvil upon the pile, and between that and the hammer break those lumps. The next step is to thoroughly well mix the sample. Begin at one edge of it and shovel the ore over upon itself. Move around to the opposite side of the pile, and from that side shovel the ore again upon itself and back to its original place upon the floor. Having it well mixed, form it into a flattened cone and sweep all the dust upon and around the pile. You have now to halve and quarter the sample as follows:

Commence at any point and shovel a road through the center of the pile, casting the shovelfulls alternately right and left as you proceed. This movement will result in cutting the pile into two elongated nearly equal ones. Beginning at the middle of one of them, shovel a road through it in the same way as was done before. And in precisely the same way cut the other pile in two; sweep upon each pile the dust belonging to it. These movements will result in four piles, as in Fig. 1.

If the sample were well mixed, when and as directed in these notes, then will each of the quarters A B C D have the same composition as have all the others. But if, upon inspecting them, you judge one or another to be poorer or richer than the others, you will have then sufficient evidence that the work has been badly performed. In that condition of affairs, mix well together all the piles, and once more halve and quarter them. Having made all the quarters of the same composition, it follows that any two of them may safely be accepted as representing the original 2,000 pounds of rough sample. This opens a road leading in the right direction, since it enables us finally to get rid of half the sample. We may cast out two of the quarters and retain the other two for the sample. It is a matter of indifference which two are retained, say A and B. Remove from the floor C and D, together with the dust belonging to them.

We have again to break the larger stones, until there remain none larger than walnuts. Place the anvil between the piles, within easy reach of them. Take a stone from A, break it; take one from B, break that.

Fig 1.



Plan of ore piles after quartering.

Continue in this way, taking stones alternately from each pile, until all are reduced to the size stated. By proceeding in this way the sample is more or less mixed while being broken. Complete the mixing as before, by shoveling all of the sample forth and back over the floor. Form it once more into a flattened cone, and sweep the dust upon and around it. Divide the cone into two halves, and those into four quarters, precisely as you before did, and as illustrated in Fig. 1. You have now to reject two of these quarters. The unwritten law of the sampler says that it must be those holding the positions A and B, because those were retained in the last quartering. Remove A and B from the floor, retaining C and D for the sample. These would now weigh about 500 pounds.

Proceeding as before, break down the lumps of ore until none are left larger than say 1-inch cubes. Again mix well the sample, make it into a pile, sweep up the dust, halve and quarter the pile. Reject two quarters (C and D, of course), retain two, precisely as in former quarterings.

Once more break the lumps, this time down to half-inch cubes. Mix well the sample, make it into a pile, sweep up the dust, halve and quarter, reject two quarters. The two quatrers retained would weigh about 125 pounds. Break it down until comparable to fine gravel and coarse sand. Mix and quarter once more.

The two quarters this time retained would weigh about 60 pounds. With the mortar and pestle break this to something approaching coarse sand. Again mix and quarter. The quarters this time retained are to be ground yet finer, mixed and quartered.

If you have no mortar and pestle, the hammer and anvil may be substituted throughout. After getting the material into the form of coarse sand, it is best to mix and quarter it upon a sheet of paper, even an old newspaper.

At this point the sample would weigh about 15 pounds; its larger grains would be in size like coarse sand. It would be safe now, without further breaking, to mix and quarter it twice, or until its weight did not exceed 4 pounds. Run this through the mortar and then mix and quarter it twice, or down to 1 pound weight. Grind this to something approaching powder, and, for the last time, mix and quarter it. Have ready 6 wide-mouth 1-ounce bottles. Place them in a line, side by side, upon a sheet of paper. From the other paper pour the ground sample in a small stream, forth and back across the mouths of the bottles, until they are all full up to their shoulders. Cork, seal, and label them and the sampling is done, and properly done.

If there should lurk in your mind a suspicion that this half-pound residue of dust may not, after all, properly represent the rough sample with which you began, go back over the work, and try to decide precisely where in the quarterings the sample retained ceased to be a sample. If you can decide upon that point exactly, then you will know just where you failed to do your work properly. The error will be with you and not in the method.

It does not, in the slightest, matter of what solid a sample may consist, or how much or how little it may be, it should be worked down in the manner just detailed. Whether a sample consist of 20 tons or of 1 ounce, it matters not, except as to breaking and grinding.

A word may be added as to larger and rougher ore-piles than have as yet been mentioned. It is not unusual for one to have a pile of 100 tons, or 200 tons, which one would like to sample. Such piles are apt to consist of lumps larger than a man's head, together with masses of all smaller sizes. Where a pile is formed by dumping ore uniformly upon its top, the likelihood is that the pile is homogeneous. In such a case, it is safe to make short cuts into it at several points around its base, and to consider as sample the ore so gotten. It is safer to make one cut through the pile, retaining as sample each third shovelful, as in the case of the copper ore we have just considered. In forming ore-piles of the weights given, it is a good custom to put upon a separate platform each tenth or twentieth barrow-load coming from the mine; the small pile will prove a fairly good sample of the large one. But no matter how it may be gotten, the rough sample is to be broken and mixed and proceeded with after the regulation method.

No account is here taken of moisture-samples or of sampling train-loads or ship-loads. This paper is meant to help beginners, but it would be, in the writer's judgment, a benefit to others also, if our members, who are practically acquainted with sampling would present their own methods with regard to the various branches of the art. The precautions especially required in sampling rich silver ores, for instance, might well be made the subject of comparison and discussion.

DISCUSSION.

R. W. Raymond, New York City: I am glad that this subject has been brought to the attention of the Institute. Mr. Glenn has by no means overstated its importance; and yet, with the exception of the paper of Mr. D. W. Brunton (*Trans.* xiii., 639) describing a mechanical ore sampler, I can recall little or nothing in our *Transactions* concerning it. The practice in the West, with regard to silver ores, etc., is affected by various considerations. As a general rule, such ores are either already fine or are crushed before treatment. I think it is now generally admitted that a good mechanical sampler connected with the crushing-machinery takes a fairer average sample (usually one-fifth or one tenth of the total lot of ore, according to the richness and the consequent importance of exact determination of value as a basis of payment to the miner) than can be got by throwing aside the fifth or tenth shovelful in unloading. At all events, the mechanical sampler cannot be suspected of bias, conscious or unconscious, provided it is so constructed as to deliver impartially the coarser and finer particles of the stream of ore passing through it. Disputes are therefore avoided by using it.

But for many classes of ore the sample is still taken with the shovel; and it is after this has been done, whether mechanically or by hand, that the process begins, which can properly be compared with that described by Mr. Glenn. The differences between this process and his are required by the following principal considerations:

1. The material; namely, ores carrying, besides lead or copper, more or less silver and gold, is so much more valuable that small errors in determining its contents may be the source of large loss to the buyer or seller.

2. It is almost always finer than the crude material contemplated by Mr. Glenn. Either it has been crushed before the sampling begins, or it is so generally fine when received that the preliminary stages of sampling may be, in the judgment of the manager, performed without crushing. This, however, always involves a risk, the assumption of which by a prudent manager, is justified only when the conditions are favorable; for instance, when the character of the ore is well-known; when its grade is not too high; when the difference in richness between coarser and finer pieces is not great; when careful experiment has shown that sampling without a preliminary crushing is sufficiently accurate; when avoiding the extra cost of crushing would be an important saving, or when the crushing machinery of the establishment is fully occupied with material which must be reduced before sampling. The nature of the contract between the smelter and the miner is another element to be taken into account. Perhaps the ore is not to be paid for strictly according to sample-assay (a thing which now and then happens, though not often, in the purchase of large dumps at a round price, or the treatment of ores on joint account, to be settled by the net results, instead of the preliminary assays, or under special contracts, in which the loan of money or other inducement to the miner has secured special terms). Perhaps, again, the smelter owns the mine, and can thus afford to save current expense by taking some risks in sampling his own ore which he would not take with ore for which he had to pay according to the sample-assay.

I think it may be said, however, that the sampling works proper, that is, those which are not parts of smelting works, but stand between the smelter and the miner, as agents for the latter in the sale of ore, warranting to the purchaser the accuracy of their determination of its contents, always crush everything they receive. And I think it may be said, also, that when the capacity of crushing and sampling apparatus is adequate, and the arrangements for receiving and handling ore are so perfect as to avoid both demurrage on railway cars and re-handling of material, the crushing and mechanical sampling of all lots received is not only better, but cheaper, than shovel-sampling of crude cargoes. The matter may indeed be left to the discretion of a competent manager; but the most competent mangers are not anxious to multiply the matters which are left even to their own discretion, still less to the discretion of subordinates. There are innumerable things which have to be watched daily and hourly around great smelting works; and it is a relief when any one department can be placed in the category of comparative routine, calling for fidelity rather than discretion. Moreover, the exact determination of all the elements of an ore of the class here contemplated is as important on technical as on commercial grounds. Without it, the metallurgist can neither calculate his charges successfully nor be held responsible if he fails to do so. And the sample taken of each new lot of ore received is not only assayed for its valuable contents, such as lead, copper, silver, and gold, and for sulphur, iron, silica, and zinc (which may affect the price to be paid for it), but also analyzed for all its earthy bases, so that it may be properly mixed for smelting with other ores or fluxes. Now it is quite likely that the gangue minerals of an ore may break very differently, according to their natural hardness or cleavage, in the ordinary processes of mining and shipment.

Moreover, the same car load from a given mine may contain ores from different stopes, varying so greatly in character and condition that even if the average of gold or silver were reasonably uniform, the average of silica, lime, magnesia, baryta, etc., would not be so, and the lumps might be entirely different in these particulars from the finer stuff.

With these digressions and explanations, I repeat the general statement that the ore to be sampled in the West is generally fine. But for the rough sampling of ore at the mine, or in localities where proper crushing cannot be done, the procedure described by Mr. Glenn seems to be a good one for the preliminary stages.

3. Notwithstanding the general fineness of the crude pile, and no matter to what degree it may have been reduced by crushing (short of the final reduction to impalpable powder), there is still a distinction between coarser and finer particles, and in the majority of cases this distinction is one of value as well as size. Many of our western ores carry silver, for instance, not only as an accessory ingredient of galena, but also in the form of finely-disseminated "true silver-ores" accompanying the galena. These are usually not only in fine crystals or specks, to begin with (often not distinguishable to the naked eye), but brittle besides, so that the shocks and abrasion of mining, transportation, crushing and handling reduce them to still smaller size. In the stamp-mill they make "slimes." In concentration they are very likely to escape and leave the headings impoverished, though clean from gangue—"poor but honest," so to speak. In sampling, they present the greatest danger of error.

Something similar might be said concerning the tenor of gold in many ores. Although true gold-ores are not common, yet in a lot of ore consisting largely of auriferous pyrites, for instance, there will certainly be more or less oxidized material, in which there is fine, free gold. I confess, however, that so far as my observation goes, this is not the source of as serious difficulty in sampling as are the brittle ores of silver. That is a point on which I hope some of our members who have had wider practical experience with the sampling of gold-bearing ores will throw further light. My own knowledge comprises more particularly the practice of lead-smelters; and in that practice the gold in the ores purchased, though it is determined and paid for, has not been hitherto a point raising special questions of difficulty. Or rather, the precautions taken as to the fine dust of silver ores cover the question of gold also, so that this has not called for separate consideration. Moreover, almost all the distinctively gold-bearing ore of the country, as well as a great part of the silver-ore, is reduced by wet-crushing for amalgamation or other subsequent treatment, and consequently sampled by battery-assays—a process which is not here under consideration, and which does not encounter the precise difficulty just described. I am inclined to think that in lots of crude fine ore, or of ore dry-crushed for sampling, oxidized material containing gold would not present as much difficulty as silver ore, because it is less likely to form fine flying or sifting or rolling dust. The iron oxide tends rather to pack or adhere—at least to lie where it falls—unless it has been artificially dried and pulverized.

But the difference of value between coarse and fine particles may be due to other minerals than those already mentioned. And there may even be cases in which the greater value is in the coarser material. I need not, however, enlarge further under this head.

4. Obviously such a difference would have no effect, if the whole mass to be sampled were so thoroughly mixed that the proportions of different sizes were uniform throughout. But this is not practicable, because the coarse and fine particles behave differently as to rolling and sifting over or through the pile upon which they are shoveled. Consequently, it becomes necessary, in order to secure a correct final average, to make the distribution of sizes in each pile formed *symmetrical*, since it cannot be made truly *uniform*. At a later stage, as will be seen, the whole of the sample thus secured is reduced to powder. Yet still the precaution of making symmetrical piles for quartering is continued to the last.

With these explanations I will describe the quartering of a sample of ore (say one fifth or one-tenth of a gross lot) as practiced at some of the leading works in the West.

The mass is first shoveled into a ring on the sampling-floor, and this ring is then shoveled toward the center, each shovelful being carefully delivered upon the summit of the pile in the center, so that they shall roll equally in all directions. A conical heap having thus been formed, it is pulled down and spread out. The workmen walk round and round the pile, pulling with the shovel, as it were, the ore towards them, so that it rolls outward. The lower six inches of the pile is not disturbed, and when this process is finished, the conical heap has become a truncated cone of larger base-area and six inches height. This flat heap is now quartered by pressing a stick or a board held edgewise down into it so as to mark the diametrical divisions. Two opposite quarters are cut out with the shovel and removed. The other two are again mixed, formed into a conical heap, and flattened out as before. This procedure is repeated until the quantity has been reduced to one or two wheel-barrow-loads, when, if the material has never been mechanically crushed, it is crushed in the rolls to say half-inch maximum size. The quartering is then continued till the sample has been reduced to a panful. This is ground say to 60-mesh size (after a partial preliminary drying, if necessary to facilitate the grinding in a rotary fine crusher) and then taken to the assay-laboratory, where it is thoroughly dried (say for twenty-four hours at 212° F.), and rubbed fine until the whole will pass through an 80-mesh sieve. Quartering is then resumed and continued until the sample is only sufficient to fill three bottles, one of which is for the assay of the works, one for the customer, and the third for the umpire-assay, if such should be required.

The details of this practice may vary in different works, and I trust our members, many of whom are engaged in such work, will give us, in the way of criticism or suggestion, the benefit of their experience. It is perfectly evident, as Mr. Glenn says, that a vast amount of skill and precision is daily wasted by our chemists in the delicate analysis of samples that mean nothing. To cite a single instance, I have recently studied with much interest the various papers in our *Transactions* concerning the practical results of the magnetic concentration of iron-ores. In Mr. Birkinbine's paper, presented at the New York meeting, there is a simple formula, by which he calculates from the percentages of iron in the crude ore, the concentrates, and the tailings the quantity of crude ore required to furnish a ton of concentrates; and he applies this formula in testing the comparative economy of different magnetic concentrators. But in several instances the actual quantities of crude ore, concentrates, and tailings have been reported, and they do not agree with the results of calculation by this formula. Now the formula is mathematically accurate, and there is no reason to doubt the accuracy of the chemical work. It follows that the samples, either of the crude ore, of the concentrates, or of the tailings, could not have been accurate. It is certainly to be desired that future tests of such work should include more thorough sampling, and that future accounts of such tests, should include descriptions of the method of sampling employed. In the absence of certainty as to the fundamental data, the application of mathematics to the discussion of results seems to be labor thrown away.

ELECTRIC MINING MACHINERY.

At the tenth ordinary meeting of the Institution of Civil Engineers (England), a paper was read on "Electric Mining Machinery," by Messrs. Llewellyn B. and Claude W. Atkinson, Assoc. MM. Inst. C. E. During the last four years, the authors had been connected with the application of electricity to mining, and had spent a considerable amount of time underground, in experimental work and in teaching those who would have charge of the electrical machinery.

It was pointed out in what way the conditions of mining work differed from those existing in other industries, and how they had been dealt with, and some of the machinery now actually employed was described. The use of compressed air was then discussed, and the results of experiments were given, showing that the efficiency of this method of transmitting power was 45·8 per cent. for an air pressure of 19 lbs. per square inch, decreasing to 25·8 per cent. for an air pressure of 40 lbs. From more recent experiments by Professor Kennedy, F. R. S., M. Inst. C. E., it was found that in practice an efficiency of 31 per cent. might be realized, or 45 per cent. if the air was heated before being passed into the motor. In the case of the electrical transmission of energy, except when distributed into very small units, there was little difficulty in obtaining 50 per cent. of the power expended in the engine, and there were cases in which an efficiency of 75 per cent. had been realized. One of the most important points with regard to the employment of electricity in coal mines was whether a motor would be likely to cause an explosion. It was necessary in the case of a machine which, perhaps, might have to work for several hours without attention, to guard against the possible accumulation of an explosive atmosphere around the brushes. For this purpose the authors had enclosed either the whole armature or the commutator only in a practically air-tight casing, and the method had been successfully applied to a motor of 40-horse power. The temperature had been kept down to 70 degs. Fahr. above that of the atmosphere by allowing a sufficiently large cooling surface, namely, 2·3 square inches per watt. To meet the objection that if the fire-damp should leak into these covers the resulting explosion might be as disastrous as if they did not exist, it was pointed out that whenever the proportion of marsh gas to air exceeded 3 to 4 per cent. combustion would take place quietly, and the resulting carbonic acid would tend to prevent explosion in the case of further leakage. Moreover, the authors proposed, in special cases, to introduce a constant supply of carbon dioxide from a steel cylinder into the interior of the casing, thus preventing the ingress of an explosive mixture. Similar methods were adopted for enclosing the switches, and sparking was prevented by providing a resistance coil of small self-induction, which was always connected to the ends of the magnetizing coil so as to form a path through which the current in the latter might continue even when the main circuit was broken. The switch itself also had a resistance coil connected to the several points with which it made contact, so that by slowly opening the circuit sparking was practically done away with. The application of electricity to pumping in mines was then described and illustrated. The use of belts for driving was not recommended on account of the want of space and the difficulty of keeping them in good condition in dirty and wet situations. The employment of electric power for actuating coal-cutting machinery was suggested in 1873 by Mr. Henry Wilde, and first practically applied by Mr. F. Mori, in 1887, whose machine was illustrated. It had a cutter of the bar type, revolving upon its axis, and was driven by a dynamo having a normal output of 10 horse power, situated at a distance of about a mile. It was built by Messrs. W. T. Goolden and Co. Their next machine was one in which the armature shaft itself was made to carry the cutter bar. Later developments of these electrical coal cutters were given. The proper form and dimensions of the cutters were then discussed at some length, the authors preferring the bar type to that in which the tools were fixed into the periphery of a disc, not only as being less liable to be held fast by a fall of coal, but as cutting to a much greater depth. The cutter bar ran at a rate of 500 revolutions per minute, and on an average, including stoppages, from 20 to 30 square yards per hour might be cut in fairly hard coal. At Lord St. Oswald's Colliery, at Nostell, 55 yards were bored to an average depth of 3 ft. 8 in. in seventy-five minutes. The relative cost of cutting coal in this way and by hand showed a difference in favor of the machine of 1s. 6d. per ton. An electric boring machine was described, and also an arrangement for driving an Ingersoll percussive rock-drill by electricity, as well as a special form of dynamo adapted for use in transmitting power for electric mining work, with a high voltage. The authors arrived at the following conclusions:

(*a*). That electric power was destined to become an important factor in mining mechanics, on account of: (1). The facility with which it could be used with machines which required to be moved from time to time; (2), the great economy in first cost and reduced cost of working owing to its efficiency being higher than that of compressed air, or any other medium of power transmission; (3), the smaller cost of maintaining the cables, as compared with piping, on shifting floors in roadways, etc.

(*b*). That the methods described were sufficient to obviate all objections to the use of electric motors in coal mining, whether by excluding inflammable gases or by constructions which would allow of their safe combustion.

(*c*). That the experiments, trials, and practical work, extending over four years, showed that: (1). Electrical pumps might be used with advantage and economy for mine draining; (2), electrical coal cutters could replace hand labor, with saving in cost, and increased production of coal; (3), electrical drilling machines were available in place of machinery worked by hand or compressed air.

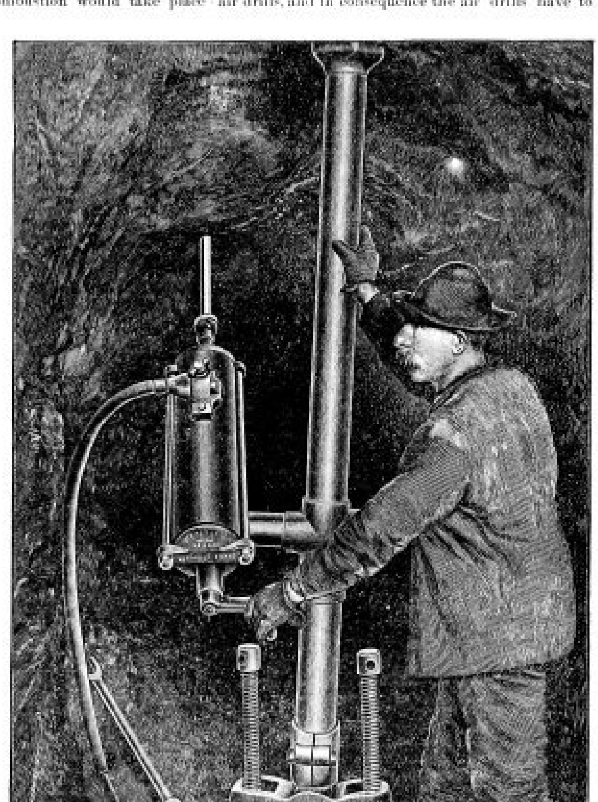
Electric Percussion Drills.

The following is an extract from a letter received by H. Ward Leonard, of the Edison General Electric Company from the engineer in charge of the "Last Chance" Mine, at Wardner, Idaho:

"Operating two air drills for twenty-four hours, required five cords of wood, while, for running four electric percussion drills for the same length of time, each drill doing more work than the air drills, it required only one and one-half cords of wood. The electric percussion drills have been found to do more work than air drills, and in consequence the air drills have to be replaced by electric drills.

"The air plant was situated 1,000 feet higher up the mountain than was required with the electric drill and the fuel had to be carried to the air plant this increased distance over that necessary for the electric percussion drill."

We show herewith a view of the electric percussion drill on a shaft column as taken from a photograph in the "Last Chance" Mine.



Correspondence

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

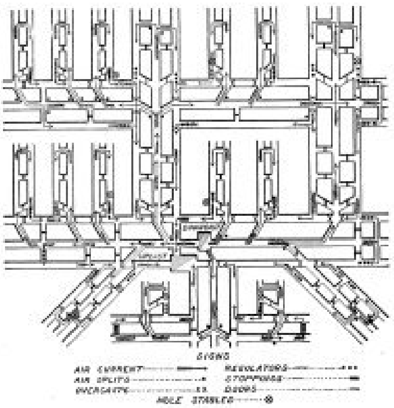
The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.*

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following plan for ventilating mine submitted by Arthur Crosland in the June issue of THE COLLIERY ENGINEER:



I would use to ventilate this mine a Guibal fan 12′ 6″ in diameter, and 5′ 8″ in width. It should produce 25,000 cu. ft. of air, making 210 revolutions per minute with a water-gauge of 2½ inches. This ought to be sufficient to overcome any emergency which might occur in the mine. I would have it a force fan.

Yours, etc.,
JACK.

Delaney, Pa., June 22d.

Ventilation.

The Colliery Engineer:

SIR:—I submit the following in answer to "T. S. C.," of Gardner, Ills.:

(1). We can solve this question by the use of the formula

$$\frac{K\ l\ o\ q^2}{a^3},$$ and as K, o, and q, are the same in each airway they will cancel, we have left $\frac{l}{a^3}$. Assuming 1,000′ to be the length of the 6′ × 6′ airway, then

$$\frac{l}{35^3} = \frac{1{,}000}{36^3},$$

and by transposing

$$\frac{1{,}000 \times 35^3}{36^3} = 857',$$

length of the 5′ × 7′ airway, and

$$\frac{1{,}000 \times 32^3}{36^3} = 702',$$

length of the 4′ × 8′ airway.

(2). Murchline, on page 87 of his book, gives the following formula:

$$a = \frac{\cdot000385 \times q}{\sqrt{w}},$$

where a = equivalent orifice in sq. ft., q = cubic feet of air per minute, and w = height of water-gauge in inches. The pressure required for the large airway = ·32 lbs., and for the small airway 2·41 lbs., then 2·41 − ·32 = 2·09 lbs. to be spent on the regulator. This is equal to a water-gauge of 2·09 ÷ 5·2 = ·4019, then

$$\frac{\cdot000385 \times 12{,}000}{\sqrt{\cdot4019}} = 7{\cdot}28' +.$$

Yours, etc.,
M.

Hollowayville, Ill., June 19th.

Pumping.

Editor Colliery Engineer:

SIR:—Would you kindly place the following question in your columns for answer and explanation:

In a shaft 100′ deep a pump is placed with 5′ suction and 95′ discharge. Will it require more, or less power, if the pump is placed up the shaft with 20′ suction and 80′ discharge?

Yours, etc.,
BEGINNER.

Mount Pleasant, Pa., July 1st.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to "T. S. C.," of Gardner, Ill.:

The formula used in finding the rubbing surface is

$$S = \frac{P\ a}{K\ v^2},$$

and when S is found and dimensions of airway are given the length is easily obtained. In this question P K and v are the same and by canceling these factors the formula becomes

$$\frac{a}{v^2} : \frac{a}{v^2} :: 1 : x.$$

Assuming the length of the large airway to be 1, the length of the second would be

$$\frac{1{\cdot}03}{1^2} : \frac{1}{1{\cdot}03^2} :: 1 : {\cdot}91,$$ and the length of the third would be

$$\frac{1{\cdot}125}{1^2} : \frac{1}{1{\cdot}125^2} :: 1 : {\cdot}702.$$

Therefore, the comparative lengths are 1, ·91, ·702.

(2). Their lengths are as 1 is to 2·25, then

$$\sqrt[5]{2{\cdot}25^2} : \sqrt[5]{1^2} :: 36 : 25,$$

and the $\sqrt{25}$ is 5, the size of the regulator.

Yours, etc.,
A. B.

Hanna City, Ill., June 16th.

Ventilation and Mining.

Editor Colliery Engineer:

SIR:—Will some of your correspondents kindly answer the following questions:

(1). In Wilson's book on mine ventilation the following formula is given to find the perimeter of an elliptical shaft:

$$\frac{\sqrt{\frac{A^2 + a^2}{2}} + \frac{A + a}{2}}{2} \times 3{\cdot}1416.$$

Please explain it by working it out fully.

(2). In opening out a gangway to the width of a double track or turnout, how would you increase the length and diameter of your collars?

(3). If there are two airways of the same length one being 12′ by 6′, and the other 9′ by 9′, what pressure applied to the former would give the same quantity of air that a pressure of 10 lbs. per sq. ft. gives to the latter?

Yours, etc.,
A. L. G.

Audenried, Pa., June 22d.

Mensuration.

Editor Colliery Engineer:

SIR:—I submit the following in answer to question (2), by "Inquirer," in the May issue:

The perimeter is found as follows:

$$8^2 + 5^2 = 89, \text{ and } 89 \div 2 = 44{\cdot}5.$$

$$\sqrt{44{\cdot}5} = 6{\cdot}67'.$$

And, 8′ + 5′ = 13′ ÷ 2 = 6·5′, then

6·67′ + 6·5′ = 13·17′ ÷ 2 = 6·585′, which multiplied by 3·1416 = 20·687′ perimeter.

Yours, etc.,
J. A.

Nanticoke, Pa., June 30th.

Sustaining Life Under Pressure of Air.

Editor Colliery Engineer:

SIR:—In answer to questions by "Rescuer," of Jeanesville, Pa., in the June issue, please insert the following:

(1). There is a slope 624 feet long having a perpendicular depth of 100 feet and it is filled with water. Breasts are driven up 416 feet in length and 100 feet perpendicular height from a gangway which is level from bottom of slope. The compressed air holds the water back 80 feet from face of breast.

How many cubic feet of air is in one of the breasts which is 4 feet high and 30 feet wide, and what would be the volume of this air if the pressure of water were removed? Allow the temperature to be 62° Fahr., the weight of a cubic foot of air to be ·0763122 lbs., and of water 62·355 lbs.

The head of water standing over the chamber considered will be

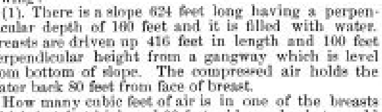
$$\frac{80 \times 100}{416} + 60 = 79{\cdot}2'.$$

And

$$\frac{79{\cdot}2 \times 62{\cdot}5}{144} = 41{\cdot}3 \text{ lbs. per sq. in. pressure above}$$

the atmosphere.

41·3 + 14·7 = 56 lbs. total pressure, which equals 3·8 atmospheres.



Now

4 × 30 × 80 = 9,600 cu. ft., volume of breast, and 9,600 × 3·8 = 36,480 cu. ft., with air at natural pressure.

(2). How long would the amount of air contained in a breast as above described, maintain the lives of four men? I gave a similar question which was published in the *Mining Herald* five years ago, taking figures and conditions from an accident in Wales where the shaft workings broke into a creek and some of the miners were enclosed for ten days. By cutting through a pillar 40 yards thick from an adjoining colliery all were rescued alive, but one of the rescuing party was killed by the pressure of the air driving him against the sides of the opening as they broke through.

A grown man at rest requires ·25 to ·35 cu. ft. of air per minute, which when breathed vitiates from 4 to 5 cu. ft., so that from a sanitary point of view the air could be breathed for 38 hours only.

However, under these circumstances taking ½ cu. ft. per man per minute, there is enough oxygen to sustain life for 608 hours, or 25 days.

Of course it all depends on whether the men are of sufficiently healthy physique to withstand the unhealthy conditions for so long a time.

Yours, etc.,
HUCKLEBERRY.

Montreal, Canada, June 17th.

Answers to Miscellaneous Questions.

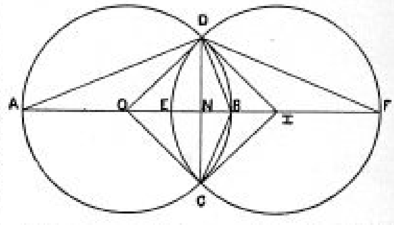
Editor Colliery Engineer:

SIR:—Please insert the following in answer to "Inquirer," whose questions appeared in the May issue of your journal:

(1). By "P a" is meant the total pressure or the area multiplied by the pressure per square foot. There is no other method to find the velocity under the above conditions. The formula may be reduced, however, to

$$V = \sqrt{\frac{P\ a}{K\ s}}$$

(2). By hypothesis the perimeter of the ellipse is equal to the arcs D B C and D E C, with a radius equal to B O = E H.



In the diagram let D C represent chord of arc D B C, and A F its bisector. Then will D B = B C; and the angle B N D = B N C. Now D O B = O D A + O A D (being supplements to D O A); and O D A = O A D, therefore D O B = 2 (O A D).

Again O A D = N D B (being measured by equal arcs); hence B O D = 2 (N D B). Then,

$$\frac{B\ N}{D\ N} = \text{tan. } B\ D\ N = \frac{2{\cdot}5}{4} = {\cdot}625 \text{ tan. } 32° \text{ in}$$

round numbers, hence

D O B = 64°, therefore D O B + B O C = 64° × 2 = 128°, again,

B A : B D :: B D : B N, then

$$\frac{B\ D^2}{B\ N} = B\ A. \text{ But,}$$

$$B\ D^2 = B\ N^2 + D\ N^2 = 2{\cdot}5^2 + 4^2 = 22{\cdot}25, \text{ hence}$$

$$\frac{22{\cdot}25}{2{\cdot}5} = 8{\cdot}9 = B\ A, \text{ and } 8{\cdot}9 \div 2 = O\ B = 4{\cdot}45.$$

Again, 8·9 × 3·1416 = 27·96024, circumference, and 27·96024 ÷ 360° = ·076 length of one degree. Therefore

·076 × 128 = 9·728 = D E C, then

9·728 × 2 = 19·556 = D E C B, or perimeter of ellipse.

An approximate rule to find the length of an arc is

$$\frac{8\ c - C}{3} = \text{arc, when}$$

c = chord of half arc.
C = chord of arc.

Applying the above rule we have

$$c = \sqrt{22{\cdot}25} = 4{\cdot}71, \text{ then}$$

$$\frac{(4{\cdot}71 \times 8) - 8}{3} \times 2 = 19{\cdot}78 \text{ the perimeter.}$$

Yours, etc.,
R. M. S.

Avoca, Pa., June 18th.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to question by "Thomas H. Picton," which appeared in the June issue:

[Solution is similar, and same result obtained as that of "J. E. J.," received on June 24th.—ED].

J. D.

Clay City, Ind., July 1st.

Siphon.

Editor Colliery Engineer:

SIR:—I would like some of your readers to answer the following question:

Can a siphon have too much fall for its lift, and why?

Yours, etc.,
MINER.

Elizabeth, Pa., June 22d.

The Practical Work of Engines.

Editor Colliery Engineer:

SIR:—I notice in the July issue of your journal that "Equity," suggests that "I apply the same rule to direct, as I do to geared engines." I would say that I did so in my communication, with the exception that I deducted one-third of the load for frictional resistance in first motion engines, and one-half in geared engines. In either case my rule formulated would be:

For first-motion engine

$$A \times P \times V \times \cdot 67.$$

For geared engine

$$A \times P \times V \times \cdot 5.$$

A = area of cylinders.
P = $\frac{2}{3}$ of boiler pressure.
V = velocity ratio.

The decimals are constants. Taking the data given by "Equity" and using these rules we have:

904·8, area of cylinder, × 40 lbs., which is $\frac{2}{3}$ of boiler pressure = 36,192 lbs., and

$$36{,}192 \text{ lbs.} \times \frac{125\cdot 664}{452\cdot 4}, \text{ or } \cdot 28 \text{ nearly,}$$

velocity ratio, = 10,133·76 × ·67 = 6,789·6192 lbs.

The actual ability of "Equity's" engine is 7,988 lbs., so that my rule would be on the safe side by 1,199 lbs., nearly.

If we take the data given by "Equity," but use $\frac{11}{12}$ of boiler pressure as "Mechanical Engineer" does, and use "Mechanical Engineer's" rule we have:

452·4, area of cylinder, × 55 lbs., which is $\frac{11}{12}$ of boiler pressure, = 24,882 lbs.

And

$$24{,}882 \times 20'' = 497{,}640 \div 72'' = 6{,}911 \text{ lbs.}$$

So that there is only a difference of 122 lbs. of load between "Mechanical Engineer" and myself. "Mechanical Engineer" is fully 1,000 lbs. on the safe side if we take "Equity's" figures as the actual ability of his engine.

The theory given in these formulæ are *stated laws of mechanics*, but the assumptions are the results of experience. The actual load given by "Equity" shows that the practical part is in error—what shall be done? Shall we assume the coefficient of friction to suit this one case, or shall we go by the old golden rule which our fathers in England and Scotland used after many years of practical experience? If engine builders have a higher state of perfection in their engines in these latter days they should let us know it so that we can deduct the proper amount of load for frictional resistance.

I feel indebted to "Equity" for the data he has laid before us and I hope many will follow his example. With the permission of my superior officers I intend at an early date to make a like experiment which will be laid before your readers.

In conclusion I would say in one or two articles (not the one "Equity" refers to) I sent your journal I did wrong in using the double stroke of piston as diameter of crank circle. Those examples will easily be detected as I made a full statement of the law on the subject as given by Ball. The results given, divided by 2, will be correct answers in those cases.

Yours, etc.,
H. L. D. W.

Lethbridge, N. W. T., Canada, July 24th.

Mensuration.

Editor Colliery Engineer:

SIR:—Please insert the following in reply to "Inquirer," question (2).

(Same as solution of "F. B.," of Maccan, Cumberland Co., N. S., inserted in July issue).

Yours, etc.,
J. D.

Clay City, Ind., July 2d.

Ventilation.

Editor Colliery Engineer:

SIR:—I submit the following answers to questions by "Inquisitive" in the April issue:

(1) Using Atkinson's co-efficient, what would the w. g. be in a mine having 3 circular shafts, two downcast, 11′ and 10′ in diameter respectively, and one upcast 800′ deep, 8′ in diameter, the quantity being 100,000 cubic feet per minute?

Since the depth of the downcast shafts is not given, we shall assume it to be 800′. Now, in order to find the quantity passing in each shaft we shall apply the rule—the quantity passing is proportional to the square root of the result of the area divided by the rubbing surface multiplied by the area, or

$$\sqrt{\frac{a}{s}} \times a,$$

which for the 10′ shaft is ·49502 cubic feet, and for the 11′ shaft is ·57,175. These results being the relative quantities for each shaft; we find the actual quantities by proportion for as the total relative quantity is to the relative quantity in each shaft, so is the total actual quantity to the actual quantity in each shaft, thus for the 10′ shaft

1·06677 : ·49502 :: 100,000 : (x), or 46,394 cubic feet, and for the 11′ shaft

1·06677 : ·57175 :: 100,000 : (x), or 53,606 cubic ft.
46,394 + 53,606 = 100,000 cubic feet.

We find the pressure for each shaft by the formula

$$P = \frac{K\ S\ V^2}{a}$$

For the 10′ shaft we find P = 2·417
For the 11′ shaft we find P = 2·001
4·418 lbs.

This is equal to an average pressure of 2·209 lbs. in each shaft. Although this is a high pressure, it is small compared with that encountered when attempting to force 100,000 cubic feet of air through one 8′ shaft.

The area of the upcast is 50·2656 square feet, and the whole quantity passing divided by this gives 1988 feet passing through one square foot per minute. Then, by the formula

$$P = \frac{K\ S\ V^2}{a}$$

We find that we have a pressure of 36·025 lbs. per square foot. By adding this to the pressure in the downcast shafts we have

36·025 + 4·418 = 40·443 lbs., and this divided by 5·2 lbs. gives a w. g. of 7·78.

This, of course, is for the shafts alone, and is not obtained in practice. It represents a horse-power of 122·5, and assuming that 75% of useful effect can be realized from an engine, it will require one of nearly 163 horse-power.

(2) Would the w. g. resulting from this ever be met with in practice?

This w. g. would not be met with in practice, as the velocity in the upcast is too high, as it is impossible to force such large quantities of air through such small passages.

(3) Is it possible for such a quantity of air to be circulated under the above conditions?

It is not possible to force such a volume of air through one outlet, it would be necessary to provide more or larger outlets.

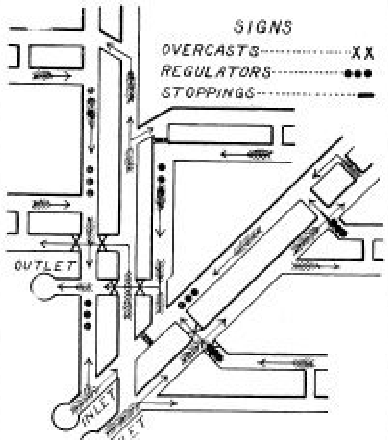
Yours, etc.,
S. U. P.

Red Bank, Pa., June 24th.

Ventilation.

Editor Colliery Engineer:

SIR:—I submit the following plan in answer to "S. U. P.," in the June issue:



There could be a double door placed between No. 1 and No. 2 inlets (No. 1 inlet being the lower one as shown in figure), if the south side coal was brought to No. 2 inlet only. This would avoid the least confusion in the two currents, the regulators could be more easily arranged, and less of them would be required according to the length of each split, other things being equal. But if all the coal is brought to No. 1 inlet, or to both, so as to suit outside arrangements, then the passage from one inlet to the other should be kept free from doors, and regulators used as shown.

Yours, etc.,
JOSEPH CAIN.

Whitwell, Marion Co., Tenn., June 26th.

Examination Question.

Editor Colliery Engineer:

SIR:—I submit the following in answer to "J. W. S.:"

The weight of a cubic foot of air in the downcast is found as follows:

$$W = \frac{1\cdot 3253 \times 30}{459 + 40} = \cdot 07967 \text{ lbs.}$$

$$\text{The motive column} = \frac{5\cdot 2}{\cdot 07967} = 65'.$$

The temperature of the upcast will equal the depth of the shaft multiplied by 459 plus the temperature of the downcast, divided by the depth of the shaft minus the motive column, then subtract 459.

$$T = \frac{400 \times (459 + 40)}{400 - 65} - 459 = 136\cdot 8°.$$

Proof,

$$\frac{1\cdot 3253 \times 30}{459 + 40} \times 400 = 31\cdot 8 \text{ lbs. weight of column}$$

in downcast.

$$\frac{1\cdot 3253 \times 30}{459 + 136\cdot 8} \times 400 = 26\cdot 6 \text{ lbs, weight of column}$$

in upcast. Thus, 31·8 − 26·6 = 5·2 lbs. the ventilating pressure.

NOTE.—The quantity passing is an unnecessary factor in the question as it will vary with the area and rubbing surface, the pressure remaining constant. In other words, a larger shaft will pass a larger volume than a smaller one with the same pressure.

Yours, etc.,
T. S. C.

Gardner, Ill., July 28th.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to "A. S.," of Wilkinsburg:

To find the pressure we must first find the weight of a cubic foot of air in each shaft, and multiply the difference by the depth of shaft. By using the formula

$$W = \frac{1\cdot 3253 \times B,}{459 + T}$$

and assuming the barometer to be 30″, we find the weight of a cubic foot of air in the downcast to be ·07952, and in the upcast to be ·05729, then

$$\cdot 07952 - \cdot 05729 = \cdot 02223,$$

which multiplied by the depth of the shaft, 500′, gives 11·115 lbs., the pressure. Then by the formula

$$q = \sqrt{\frac{P\ a}{K\ S}} \times A,$$

we find the volume to be 16,332·5 cubic feet per minute.

Now, when the length is increased 4,000′ the volume will vary in inverse proportion as the square root of the length. In both calculations the depth of shaft is added to the length of airway making the first airway 1500′ long and the second 4,500′ long, then as the lengths are as 45 is to 15 we have the proportion

$$\sqrt{45} : \sqrt{15} :: 16{,}332\cdot 5 : x,$$

or 9,506·9 cubic feet the volume in long airway.

The lengths are only considered to the furnace, the velocity will be greater in the furnace shaft on account of the expansion of the air. The difference in temperature is 193·9°, and as air expands $\frac{1}{459}$ of itself for each degree of heat added the volume becomes $\frac{193\cdot 9}{459}$ greater in the upcast, or 6,899·68′ = expansion, and

$$16{,}332\cdot 9 + 6{,}899\cdot 68 = 23{,}232\cdot 58,$$

which gives a velocity of 929·3′ per minute when passing through short airway.

Yours, etc.,
S. U. P.

Red Bank, Pa., July 29th.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following for solution in your next issue:

If an airway 6′ × 6′, and 15,000′ long, can pass 12,000 cubic feet per minute, what should be the length of a square box with an area of 28·5714 sq. ft. and a rubbing surface equal to 18,000 sq. ft. placed in an airway 7′ × 8′, and 600′ long to pass the same quantity—the section between the box and the airway to be closed?

NOTE.—The box may be taken as a separate airway.

If Jas. Stirling should happen to see this question, I would like him to solve it by the same principle as he solved the regulator question in your July issue.

Yours, etc.,
S. M. ROBERTS.

Avoca, Pa., July 29th.

Ventilation.

Editor Colliery Engineer:

SIR:—Will some of your readers kindly answer the following questions:

(1). In an elliptical shaft, whose diameters are 8′ and 14′ respectively, and whose depth is 600′, with a volume of 43,982·4 cubic feet of air passing per minute, what is the velocity?

(2). Using Atkinson's coefficient of friction, what would be the pressure and water-gauge resulting?

Yours, etc.,
S. U. P.

Red Bank, Pa., July 30th.

The Practical Work of Engines.

Editor Colliery Engineer:

SIR:—"Equity," who writes in the July number, evidently mistakes the principle of moments from that of work in comparing the formulæ with "the practical work of engines."

The load which an engine can *pull at a certain speed* is a different quantity from that which it can *start*. I beg leave to offer this solution to his quandary:

The steam pressure total upon the piston multiplied by the lever arm of its application, cannot be exceeded by the products of the load L, by its lever arm. This is a question of static equilibrium, whence, for the direct acting hoister the relation is:

$$2\ A\ a\ P\ C\ f = L\ R + \text{friction},$$

which with the figures given, F = $\frac{1}{3}$, gives L = 10,000 as the *maximum* load which the engine can start.

If we desire to investigate the dynamic equilibrium, an element of time enters which has therefore the relation

$$D\ L + \text{friction} = 4\ A\ a\ P\ S\ f, \text{ or}$$

L = 6,347, if F is $\frac{1}{3}$, and f the coefficient of engine 1, with a second motion engine, the formula, respectively is:

$$A\ a\ P\ C\ y\ f = L\ R\ x + \text{friction},$$

in which x and y are the number of teeth in the pinion and drum wheels.

"Theory" is but a formulation of the phenomena of "practice" and its statements properly applied and properly understood need not give any such confusion as "Equity" is laboring under. If "theory" were so badly in error as he fears, it would have, long since, been replaced by a more serviceable "practical" formula.

Yours, etc.,
THEORIST.

Golden, Col., July 27th.

Arithmetic.

Editor Colliery Engineer :

SIR :—I submit the following in reply to "S. U. P.," of Red Bank, Pa.:

The general rule for extracting the root of any number is

(1). Prepare the given number for extraction by pointing off as the root directs.

(2). Compute the first figure in the root by trial, and, in this case, raise it to its fourth power and subtract the result from the first period in the dividend.

(3). To the remainder annex the first figure in the next period, treating this as a new dividend.

(4). Raise the root already found to the given power less one, and multiply this by the index of the given power, the result will be the new divisor.

(5). Find a quotient figure by division, and annex it to the root.

(6). Involve the new root thus found the number of times indicated by the given power, and subtract this result from the number of periods in the given number as are represented by the last figure brought down.

(7). To the remainder bring down the first figure of the next period for a new dividend.

(8). Find a new divisor as before, and thus proceed to the end.

For example what is the 4th root of 56,249,134,561 ?

562,4913,4561 (487
256
256) 3,064 Dividend.
5,308,415 Subtrahend.
442,368) 3,164,974 Dividend.
56,249,134,561 Subtrahend.

$4 \times 4 \times 4 \times 4 = 256 =$ Divisor.
$48 \times 48 \times 48 \times 48 = 5,308,416 =$ Subtrahend.
$48 \times 48 \times 48 \times 4 = 442,368 =$ Divisor.
$487 \times 487 \times 487 \times 487 = 56,249,134,561 =$ Subtrahend.

Yours, etc.,
F. W.

Grassy Run, Pa., July 27th.

Answers to Miscellaneous Questions.

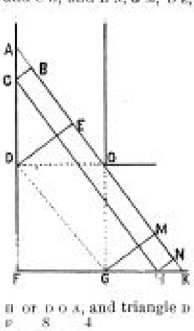
Editor Colliery Engineer :

SIR :—Please insert the following in answer to Joseph Quigley, whose questions appeared in the June issue :

(1). What is the longest rail or prop that can be taken down a shaft 6′ × 6′ and 8′ high in the bottom?

If a line A K was taken down, the point where it would meet at O, would be the middle of that line, which proves to be twice D G. Now, the length of the prop B U H C will depend upon its thickness; suppose the thickness of the prop B C, to be 1 foot.

Now, N A is parallel to D G and C H, and B N, G M, D E, and B C are parallels.



Again, D E = G M, and G K = D O, and the angle G M K = the angle D E O, then triangle D E O = triangle G M K, and E O = M K, and M E = O K = D G = $\sqrt{(OD)^2 + (OG)^2} = \sqrt{6^2 + 8^2} = 10$, and A K = 20 K = 20.

Then angle M G O + O G D = right angle, M G K + M G O = right angle ; then, O G D = M G K = N H K; and $\frac{OD}{OG} = \tan. DGO \frac{6}{8} = \cdot 75$.

Again, the angle B A C = N H K, therefore B C A = N K H or D O A, and triangle D O A = F G D; tan. $ACB = \frac{DF}{FG} = \frac{8}{6} = \frac{4}{3}$.

Hence, $1 \times \cdot 75 = \cdot 75$, or (tan. N H K) (N H) = N K; and $1 \times \frac{4}{3} = \frac{4}{3}$, or (tan. A C B) (C B) = B A.

Then,

$$\cdot 75 = \frac{3}{4}, \text{ and } \frac{3}{4} + \frac{4}{3} = 2\tfrac{1}{12};$$

whence,

$$20 - 2\tfrac{1}{12} = 17\tfrac{11}{12} = \text{N B or length of prop.}$$

Reducing the above work to a formula, we have

$$2\sqrt{H^2 + W^2} = \left(\frac{W T}{H} + \frac{H T}{W}\right).$$

H = height at bottom of shaft.
W = width of shaft.
T = thickness of prop.
All taken at the same denomination.

NOTE.—In the above demonstration no allowance has been made for width and breadth.

(3). What actual quantity of air can be expected from a fan of 20 feet diameter 7 feet in breadth of blades, with an orifice of 8 feet, and velocity of 50 revolutions per minute?

It is impossible to know what quantity of air any fan will produce without knowing the condition of the mine (or water-gauge due to the resistance of the mine), and water-gauge due to resistance of fan. Also the percentage such fan is given.

In regard to the latter part of the question, which reads as follows : "The area of an airway at entrance of upcast to the fan is 90 feet and an anemometer applied at that point, indicates more air than the capacity of the fan as computed from the above dimensions. Can such ever be the case? If so, I do not understand the cause, and would like the opinion of some of your readers on it.

I say that no machine can produce more than its capacity.

If theory don't correspond with practice, I say that it is not a correct theory.

If Mr. Quigley will be so kind as to show us how he made his calculation and experiment, then perhaps it will be possible to show him where he is wrong. I would refer Mr. Quigley to D. Murgue's "Theories and Practice of Centrifugal Ventilating Machines," by A. L. Steavenson.

Yours, etc.,
R. M. S.

Avoca, Pa., June 17, 1891.

Correction.

Editor Colliery Engineer :

SIR :—My pump formula in the April issue was incorrectly stated. It should have been $D^2 L N \times \cdot 034 =$ gallons, and removing decimal point one place to right = lbs. Am much obliged to the two gentlemen for their corrections, but think that "Tyro" made the thing more absurd than it really was by moving the decimal point to the left instead of the right, as I stated it.

Yours, etc.,
J. V.

Punxsutawney, Pa., July 26th.

Examination Question.

Editor Colliery Engineer :

SIR :—In answer to problem by "J. W. S.," of Westville, Pictou Co., N. S., the first thing necessary is to find the weight of a cubic foot of air in the downcast, which is done by the use of the formula

$$W = \frac{1 \cdot 3253 \times B}{T + 459},$$

assuming the barometric pressure to be 30″, we have

$$\frac{1 \cdot 3253 \times 30}{40° + 459°} = \cdot 0796773.$$

Now $5 \cdot 2 \div 400 = \cdot 013 =$ difference in weight of 1 cubic foot of downcast and upcast air, therefore

$W - p$, or $\cdot 013 - W = \cdot 0666773$, and

$$\frac{1 \cdot 3253 \times B}{W} = 596 \cdot 29°,$$ subtracting the constant 459°, we have 137·29° as temperature of upcast.

Yours, etc.,
J. V.

Punxsutawney, Pa., July 26th.

[Similar solutions to this question were received from "S. U. P.," of Red Bank, Pa., July 29th, and from David P. Brown, of Adelaide, Pa., July 30th.—ED.]

Mensuration, Mining, and Ventilation.

Editor Colliery Engineer :

SIR :—Please insert the following questions in the Correspondence Department of THE COLLIERY ENGINEER:

(1). The inside measurements of a pit car are length, 6′ 6″; depth, 2′ 6″; the bottom section 1′ in height, and 3′ 2″ in width; the top measurement of upper section is 4′ in width, how many bushels of coal will it contain, computing 2,688 cubic inches to the bushel?

(2). How would you proceed to develop a coal field of 1,000 acres, 4′ thick and lying 500′ below the surface, with an inclination of 1′ in 300′ West to East. Also give a description of all the necessary appliances required, the output to equal 1,200 tons daily.

(3). In a mine generating a large amount of fire-damp, where the coal vein dips 10′ in every 100′, what ventilating apparatus would be best, and where would you erect the same?

(4). If a mine generated 200 cubic feet of fire-damp per minute, and 1,000 cubic feet of black-damp, there being 120 persons employed, how much air would be required to keep the workings in a healthy condition?

Yours, etc.,
MINER.

Philipsburg, Pa., July 27th.

Arithmetic.

Editor Colliery Engineer :

SIR :—In answer to "S. U. P.," of Red Bank, Pa., I would say that the simplest rule for extracting the 4th root is by logarithms. For example the log. of 28,561 = 4·455760, which divided by index of root

$$\frac{4 \cdot 455760}{4} = 1 \cdot 113943,$$

which is the log. of 13 the required result.

I would like to say to all readers and students of mining that THE COLLIERY ENGINEER POCKET-BOOK contains a table of logarithms, and a large amount of formulæ not to be found in any one book published, and is just the book for students of mining who cannot afford a large number of books and who wish to advance themselves.

Yours, etc.,
J. V.

Punxsutawney, Pa., July 26th.

Certificated Mine Bosses and Mine Superintendents.

Editor Colliery Engineer :

SIR :—In the last issue (July) of THE COLLIERY ENGINEER, "L.," of Mansfield, Pa., seems to take great objections to mine superintendents passing an examination. I would ask him if he thinks it would be a degredation to do so, or does he think that a mine superintendent is simply a figurehead to draw his fat salary every month. One is led to think by his letter that a superintendent has no care for the management of the valuable mining property, or for the protection of precious lives. He seems to think that any kind of a man will do for mine superintendent—men even who have no tastes or ability for mining pursuits, but whose only object is a remunerative situation, and who are entirely dependent upon the mine bosses under them for carrying on the work in and around the mines. I again would say that I know *scores* of just such mine superintendents, and "I have not had a great many changes, neither have I had a great many superintendents over me." But I have come in contact with a great many. Mine bosses need not fear "L.'s" assertion, viz.: "I think if the superintendent has to hold a certificate of competency, it will benefit his position by giving him more pay, and will lessen that of the mine boss by giving him less pay and all the hard work." That is just the position the mine boss stands in now.

In conclusion I will say that my mining experience convinces me that the *educated practical* man is the most *successful* manager, when all other things are equal.

Yours, etc.,
M.

Ohio, July 23d.

Ventilation.

Editor Colliery Engineer :

SIR :—I submit the following in answer to Thomas H. Picton's questions on ventilation which appeared in the June issue :

[This solution is similar to that by "J. E. J.," of Moosic, Pa., which was inserted in the July issue. The result obtained is the same, 498·38′.—ED.]

Yours, etc.,
T. S. C.

Gardner, Ills., July 7th.

Arithmetic.

Editor Colliery Engineer :

SIR :—In reply to "S. U. P.," of Red Bank, Pa., I would say that the simplest method of extracting the 4th root of a number is to extract the square root of the square root. Thus

$$\sqrt{28,561} = 169, \text{ and } \sqrt{169} = 13, \text{ therefore}$$
$$\sqrt[4]{28,561} = 13.$$

Yours, etc.,
A. B. C.

Pittston, Pa., July 24th.

[Similar solutions to this question were subsequently received from "W. N. S.," of Falls Creek, Pa., and "J. E. J.," of Moosic, Pa.—ED.]

Ventilation.

Editor Colliery Engineer :

SIR :—Please insert the following in answer to "A. S.," of Wilkinsburg :

SIR :—Supposing we have 2 shafts of equal depth, 500 feet each, and 5′ x 5′ area. The average temperature in the downcast shaft is 41°, and in the upcast or furnace shaft, 234·9°. What amount of air will this furnace power produce in an air-course 1,000 feet in length, and 5′ x 5′ area? And what amount of air will this same power produce in an air-course of the same size, and 4,000 feet in length?

The pressure produced under the above conditions is found thus :

$$\frac{1 \cdot 3253 \times 30 \times 500}{459 + 41°} - \frac{1 \cdot 3253 \times 30 \times 500}{459 + 234 \cdot 9} = 11 \cdot 11 \text{ lbs.}$$

Now,

$$V = \sqrt{\frac{P a}{K s}}$$

Substituting their values we have

$$\sqrt{\frac{11 \cdot 11 \times 25}{\cdot 0000000217 \times 20,000}} = 799 \cdot 985,$$

and $799 \cdot 985 \times 25 = 19,999 \cdot 625$ quantity in the short airway.

Airways with the same power pass quantities according to

$$\frac{1}{\sqrt[3]{s}} \times a,$$

then for the first airway we have

$$\frac{1}{\sqrt[3]{1 \times 1}} = 1.$$

For the second

$$\frac{1}{\sqrt[3]{4 \times 1}} = \cdot 63.$$

The quantity passing in the long airway will be $19,999 \cdot 625 \times \cdot 63 = 12,599 \cdot 763$ cubic feet.

Yours, etc.,
A. B.

Hanna City, Ill., July 21st.

Examination Question.

Editor Colliery Engineer :

SIR :—Please insert the following in answer to "J. W. S.," of Westville, Pictou Co., N. S.:

First find the motive column from the pressure, thus

$$\frac{5 \cdot 2}{5 \cdot 2} = 1 \text{ water-gauge.}$$

Assuming water to be 833 times heavier than air, we have

$$\frac{833 \times 1}{12} = 69 \cdot 4′,$$

the length of the motive column producing ventilation.

As air expands $\frac{1}{459}$ of its volume for every degree of heat added to its temperature we have

$$\frac{400}{459} = \cdot 871$$

as the rate of expansion in the upcast shaft, due to the addition of 1° of heat. But from the motive column we can see that it must be expanded 69·4 ft. Therefore it must be raised as many degrees as the rate of expansion due to 1° is contained times into the motive column, thus

$69{\cdot}4 \div {\cdot}871 = 79{\cdot}67^\circ$ the number that must be added to the temperature, or

$79{\cdot}67^\circ + 40^\circ = 119{\cdot}67^\circ$ the average temperature required in the upcast shaft.

Yours, etc.,
J. I. P.

Whitney, Pa., July 24th.

[A solution to this question using the same principles, and obtaining the same result was also received from D. M. Harr, of Hoult, W. Va., July 26th.—Ed.]

Mechanics.

Editor Colliery Engineer:

SIR:—Will some of your correspondents kindly answer the following question in your next issue, as I am very anxious to have it solved:

At what inclination must a self-acting incline 700′ in length be laid in order that a trip of three cars may be run in two minutes, a full car weighing 3 tons, an empty car ½ ton, the rollers and sheaves 700 lbs., and the rope 200 lbs.

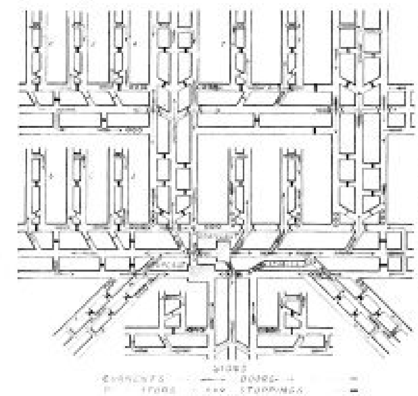
Yours, etc.,
LEARNER.

Westville, Pictou, Co., N. S., July 13th.

Ventilation.

Editor Colliery Engineer:

SIR:—I send in the following plan of ventilation as requested by Mr. Arthur Crossland:



I would say that if this is a true plan of underground colliery entries, it is the first local mine I ever saw that had enough openings, for certainly this has enough. I have numbered some of the double entries on plan, 1, 2, 3, 4, etc., as it may not be necessary to arrange them in separate currents for the distance they are to be driven, by so doing we avoid 5 overcasts, and add 5 doors, but if the mine is a gaseous one it would be best to have the overcasts and avoid the doors. I believe it is wise to avoid doors at all times wherever possible.

I would have the haulage ways in the intake entries, which are the middle entries. These entries should be wide enough for double track, and the endless-rope system could be adopted, using the tail-rope system for slants.

For 400 men and 20 mules it would require not less than 100,000 cu. ft. of air per minute. The selection of a fan requires careful consideration, I would use a Guibal exhaust fan.

All splits equal in length will not require regulators, so it may be possible to do away with some of the regulators shown.

Yours, etc.,
JOSEPH CAIN.

Whitwell, Marion Co., Tenn., June 20th.

Algebra.

Editor Colliery Engineer:

SIR:—Will some of your correspondents kindly work out the following algebraic equation:

$x^2 + y = 7$, and $x + y^2 = 11$,

what are the values of x and y?

Yours, etc.,
A. B. C.

Pittston, Pa., July 24th.

Examination Question.

Editor Colliery Engineer:

SIR:—I submit the following in answer to question by "J. W. S.," of Westville, Pictou Co., N. S.:

A furnace at the bottom of a shaft 400′ deep produces 15,000 cubic feet of air per minute with 5·2 lbs. pressure per square foot. The temperature in the downcast shaft is 40° F., what is the temperature in the upcast shaft?

Assuming the barometer to stand at 30″, we will find the weight of a column of air 1′ square and 400′ deep in the downcast by the following rule:

$$\frac{1{\cdot}3253 \times 30'' \times 400'}{459 + 40^\circ} = 31{\cdot}87 \text{ lbs.}$$

Supposing the shafts to be the same depth, the ventilating pressure being 5·2 lbs. the weight of a similar air column in the upcast will be

$$31{\cdot}87 - 5{\cdot}2 = 26{\cdot}67 \text{ lbs.}$$

Having found the weight of the air column in the upcast the temperature is found by the formula

$$\frac{1{\cdot}3253 \times 30'' \times 400'}{26{\cdot}67} - 450^\circ = 137^\circ.$$

The quantity passing is not a necessary factor in solving the question.

Yours, etc.,
A. B.

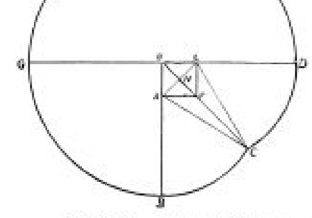
Hanna City, Ill., July 21st.

[Answers to this question, precisely the same as above, were received from "P.," of Whitney, Pa., July 27th, and from Thomas Mather, of South Fork, Pa., July 30th, as they are the same they are not inserted. —Ed.]

Mensuration.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to T. W. Hale, of Scranton, Pa., whose question appeared in the May issue:



The area of D G B = $100^2 \times 3{\cdot}1416 \times \frac{3}{4} = 23{,}562$ square ft.

The sum of the angles that can be formed around the point F = 4 right angles. The angle E F A = a right angle, and the exterior angle = 3 right angles or 270°. The line O C bisects it; then, A F C = E F C = 135°.

In the triangle A F C, A F = 25′; A C = 75′; and A F C = 135°. Therefore

A C : A F :: Sin. 135° : Sin. C, or

75 : 25 :: ·70111 : ·23571; C = 13° 38′.

The angle A = 180° − (135° + 13° 38′) = 31° 22′; the angle C A B = 90° − 31° 22′ = 58° 38′.

The area of the sector A C B = $75^2 \times 3{\cdot}1416 \times \frac{58^\circ\ 38'}{360} = 2883$ square feet.

The area of the triangle A F C = A C ½ Sin. A = 75 × 6·51 = 488·25.

Sin. 31° 22′ = ·52051 × 25 = 13·01 = Sin. A.

The area = 23562′ + 2 (2883 + 488·25) = 30304·5 square ft. surface the horse can graze over.

Yours, etc.,
A. B. C.

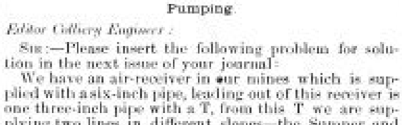
Pittston, Pa., July 24th.

Pumping.

Editor Colliery Engineer:

SIR:—Please insert the following problem for solution in the next issue of your journal:

We have an air-receiver in our mines which is supplied with a six-inch pipe, leading out of this receiver is one three-inch pipe with a T, from this T we are supplying two lines in different slopes—the Summer and Rock. Now ten feet from the T, or receiver, on the



Rock slope side the three-inch pipe with one valve and two elbows making three turns with T, we tap a six-inch pipe which runs 1,800′. Now then 100′ from the six-inch pipe we wish to run a pump, should we make the connection from the six-inch pipe to the pump which is the 100′ with two three-inch pipes, (which can be reduced down to 2½ inches to make connection to the pump) or would one three-inch line do as well leading from the six-inch pipe to the pump, which is 100′, taking into consideration the condition of the supply from the receiver as above stated?

Again, suppose we make the connection from the receiver to the six-inch line with two three-inch pipes, and run from six inch pipe to pump with one three-inch line, will we have better results.

If not too much trouble, I would be pleased to receive an early reply to the above questions.

Yours, etc.,
J. T. ROGERS.

Pratt Mines, Ala., July 18th.

Mr. Thomas Foulds, of Treverton, Pa., an old-time colliery official, has invented a metallic railway tie. The support, or under side of the tie is corrugated. A broad and flat surface is given for the support of the rails. The plate is of such width as to preserve flanges upon either side of the corrugated bearings which are V-shaped. These flanges are provided with holes to receive bolts or fastenings for holding the rails to the plate. The corrugated bearings are for supporting and resisting any breaking strain or pressure while a train is passing over the rails. They are closed at the ends by caps, so as to prevent dirt or stones entering, and also to materially enhance the supporting power of the bearings.

The Coal and Iron Region of North Carolina.

Mr. Rody Maher, of Bedford Co., this State, writes us from Greensboro, N. C., as follows:

"My visit to North Carolina began at Greensboro, and here let me say, my surprise began, for I did not expect to find it such a busy, prosperous and growing city. I recommend our young men who are contemplating a change, to go to Greensboro. There are a number of Northern people here, and all are doing well. I could write a great deal about this "City of Flowers," but coal and iron, is what I want to tell you about.

Here I found the "Greensboro Coal and Mining Co." recently organized, with mines at Walnut Cove, Stokes County, about thirty miles distant.

I visited this property, and was so interested that I remained several days, long enough to make a thorough examination. I will not tax you with a detailed account of all I saw, but will say I was most agreeably surprised. The development of the property was only fairly begun, but the coal, taken out near the surface, is of such good quality, as to encourage active operations. It is semi-Bituminous, and I think, will coke well. In burning, it produces great heat, and leaves no clinker. When sufficient depth is reached, the coal must prove of very fine quality. This is the "Dan River Coal Field," and the property must have been developed years ago, but for the lack of transportation facilities. Now two railroads are in close proximity, and the demand for this kind of coal is enormous. The Company has shipped only a small quantity, for experimental purposes, but have daily enquiries from coal consumers. The work is progressing as rapidly as possible, and they expect to begin shipping in a few weeks. There are several good seams, and this Company may work two at the same time, to enable them to supply the demand, especially so, if it cokes well, as they will then supply the Greensboro Steel furnaces.

The iron properties, in the same County, are very valuable. I was shown some of the finest magnetic iron ore and manganese I ever saw. These iron properties, are the finest in the South, and as the ore is so conveniently located for mining, the Company that develops them will reap an enormous harvest. These properties, consisting of several thousand acres, have been secured, and a Company is about to be organized, to develop them."

Explosion of Gas.

Thirteen men were burned by an explosion of gas at the Lehigh Valley Coal Co.'s York Colliery at Pottsville, Pa., on the 8th instant. One will probably die, the others will recover.

The explosion occurred in a tunnel in the second lift of the slope. A shot fired had cut into the vein toward which the tunnel was being driven, and also liberated a strong feeder of gas. As soon as the smoke had cleared away the men returned to the face, with naked lights on their hats and fired the gas. The coal and timbers caught fire, and it was with considerable difficulty that the injured men were taken out. After the work of rescue was finished, the fire was extinguished. Mine Inspector Gay visited the colliery the day before the accident, and while in the tunnel warned the men that they were approaching the coal, and directed that they go in with safety-lamps after each shot. Disobedience of this order was the cause of the accident.

Mr. H. A. Kingsbury, for many years purchasing agent for the Lackawanna Iron and Coal Co., has opened a store room and office at No. 435 Spruce Street, this City, for the sale of Mine and Mill Machinery and Supplies. Among the specialties handled by Mr. Kingsbury, at manufacturers' prices, are the standard brands of gum belting, and mechanical rubber goods, manufactured by the Gutta Percha and Rubber Manufacturing Co.; Chas. A. Schieren & Co's leather belting; the Jno. A. Roebling's Sons Co.'s wire ropes; safety-lamps of all descriptions; Gilbert's universal and interlocking wood split pulleys; boilers, engines, and pumps of all descriptions; iron and steel in bars or sheets; water and gas pipe; chute plates; forgings; shafting, and hangers; and in fact all kinds of machinery and supplies used in mine or mill work. Mr. Kingsbury's experience with the Iron and Coal Co. has specially fitted him for the business in which he has engaged, and we heartily commend his establishment to our readers as one in which they can secure first-class goods at prices that will compete with any establishment in the country.

The Lidgerwood Manufacturing Company, New York, Chicago, and Boston, are doing an immense business in their standard hoisting engines. They are enlarging their present works in Brooklyn, N. Y., and have just opened a branch house in Pittsburgh, at 99 First Avenue. It will be in charge of Mr. A. G. Harmes, of that city, and anyone desiring anything in the line on hoisting machinery will do well to give him a call. Our readers are cordially invited.

Mr. W. L. Bellis, of Cleveland, Ohio, manufacturer of the Bellis Mining Collar, writes us as follows:

"Enclosed please find check in payment of bill of July 1st. Among recent new orders are those from Abbott and Blakslee, Coal Glen, Jefferson County Pa.; The Cresson and Clearfield Coal and Coke Company, Frugality, Pa.; The Moundsville Coal Company, of West Virgina; John Cooper & Co., Coopers, West Virginia, (two orders); St. Bernard Coal Company, Earlington, Ky.; H. S. Odbert, Canal Dover, Ohio; The Davis Mining Co., Davis, West Virginia, and many others. All purchasers speak in the highest terms of the collar, and have adopted it for general use. My advertisement in THE COLLIERY ENGINEER is the best one I have out."

THE COAL PRODUCTION OF THE UNITED STATES.

WE have compiled from the Census Bulletins compiled by Mr. John H. Jones and issued under the supervision of Dr. David T. Day, special agent in charge of the Division of Mines and Mining, an interesting table, which shows the wonderfully rapid development of our vast coal resources.

A study of this table reveals some interesting facts. It shows that coal is mined in 29 of the 44 states of the Union, and that the coal fields are so located as to be convenient not only to the present great centers of population, but also convenient to the portions of our territory that are most rapidly being populated by immigrants from the North and East, and emigrants from Europe.

The coal production has almost doubled in the past decade, though the population has only increased 24·57%. As the coal mined was all utilized it is evident that not only has the domestic consumption largely increased, but the consumption of coal for steam, purposes in manufacturing establishments must have been increased in a ratio at least twice as large as that shown for the growth of the population. Comparatively none of this coal was exported.

In 1880 the Anthracite coal produced comprised about 40% of the total amount mined. In 1889 it represented about 32·36% of the whole production. That the ratio remains so high for Anthracite is remarkable, as the region producing it is of limited area, and the development of the western and southern fields placed a competitor in many markets, that owing to closer proximity and less cost of mining, could be sold at much lower prices. There were two features, however, that tended to keep the higher priced Anthracite from falling lower in the percentage, and they were its favorable location, so near the great centers of population and manufactures in the East, and its superiority as a domestic fuel. It will be seen from the table that while the production of Anthracite increased but 59%, the production of Pennsylvania Bituminous coal increased about 97%, and this greater increased production of Pennsylvania Bituminous, in connection with the remarkable increase in the neighboring States of Ohio, West Virginia, and Virginia, has materially restricted the growth of the Anthracite trade in eastern markets, and has been the cause of the low prices at which Anthracite has been sold and is now selling.

The development of the western and southern fields has also tended to restrict the market for Anthracite not only by meeting it in southern and western markets as a competitor, but by also wresting a large portion of the western and southern trade from the Pennsylvania Bituminous, and thus diverting it into eastern markets to compete with Anthracite.

Another interesting feature of the table is the number of employes at American collieries. The total number of 296,974 employes shows that a population of nearly or quite 1,200,000 people is directly dependent on the working of the coal mines; for a ratio of four to one in this instance is a very moderate one.

The number of collieries given represents only those that ship their product to market by rail or water. The small mines worked for local sales are not included.

TABLE SHOWING A CONDENSED CENSUS OF THE COAL INDUSTRY OF THE UNITED STATES.

STATES.	Production in Short Tons in Year 1889.	Production in Short Tons, in Year 1880.	Increase.	Number of Persons Employed at Collieries.	Number of Collieries.
Pennsylvania { Anthracite	45,544,970	28,640,819	16,904,151	125,229	342

* Decrease.

NOTE.—The production given in first column is for calendar year 1889. That in the second column is for the year ending May 31, 1880.

ROAD TAXES IN THE ANTHRACITE REGIONS.

JUDGE RICE, of Luzerne County, Pa., recently rendered a decision in the case of Coxe Bros. & Co. and the supervisors of Hazle and Foster Townships, in which he holds that Messrs. Coxe Bros. & Co. have the right to work out their road taxes, amounting to nearly $4,000. The *Scranton Republican*, in its issue for the 7th inst., designates the law under which this decision was made, "an absurd law" and criticises Hon. Eckley B. Coxe for taking advantage of it. In the course of the editorial it is stated that "The lower end of Luzerne County is flooded with the cheapest kind of cheap foreign labor, brought there by Mr. Coxe and other coal operators, and it will probably not cost Mr. Coxe more than $2,500 to work out the $4,000 of his road taxes."

It is surprising that the *Republican* is so ignorant of the state of affairs in many of the townships in each of the coal counties of the State, and also ignorant of the notorious fact that many township officials are best described by a term sometimes applied to them in Schuylkill County, viz.: "Township Robbers." Taxes for years, in some of these townships were either stolen outright or paid to cliques who did a minimum amount of work on the roads for a maximum price. The roads have been in miserable conditions at all seasons of the year, and as the heaviest taxpayers are the most frequent users of the roads, they naturally want them kept in good condition, especially when they pay the tax to have it done. With this object in view, the Philadelphia and Reading Coal and Iron Co., the Lehigh Valley Coal Co., and the Girard Estate have for years been working out their road taxes in Schuylkill, Columbia, and Northumberland Counties. The work is always done under the direction of the township supervisor, but a check is kept on him by the employment of a time-keeper, whose wages are paid by the corporations in addition to the full amount of the taxes levied. The result is better roads because some return is obtained for the money expended upon them. In Lackawanna and Luzerne Counties, the same system has prevailed to a lesser extent and always with beneficial results to the taxpayers. In Pittston Township, Luzerne County, and Carbondale Township, Lackawanna County, it has resulted in the full amount of money paid as road tax being spent intelligently on the roads, and prevented it from being diverted to line the pockets of dishonest township officials.

Mr. Coxe in working out his road tax benefits the public. The roads will be kept in repair to the extent of the amount of his taxes at least, and the public will have better roads in Hazle and Foster Townships than they have had for years. Mr. Coxe will have the trouble and expense of seeing the taxes judiciously expended but his own teams will also have the advantage of good roads.

As for the cheap labor in the lower part of Luzerne County, it was not brought there by "Mr. Coxe and other operators," any more than the better class of Irish, Welsh, and German emigrants were. They came at first in small numbers, and came voluntarily. Each Hun found that work was plenty and wages higher than he ever dreamed of at home, and each one of them became an emigrant agent, and induced others to come, and later arrivals are doing the same thing. Their presence in the coal regions is due to our loose emigration laws. If any of them work on the township roads, it is because the supervisors employ them, and they are paid the same wages as other laborers, when supervisors do not charge them premiums on their jobs. The supervisor has the power to employ the workmen, Messrs. Coxe Bros. only ask the right to pay them, and keep a check on the time-book.

In connection with this matter the *Republican* commends Mr. Albert Lewis and Genl. Paul Oliver for the construction of a road from Laurel Run to Bear Creek, in Luzerne County, which is an excellent piece of work, and was built at the expense of the gentlemen named. Inasmuch as the road mentioned is a greater convenience to Messrs. Lewis and Oliver than to anyone else, we cannot see how they are entitled to more credit than Mr. Coxe is, as he is spending time and money to secure good roads and thus benefiting all residents of the townships affected and thousands of others who are compelled to use the roads.

SENSATIONAL JOURNALISM AND THE COAL MINING INTERESTS.

IT is not astonishing that the mass of the American public possesses distorted and ridiculous views of the state of society and the relative positions of employers and employes in the coal fields. It is hard to see how it can possess any other views because its ideas are shared by and have been imbibed from "the Great American Educational Mediums"—the daily press.

The dispatches which convey this false information are in many instances sent to metropolitan dailies by correspondents located in the coal regions, who are paid for their services in proportion to the amount of sensation they can inject into their telegrams. They frequently convey the idea to general readers that colliery owners and colliery officials are as a rule a set of inhuman fools. We use the expression, harsh as it may seem, because it is the only one that aptly fits. The dispatches chronicling mine accidents are frequently couched in such terms as to leave the reader to infer that the colliery owners and officials have no regard either for human life or property. If such was the case they would certainly be inhuman fools. But, the colliery owners and officials are men that stand deservedly high in every mining community. They not only use every possible means to prevent accidents for Humanity's sake, but do so for economic reasons as well.

In the same manner the mine workers are indirectly traduced. The general impression throughout agricultural and manufacturing districts is that the miners are a set of roughs but little better than criminals. The reverse is the truth; there is no class of workingmen that are possessed of larger hearts or have a higher regard for morality than American coal miners.

If, owing to extensive mining operations, a slight depression of the surface occurs, it is heralded over the country as a great cave-in, by which whole towns were endangered, etc., etc. The facts usually are that a small portion of comparatively worthless surface is sacrificed to win coal beneath it that is of infinitely more value, and the colliery officials and mining engineers expected what slight caving there was.

Many reputable journals do not want such matter from their correspondents, but the news editors not having knowledge of the subject are imposed upon. There are other journals that require just such matter from their correspondents because their circulation is built up by appealing to the morbid taste for sensational news of a certain portion of the public.

In some instances, colliery owners and colliery officials are themselves to blame. Because exaggerated stories have been printed, they refuse to give reporters the facts connected with important happenings around their collieries. The reporters are therefore compelled to get their information from unreliable and ill-informed sources and this in many instances causes the publication of misstatements. It would be far better if all colliery officials would make it a point to give full and correct information to the correspondents and then hold them responsible for misstatements.

The local papers of the coal fields are not free from this fault of incorrectly reporting accidents and other colliery happenings and in their case there is not so much excuse as in the case of metropolitan journals. It is strange that editors, many of them born and raised in mining communities, will permit the publication of incorrect and often ridiculous statements in their journals. They have every opportunity to get correct information, but they neglect to do so, and many of them show a lamentable ignorance of mining matters when commenting editorially on such subjects.

The most important qualifications of a competent editor is a close acquaintance with the subjects of greatest importance to the community in which his journal is published. Yet, there are comparatively few editors in the coal regions who have even a superficial knowledge of the technicalities of coal mining, notwithstanding the industry is the source of all the prosperity of the towns in which they reside. It is a very easy matter for them to post themselves, and there is no excuse for their publishing inaccurate and misleading statements.

These sensational articles are mischievous in many ways. They perniciously affect the capital invested in coal mining, the labor employed therein, the value of real-estate in the mining communities, and the general business interests of the regions.

They affect capital by exciting the minds of the public against the operating interests, and make easy the work of mischievous demagogues who seek to further their own ends by injuring or ruining both capital and labor.

They affect the labor employed in the mines by making it appear that colliery employes are devoid of all morality, and are in general but one degree removed from the brute, when the actual fact is that the standard of morality in mining communities is superior to that of either manufacturing or agricultural communities, and the standard of intelligence among the miners is higher than that of most other classes of labor.

They affect the value of real-estate and business in the coal fields by making it appear that lawlessness prevails and that the working of the mines endangers the surface and all surface improvements.

Taken all in all, the business interests of the coal regions of the United States are seriously affected by these false and sensational publications, and it is the duty of every citizen of those regions to assist in remedying the matter. The editors of the local journals can assist in the work by making it a point to publish only correct reports of colliery happenings and news intelligently written up.

The colliery owners and colliery officials can assist by making it a point to give the newspapers full and correct reports of all important occurrences, and the general public can assist by calling sensational resident press agents to account for their work.

If all classes will combine to effect this result the prosperity of their communities will be enhanced, and capital and business will be attracted to the coal regions, instead of being scared away.

CERTIFICATED MINE FOREMEN.

THAT the employment of certificated mine foremen has been attended with increased safety in the coal mines of Pennsylvania can easily be proven by reference to the Mine Inspectors' reports. Yet there are men who, professing to be friends of the miners, advocate the abolishment of this section of the mine laws. The greater safety in mines due to the employment as mine foremen of such men as have by a careful examination proven themselves qualified to fill the position (many bosses hold service certificates) should ensure the perpetuity of the plan in Pennsylvania and its adoption in every other coal mining State in the Union.

Complaints are made by some that the examinations are too rigorous. We do not think they are. A successful mine boss is a man of broad views, and the more intimately he is acquainted with the sciences connected with mining the better he is equipped to manage the colliery with safety and economy. We wish it understood that we consider the theoretical portion of his education of fully as much importance as his practical knowledge or experience. Theory is merely some one else's practical experience recorded for the use of others, and the more of such theory a mine boss obtains the better is he qualified to fill his position.

The mine foreman who has no knowledge of mining, except that gleaned in his own narrow experience, does not amount to much. And the one who is familiar with theories and has had no practical experience, is wanting in the ability to make use of his knowledge. What is required in the successful mine foreman is a judicious combination of theory and practice. The object of the examinations is to prove that each candidate possesses these qualifications.

These examinations when the law went into effect in Pennsylvania, some five years ago, were comparatively simple. Since then they have been made more rigorous, and this is right.

To be a success the mine foreman should be familiar with the practice and theory of mine ventilation. That he knows that the simple formula

$$\text{“} p = \frac{k\,s\,v^2}{a} \text{”}$$

is so, is not enough. He should know *why* it is so. He should understand the laws of friction of air in mines; and to be able to calculate what current velocity or pressure he may require, he should thoroughly understand mensuration. His knowledge of the gases met with in coal mines should not cease with knowing that certain percentages of fire-damp in the air are explosive, and that certain percentages of other gases are poisonous. Neither should it end with a knowledge of their specific gravities. He should know all about the conditions governing the occurrence of gases in mines, and as it is impossible that any individual can obtain this knowledge by his own experience, a mine foreman must be a reader and a student to be qualified for the place. As well put a child in charge of a powder magazine, as a man who does not read, and in his ignorance professes to despise book learning, in charge of a gaseous colliery.

The mine foreman should understand not only the use of the various safety-lamps, but their construction and principles as well. Otherwise he will not know when a lamp is in safe condition or how to make it safe. He should have an elementary knowledge of geology, and the more he knows of the geology of the coal field he works in the better. He should understand mechanics, so as to be able to take advantage of every thing that will make the extraction of coal safer, and more economical. He should understand the principles involved in the construction and operation of steam boilers, and engines. His knowledge of pumps should be thorough. He cannot be too well versed in practical and theoretical mechanics. He should have a thorough knowledge of surveying, and should be able to read a mine map at a glance, and if necessary, bring the surveys up to date.

Some of our readers will say, "you would require a mine foreman to be not only a practical miner, but a mining engineer, a mechanical engineer, and chemist as well." We heartily wish he could be all four. We do not think that the examinations should be so strict as to compel the candidate to fully reach the standard outlined above, but we do think they should determine that he has an elementary knowledge of the branches mentioned. If he has this knowledge he will, as a rule, thirst for more, and will not cease his studying because he has a certificate. He will know that the little knowledge he possesses makes his work easier, and his services more valuable. He will realize that if he continues his studies he will know still more, and be able to grapple successfully with more serious obstacles, and thus be worth more to his employer and merit promotion and increase of salary. The most successful colliery officials are not those who have merely studied enough to secure certificates. They are those who keep on studying both books and the works of others. They do not expect to learn all from their own narrow experiences, and seek to profit by the experiences of others. The old saying, that "experience is a good teacher," is a true one, but it is not true of our individual experience only. We can learn more from the experience of others working in the same line as ourselves because there are more workers, and therefore more experiences to study. All that the student who is preparing himself for examination learns from books is the experience of others who have gone before, and with the advantage of their experience, and his own, he will be well equipped for his work. The mere possession of a State certificate of competency does not fit a man for successful mine management. There are other qualifications necessary, and without them no man can secure a position, or if he does, he will not hold it long. But this can be truthfully said: Every man of good habits and good judgment, who possesses the faculty of handling men, and who does not cease his studies, and observations, will eventually reach the desired goal, and be a success.

Some time ago we received the following letter from a subscriber in the Wyoming Valley: "Please stop my COLLIERY ENGINEER; I don't need it no more as I past the last examination." This man is not likely to be employed as a mine foreman. He has made the mistake of considering his mining education completed, when it has only commenced.

COMMENT AND NOTICE.

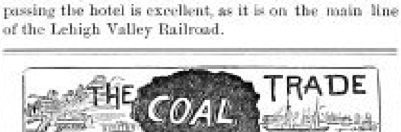
THE statement is frequently made that the use of safety-lamps is injurious to the eyes of the miners though till recently no corroborative evidence accompanied the statement. However, the matter has been practically tested in Great Britain, by Dr. J. Court, of Stavely, who investigated the matter on behalf of the Derbyshire miners, and his examination of a number of miners working with safety-lamps and an equal number using naked lights will throw considerable light upon the question. As nearly one-half the coal raised in the Midland district is worked by the use of safety-lamps, Dr. Court undertook to see 500 persons using the former and 500 using the latter. The examinations show that out of 524 persons using safety-lamps there were 164 afflicted with nystagmus, 127 had night blindness, and 61 photophobia. This clearly proves that there is a serious amount of disease, and in striking contrast with the disease found amongst the 573 miners using naked light, of whom only 32 had nystagmus, 1 had photophobia, and 12 night blindness. This difference is made greater still when it is borne in mind that out of these 32 cases of nystagmus 29 of the men had previously used safety-lamps, and the one man with photophobia and 11 of the cases of night blindness had also been employed in mines worked with the safety-lamps. In other words, of the 544 men who had always used naked lights, there were only 3 who had nystagmus, and they worked with candles. Amongst the torch-light men, 228 in number, there was not a single case. Dr. Court is of opinion that the insufficient light of the safety-lamps is the chief, if not the sole, cause of nystagmus, night blindness, and photophobia.

AT a recent meeting of the Lancashire Branch of the National Association of Colliery Managers, the chairman, Mr. J. H. Tonge, of Hulton Collieries, read an interesting paper on the effect of varying atmospheric pressures on gases in coal mines. He said, considering the effect of varying atmospheric pressure in mines, there appeared to be a divergence of opinion amongst mining engineers, and others whose attention had been directed to the subject, as to the different effects in a mine generating gas of a rising or falling barometer. Numerous experiments tended to prove that gas in the strata existed under very varying pressure. He thought they might, from experiments and from sudden outbursts with which most colliery managers were familiar, assume that this outward pressure of the gas depended almost entirely upon the nature of the strata. But what they had really to fear, when gas existed in the strata—was the removal of strata—be it coal, shale, mineral rock, or whatever might have formed the barrier—at a moment when some defective or open lamp stood directly in the path of the liberated gas. Under such circumstances the volumes of gas rushed forth at such a rate that it effectually refused to allow the pure air to mix with it. He would feel safe in saying it was probable that gas existed in the goaves of many collieries to such an extent that a sudden lowering of the barometer would mean an explosion unless—and this he thought a point well worthy of attention—the liberated gas could get to the upcast shaft without coming in contact with a naked light. He further believed that gas might exist in any of the mines—and did actually exist in some—under such conditions that nothing but the strict exclusion of naked lights from its path, nothing but the most perfect system of lighting, could ensure safety. The official who neglected or treated this question lightly deserved the severest censure; he who could improve and perfect their lighting system would deserve well of his country.

IT probably does not occur to the average reader of a technical paper that the expenses incident to its publication are much greater than those of ordinary newspapers, though the subscription price is less. If the leading technical papers of the country had only such an income as is derived from subscribers they would either degenerate into insignificance or cease publication. It is the advertising patronage that makes such journals profitable, and enables the publishers to furnish first class literature to their subscribers, by employing first-class talent. We are constantly receiving letters from all parts of the country commending and extolling this journal. These are very pleasant evidences that our efforts to make THE COLLIERY ENGINEER the leading mining journal of the world are appreciated. However, our friends can show their appreciation in another way, and a more effective one. Every advertiser in the journal, through his patronage, not only brings his goods to your attention, but he assists in building up the standard of the journal. Therefore, as long as his goods are as cheap and as of good or better quality than others he should have your patronage, and you should, when sending him either inquiries or orders, mention the fact that you saw his advertisement in THE COLLIERY ENGINEER. All our advertisers are substantial firms and are the leading firms in their li es in the country, and they are entitled to your patronage.

WE have received from Mr. Morgan G. Thomas, Inspector of the Third Mining District, of Iowa, advance sheets of his annual report, in which he very strongly sets forth the necessity of a geological survey of the State. Mr. Thomas shows in an intelligent manner the advantages that will accrue to all classes of the States' population by having the mineral resources of the State intelligently examined into and reported on. The coal resources of Iowa, alone, are far greater than many of its citizens know, and if the citizens of the State, who are most interested in its welfare, have no knowledge of the extent of their most plenteous mineral, capital and enterprise from other States can not be attracted, because strangers can not be expected to be familiar with conditions that are not known to the residents of the State. The same truth will apply to other minerals, and Mr. Thomas should have the support of every intelligent citizen of the State in his efforts to have a geological survey started and maintained. Another excellent suggestion that he makes in his report is the establishment of State mining schools. Iowa's mining interests are being rapidly developed, and they should be developed intelligently. The only way this can be done is by the application of skill and intelligence as well as brute force. The miners themselves cannot afford to maintain such schools, but the State can, and the State will profit by establishing them. More coal is lost by unskilled working each year in Iowa than would pay for the maintenance of a dozen such schools. As this coal represents a large portion of the States' wealth, it is evident that it will profit by the establishment of free mining schools as suggested by Mr. Thomas.

THE Fall Meeting of the American Institute of Mining Engineers will be held at Glen Summit, Luzerne Co., Pa., beginning October 6th. Aside from the regular attractions, both scientific and social, that render the meetings particularly enjoyable, the happy selection of beautiful Glen Summit, with its excellent hotel accommodations, will make this meeting particularly enjoyable. Glen Summit is on the top of the Wilkes-Barre Mountains. It overlooks the beautiful Wyoming Valley on one side, and on the other sides the wild mountain scenery is unsurpassed in America. At the time of the meeting the foliage will be very beautiful, and will vary in tints from the dark green of the massive evergreens to the brilliant scarlet and yellow of the maples and other varieties of mountain trees. The Glen Summit Hotel is one of the largest and most popular summer hotels in the country, and the natural attractions surrounding it are equal to those of any mountain resort in America. Its location is particularly convenient to Scranton, Wilkes-Barre, and all other points of interest in the Wyoming and Lackawanna Valleys, on one side, and to the principal points in the Lehigh region on the other side. The train service, passing the hotel is excellent, as it is on the main line of the Lehigh Valley Railroad.



THE ANTHRACITE TRADE.

Mr. C. D. Simpson Proposes Control of the Trade Which Will Control.

The Anthracite coal trade is very quiet, but prospects are very favorable for a good fall trade. The sales-agents of the large companies met on the 29th ult., and agreed to limit the tonnage for August to 3,000,000 tons, and there is good reason to believe that the coal producing interests will this month use every effort to keep the production down to these figures. In pursuance of this plan, the Philadelphia & Reading Coal and Iron Co. suspended operations at all its collieries on the 6th and 7th, and it will carry out this programme of shutting down on the last two days of the week until the market is in satisfactory shape. The other large companies will also do their share. The production for the week ending August 8th was 728,654 tons, and for the year to that date was 22,557,095 tons, an increase over last year to the same date of 2,860,200 tons. The determined effort at restriction which will now be made is a necessary one. But some method should be adopted to regulate the business. Mr. C. D. Simpson, of the firm of Simpson & Watkins, of this city, in a recent communication to *The Coal Trade Journal*, shows the great necessity for this and makes practical suggestions as follows:

"I have no faith in the theory that lower prices for hard coal would broaden the market enough to give us full time work at profitable prices, for within certain narrow limits I think that the consumption demand is definable, subject of course to such an advantage (advantage to Anthracite) as the coke strike which probably added something under a million tons to the demand this year. So even if tolls to tide-water were made $1, we should still need restriction during the first six months of the year. Of course a joint commission having charge not only of all coal mined but of routes and prices, would be of incalculable benefit to the whole trade, but such a radical change in methods is yet out of the question, the discussion should be confined to some simple plan at the start.

Even under our present theory each transportation interest knows its allotment whatever the gross tonnage for the year may be; why then should there be overproduction and forced sales early in the season? Can there be a feeling that prices are likely to decline later on? We know that dealers hesitate to buy at early spring prices having been taught by experience that prices are often if not usually lower in July and August than in April and May. Here then I put our first radical mistake. The matter should be arranged as practically to guarantee to buyers that spring prices would be the lowest of the season. If this were well understood large orders would be received early, mining, selling and transporting of coal would be more evenly distributed throughout the year, and the amount of coal now requiring expensive storage but then taken care of by dealers, would surprise all of us. But why is this not done now? I have talked with many in the trade and while individually they all agree on the main points, collectively they seem helpless, although something of this kind has been worked at since 1886. The simple thing to do as a remedy is to see that spring prices are actually *the lowest of the season and that these will gradually be advanced.* The sales-agents now spend part of their time in accusing each other of cutting prices. I suggest the employment of a clear-headed, honest, dignified man, not interested in mining but familiar with the trade, who shall make the allotment for each week's mining, after advising with representatives of each interest; this man's advice to be strictly followed. He would by means of his position be in touch with the whole trade and the best judge of the general situation. While I think there would be little occasion for such a thing, he might in addition investigate charges of price cutting so far as the interests of the trade at large might require it. *Agreement on tonnage* is the main point I would insist upon; agreement on price is secondary and might indeed be omitted altogether, if the former be lived up to. Supply and demand govern prices; we cannot get from under this law of all commerce, if we would. So if we take care of the spring prices by sufficient restriction, the later prices will take care of themselves."

Mr. Simpson in stating the Anthracite coal trade will prove most profitable when conducted on the principle of securing fair prices instead of relying for profits on a larger output secured by a policy of encouraging consumption with very low prices is not mere supposition. In the years 1877 and 1879 there was unlimited production and competition. Although the cost of mining coal those years, owing to the large production, was very considerably reduced, yet the prices fell off in far greater ratio, and the losses of all interested were so great that the companies gladly settled their differences and returned to the policy of restriction. Mr. Simpson is not theorizing. He is stating the results of experience. It has been proven that the capacity to produce Anthracite coal is greater than the markets can be made to absorb even when prices are so low as not to repay the cost of mining and transportation and that the trade can only be profitably conducted with restriction.

The trade is now supposed to be directed and managed but, it is so poorly controlled that buyers are not protected in the regulation of prices. Mr. Simpson calls attention to the greatest difficulty when he states that "dealers hesitate to buy at early spring prices having been taught by experience that prices are often if not usually lower in July and August than in April and May." His suggestion that matters be so arranged as to guarantee to buyers that spring prices will be the lowest of the season is eminently practical. In order to do this it will be necessary to have the whole trade in such control as to be able to regulate the output at beyond peradventure. This will require the strengthening of the arrangement among the coal companies by which the trade is now unsuccessfully regulated. The suggestions of Mr. Simpson's letter should receive the careful consideration of all interested in the business since there is not likely to be much money in mining Anthracite coal until they are carried into effect.

The Bituminous Trade.

The Bituminous coal trade is dull. Large quantities are being mined and shipped to markets to fill old yearly contracts. There is but little new business being done, but prices are fairly good. Consumers, as a rule, have large stocks on hand, having taken advantage of the low water freights that have prevailed for some time, not only on the coast but on the lakes as well. As a rule, harmony prevails in all regions, and there are no serious labor troubles to record in any of the American coal fields.

The Coke Trade.

The coke trade is quiet and prices still continue low. But 75% of the ovens in the Connellsville region were in blast during the past month, and production at these was restricted by running but four or five days a week. The *Connellsville Courier*, in its issue of the 7th inst., quotes prices as follows: furnace coke, $1.90; foundry coke, $2.30; crushed coke, $2.65; all f. o. b. cars at ovens, per ton of 2,000 lbs.

The new metal "Perfection Bronze," manufactured by the Eastwood Mfg. Co., of Belleville, N. J., has been proven by practical tests in the highly acidulated mine water of the Anthracite regions to be practically indestructible, and it is bound to become the favorite metal for pump rods, pump barrels, valves, etc., etc. The company manufacturing it is prepared to furnish it either in bulk or castings as desired, and we recommend those of our readers who are having trouble with their pumps or other machinery to correspond with the Eastwood Co.

ANTHRACITE COAL STATISTICS.

Statement of Anthracite coal shipments, for month of June, 1891, compared with same period last year. Compiled from returns furnished by the Mine Operators, by John H. Jones, Chief of Bureau of Anthracite Coal Statistics.

	June 1891.	June 1890.	Difference.		For Year 1891.	For Year 1890.	Difference.	
From Wyoming Region, - -	2,104,063·00	1,808,708·10	Inc.	295,354·10	9,584,252·11	7,855,732·00	Inc.	1,728,520·11
From Lehigh Region, - - -	584,100·03	571,199·06	Inc.	12,900·17	2,903,721·13	2,930,615·10	Dec.	26,893·17
From Schuylkill Region, - -	1,092,079·00	1,065,654·12	Inc.	26,424·08	5,477,119·07	4,579,605·08	Inc.	897,513·19
Total - - - - - - -	3,780,242·03	3,445,562·08	Inc.	334,679·15	17,965,093·11	15,365,952·18	Inc.	2,599,140·13

The stock of coal on hand at tide-water shipping points, June 30, 1891, was 678,144 tons; on May 31st, 1891, 692,874 tons; decrease, 14,730 tons.

CERTIFICATED MINE OFFICERS IN ILLINOIS.

The Law Recently Enacted Requiring Mine Foremen to Have Certificates of Competency.

An Act to provide for the Examination of mine managers, and to regulate their employment.

SECTION 1. *Be it enacted by the People of the State of Illinois, represented in the General Assembly*: That in order to secure greater efficiency in the management of coal mines, and a higher standard of qualifications in those who have immediate responsibility for the health and safety of persons employed in coal mines, it shall be unlawful, except as hereinafter provided, after the first day of January, 1892, for any person to assume or attempt to discharge the duties of mine manager, at any coal mine equipped for shipping coal by rail or water, or any mine whose output may be twenty-five or more tons per day, unless he shall hold such a certificate as to his qualification for that position as may be required by this act from the State Board of Mine Examiners: *Provided*, that the term mine manager is here intended to mean any person who is charged with the general direction of the underground work, or of both the underground and top work, of any coal mine, and who is commonly known and designated as mine boss, or foreman, or pit boss.

SEC. 2. The certificates provided for in the first section of this act may be either certificates of competency or certificates of service, and any person may acquire such certificate by appearing before the State Board of Examiners appointed by the commissioners of labor for the examination and inspection of mines, and submitting to such an examination as to his competency, or length of service, as may be prescribed by this act and the said examiners.

SEC. 3. Meetings of said boards shall be held at such times and places, and shall be conducted under such rules, conditions, and regulations as the members of said Boards may deemmost efficient for carrying into effect the spirit and intent of this act. Said Board shall, after each of its several meetings, make report of its action and of its term of service to the State Commissioners of Labor, and the sum of three dollars a day and traveling expenses for each day devoted to the service required by this act, which shall not exceed eighty days in all during any one year, shall be paid to each of the members of said board upon vouchers sworn to by them and approved by the Governor, and the Auditor of Public Accounts is hereby authorized to draw his warrant on the Treasurer, payable out of any money in the treasury not otherwise appropriated, in favor of the said members of the Board of Examiners for the amounts thus shown to be due them.

SEC. 4. Certificates of qualification or competency shall be conferred upon any citizen of the United States who shall submit to and satisfactorily pass such an examination as to his fitness for the duties and responsibilities of mine managers as said examiners shall provide; and certificates of service shall be conferred upon any citizen of the United States who shall present satisfactory evidence of having had at least four years' practical experience in coal mines, and of having served as mine manager continuously and satisfactorily, and for the same person or firm, for one year next preceding the passage of this act, but the holder of such certificate shall not be eligible to employment by any other person or firm until he shall also have obtained a certificate of competency upon examination. The certificates herein provided for shall be issued by the State Board of Examiners, and be registered in the office of the Commissioners of Labor at the capitol, where a record of all certificates issued shall be kept. Such certificates shall contain the full name, age, and place of birth of the recipient, and also the length and nature of his previous service in and about coal mines. All applicants for the certificates herein provided for shall, before being examined, pay to the Board the sum of one dollar each, and those who receive certificates shall pay an additional sum of two dollars each, all of which fees shall be accounted for and covered into the State treasury.

SEC. 5. After January 1, 1892, no owner, operator, or agent of any mine to which this act applies shall employ any mine manager who does not hold either the certificate of competency or service herein provided for, and if any accident shall occur in any mine in which a mine manager shall be employed who has no certificate of competency or service as required by this act, by which any miner shall be killed or injured, he or his heirs shall have right of action against such operator, owner, or agent, and shall recover the full value of the damages sustained: *Provided*, that in case no suitable or satisfactory certified mine manager can be obtained by any operator at the date herein specified, such operator may place any competent man in temporary charge of his mine to act as mine manager until such time as a suitable certified manager may be found: *Provided*, that the time be not more than three months from the date aforesaid. The said Board of Examiners shall be furnished by the Secretary of State with the necessary blanks, blank books, and stationery. Any violations of the provisions of this act shall be deemed a misdemeanor and be punished accordingly.

Approved June 18, 1891.

Mine Inspectors' Examination.

An examination for two Inspectors was held at Wilkes-Barre, Pa., during the week commencing August 3d, by the following Board of Examiners: Chairman, John B. Law, C. E., Pittston, Pa., L. O. Emmerich, C. E., Hazleton, Pa., Geo. Frye, Dunmore, Pa., Martin McCormick, Dunmore, Pa., and Lewis Harris, Wilkes-Barre, Pa. Mr. Andrew Bryden, of Pittston, Pa., was appointed Secretary by the Board. The positions to be filled were caused by the expiration of the term of Patrick Blewitt, and that created by the division of Mr. Blewitt's, or the First district, with the addition of several collieries from the Second district.

There were fourteen applicants, as follows: Anthony J. Gallagher, Wilkes-Barre; Patrick Blewitt, Scranton; Wm. E. Howell, Plymouth; Thomas Prothetoe, Dunmore; John T. McDonald, Forty Fort; Wm. H. Hoskins, Wilkes-Barre; Jenkin T. Reese, Scranton; Edward Roderick, Stockton; D. O. Pritchard, Nanticoke; Thomas S. Morgan, Scranton; E. W. Scharar, Scranton; Alexander Aikman, Scranton; David E. Jones, Glen Lyon; Anthony Ferd, Pittston.

Complimentary Banquet to Ex-Inspector King.

Mr. Austin King, who resigned the inspectorship of the Eighth Bituminous District of Pennsylvania, to accept the superintendency of the Leisenring No. 3 Shaft and coke plant of the H. C. Frick Coke Company, was tendered a banquet at the Passmore House, Philipsburg, Pa., on the evening of July 30th, by a number of the miners of his district. The occasion was a most enjoyable one and the speeches made were the sincere expressions of the good will of the miners of Mr. King's district. During the course of the evening Mr. R. A. Kinsloe, editor of *The Wage-Earner's Journal*, presented Mr. King, on behalf of the company assembled, the following address, which was handsomely printed on white satin:

AN ADDRESS TO AUSTIN KING,

LATE MINE INSPECTOR OF THE EIGHTH BITUMINOUS COAL DISTRICT OF PENNSYLVANIA, MADE AT A BANQUET GIVEN IN HIS HONOR, IN PHILIPSBURG, JULY 30, 1891, BY A NUMBER OF HIS APPRECIATIVE FRIENDS AMONG THE MINERS.

SIR:—You are this evening the guest of only a few of the thousands of miners, as well as others, who, had the opportunity been extended them, would have been present and given personal endorsement to the sentiments contained in this address. It is sometimes, and by some persons, held that to give the meed of praise to a deserving official or public servant is unnecessary, if not out of place, because the faithful official or public servant is self-satisfied with the consciousness of having performed his duty, and having done only his duty, no more or no less, is entitled to nothing further, except the material reward such service brings. That is, possibly, true from the standpoint of one who, seeking to know his duty, performs it without fear, favor, or affection, yet hardly true from the standpoint of those who have been the beneficiaries of his services. Your friends, gathered on this occasion, Mr. King, believe most heartily that in doing your duty, in accordance with your understanding of the several provisions of a not-at-all onerous law, are entitled to carry away with you some token of their esteem and appreciation for your uniform course in insisting that the law should be obeyed, no matter whether it affected this or that operator, or this or that boss, or this or that miner. In the performance of your various duties—no doubt often unpleasant—you were no respector of persons, and that you were not able in each instance to better the conditions under which the miners worked, was much more the fault of a weak and ambiguously-worded law than it was any shortcoming of yours. Had the law been more guardedly worded, the improvements—great and many as they have been—comparatively speaking, would have been more pronounced and more numerous. In the matter of air, alone, there is hardly a mine in which an improvement has not taken place under your administration, and on account of your watchfulness; and in the matter of accidents, that these have not been less frequent is largely owing to the persistence with which many miners disobeyed your very plain orders. For the miners to fail to make some public acknowledgement of the good things you have done for them, and indirectly for the operators, would, whatever you may say or think about, be a failure on our part to give you that encouragement for further faithfulness to which the conscientious workman in every sphere is entitled, as well as an encouragement to the others who may come after you, to acquit themselves as you have acquitted yourself—not to say this much would be a failure on our part to show the measure of appreciation that is due from us as a recognition of merit and worth wherever the same may be found. In the new field of labor to which you have been called, while we, here, feel and express our regret at your departure, we desire to offer you our best wishes for your success, feeling assured that in whatever field you may labor, the reward that always follows able, honest, and conscientious discharge of duty, together with genial, courteous intercourse with those whom you work, will be yours.

A Few Words About Painting.

There is a class of oils which, when thinly spread, in contact with the air undergo a certain chemical change called "drying." Linseed oil has this "drying" property in a high degree; hence its value in the preparation of oil paints. The drying property of the oil is increased by the addition of what are called "dryers;" they enable the oil to become more quickly converted into a tough, elastic solid. Too much dryer causes the paint to peel or blister. Paint properly spread should be in a thin layer, as the paint begins to dry first at the surface. Paint laid on by an unpracticed hand may require weeks to dry, whereas, if the coat had been properly applied, it would have dried in eight or ten hours. Paint too heavily laid on will show the want of skill in the hand that applied it by its "pitted" and wrinkled appearance.

The amount of paint required to cover a given surface will vary with the temperature at which it is applied, and will also be modified by the nature and character of the surface to be covered, and whether the surfaces are horizontal or vertical. Lastly, all other conditions being the same, the amount of paint required to cover any given surface will vary with the skill of the hand that applies the paint. This has been most strikingly illustrated in a large number of tests that we have caused to be made in order to determine the spreading power of Dixon's Graphite Paint, manufactured by the Jos. Dixon Crucible Co., Jersey City, N. J., in comparison with the lead and mineral paints. Innumerable tests, made by painters who have had no self interest in the matter whatever, have shown that when used side by side, and under conditions similar in every way, Dixon's Graphite Paint will cover three times more surface than any lead paint, and from two to three times more surface than any "mineral" or "metallic" paint. Twenty years' experience has demonstrated beyond question that a tin roof, well painted with Dixon's Graphite paint will not require repainting in ten to fifteen years. This makes it the most economical paint now in the market.

Lightning Enters a Mine.

Mr. M. W. Jenkins, of Sharon, Pa., who recently accepted the position of superintendent and mine foreman of the H. K. Wick Coal Mine, at Chestnut Ridge, Pa., had a singular experience with lightning during a storm on July 14th. Mr. Jenkins and Mr. McKnight were in the mine during some surveying, there being no miners at work. The former had his instrument in the center of the track while the latter was a short distance from him. They heard it thunder and knew there was a storm above. Suddenly a ball of fire came rolling along the rails, and when near Mr. Jenkins it jumped from the rail and exploded with a loud report, the fire going in every direction, a spark striking his right hand which benumbed the whole arm. Mr. McKnight had been standing with one heel near or against the rail, from which he received a severe shock. At the time the men were fifty feet under ground and two hundred feet from the shaft. On ascending they found that the engine house had been struck, and the engineer, Mr. Kennedy, stunned. Mr. Kennedy stated that when he rallied from the shock, which he thought was within two or three minutes, he found some clothing that had been hanging on the wall burned and the boards on fire, which he extinguished with a bucket of water.

The Evening Chronicle, that very lively Pottsville paper, is authority for the statement that Inspectors McMurtrie, of Ashland; Stein, of Shenandoah, and Gay, of Pottsville, held their regular weekly meeting at the latter city on Saturday. The boys are in the habit of meeting around and having confabs, and the statement would not attract unusual attention were it not for the fact that the receipt of the Shaw machines is given as the subject under discussion. "The machine is not to be taken into the mines," continues *The Chronicle*, "it remains in the office of the mine inspector. This official gathers the gas by means of rubber bags, which have a pumping apparatus attached." Such being the case, we don't wonder the inspectors met and talked it over. *The Black Diamond* knows these gentlemen very well. They are all three great, broad-shouldered, noble-hearted men, capable of lifting a baby with infinite tenderness or resenting an insult with ferocious severity; but when it comes to carrying bags of gas around the country the subject certainly requires careful consideration on their part. Oh! for another excursion! one of the features of which shall be a procession of mine inspectors, each with a well filled gas-bag. Oh! for a glimpse of the expression on Inspector Gay's face when he brings home his first charge.—*Black Diamond.*

BOOK REVIEW.

ELECTRIC TRANSMISSION HAND-BOOK, by F. B. Badt, Chicago, Electrician Publishing Co. This little book belongs to the Hand-Book series, which, owing to convenient shape and condensation of matter has been so favorably received during the past few years. Prof. Badt, the author, is a practical electrician and before locating in America was a First Lieutenant in the Royal Prussian artillery. He has made electricity a life study, and his *Electric Transmission Hand-Book* is a valuable contribution to technical literature. It is just such a book as has been needed by electrical students and all persons interested either directly or indirectly in the subject of electrical transmission of power, and we predict for it a large sale. It is neatly bound in cloth and sells at the reasonable price of one dollar. Orders will be promptly filled by THE COLLIERY ENGINEER CO.

HANDY LIST OF BOOKS ON MINES AND MINING.—A Reference Catalogue by H. E. Haferkorn. Milwaukee, H. E. Haferkorn; London, Gay and Bird. This is a convenient publication embracing an alphabetical reference catalogue, arranged under authors and subjects, and including analytical references to the contents of important works, together with a list of periodicals and annuals devoted to mines and mining. It is a reference book that will be found of great value to all persons interested in mining literature, as it contains a complete list, up to date, of all works on any branch of mining.

We have also received the following publications, which we are compelled to notice by title only:

U. S. COAST AND GEODETIC SURVEY.—Report 1889; Journal and Proceedings of The Royal Society of New South Wales; Proceedings of the U. S. Naval Institute, Volume XVII; School of Mines Quarterly, Columbia College, N. Y., April 1891; The Journal of the Franklin Institute, July 1891; Annals des Ponts et Chaussees, Paris, January to June, 1891, and Personnel 1891; Norsk Teknisk Tidsskrift, Kristiania, de Argang, 1 *ste* Hefte and 2 *det* Hefte; Foldtani Kozlony, Budapest, January to May 1891; Twenty-seventh Report of the Oberhessischen Gesellschaft fur Natur und Heilkunde; Bulletin de la Societe Scientifique Industrielle de Marseille; Journal of the Royal Institution, of Cornwall, Volume X, Parts 1 and 2; Proceedings of the Cleveland (England) Institution of Engineers, Session 1890-1891, No. 6; Journal of the British Society of Mining Students, Vol. XIII, No. 5; Transactions of The Mining Institute of Scotland, Vol. XIII, Part 1; Transactions of the American Institute of Electrical Engineers, June and July, 1891; Transactions of the Institution of Engineers and Shipbuilders in Scotland; Bulletin de la Societe Industrielle du Nord de la France.

MINING AS IT WAS,

As it is Now, and as It Ought to Be.

BY WM. GILLIE.

(Transactions of the Western Pennsylvania Central Mining Institute).

It is not the object of this paper to treat of the ancient history of mining, for I presume you are already acquainted with the rude appliances that were adopted for getting the mineral from the mines and the methods adopted of ventilating and lighting them.

But the reader of such history will no doubt be surprised as he reviews the primitive appliances that were brought forth from time to time, to meet the various difficulties that were ever presenting themselves before the pioneers of this great industry of coal mining.

Each of these innovations were brought forth by a brighter and clearer mind than that of his fellows, but the conservative spirit of the miner exerted itself then the same as it does now. So that it required no small amount of persuasive force in order to introduce any new method or appliance that would be of any practical benefit to them.

When mines became dangerous, and could no longer be worked on account of fire-damp being generated, a premium was offered to the miner that could work best in the dark, after which the weak phosphorescent light of fish skins, or the small intermittent spark of the steel mill was given them to overcome the difficulty, but these all failed to accomplish the purpose, and only added misery to the dangers that they were already surrounded with. Explosion followed explosion until Sir Humphrey Davy's attention was called to the matter and his aid solicited in order to prevent the great sacrifice of human life and destruction of property. He came to the rescue and conquered, for by his invention thousands of acres of coal were worked that could not have been operated and hundreds of lives have been saved by the use of the safety-lamp in gaseous mines. Various lamps have been presented to the mining world, each inventor claiming that his lamp possesses advantages that none other possesses, and that he has brought about the millennial dawn as far as the lighting of mines and the safety of the miner is concerned; but all these improvements of the safety-lamp are based on the principles of the Davy. When this great philosopher wrote to a friend on this subject, he said: "I never received so much pleasure from the result of any other of my chemical labors, for I trust the cause of humanity will gain something by it." The same conservative nature that possessed our predecessors in the art of mining, seems to be hereditary, for the miners, and officials now in the profession, seem to stick tenaciously to the old forms and customs of our forefathers. Certainly we have made great improvement of late years, and especially since the introduction of the present mining law; and notwithstanding the very serious accidents that have taken place of late, I don't hesitate in saying that the miners are more intelligent and a better class of managers and officers exist at our mines than there did a few years ago. The mines are better looked after and in a better sanitary condition than they once were, yet there is room for improvement and we ought not to be slow to take advantage of it. We should not foster and cherish any pet theory or system if a better can be adopted.

There is one particular point that I will try to bring out in this paper, and will be glad to hear the opinions of the gentlemen present on the subject, and that is the present system of ventilation, as is carried on in very many of the mines in working operation in Western Pennsylvania.

The system that I refer to is the wheel system, or of coursing the air from one end of the mine to the other, in one volume and in one continuous route. By this system the noxious gases are collected in the course and are passed from room to room and from the first miner to the man in the last working place, and how often have you heard the remark and seen the wan face that was once flushed with the vigor of health appealing for a room in the first of the air, because his system was wrecked, his constitution was weakened, and he was no longer able to fight and overcome the deadly poisonous gases that were passed on to him when he had to labor where he received the last of the air under this obnoxious system.

Another point in connection with the laying out of the mine is the driving the butt headings or entries so far without breaking off the face entries again. I think it would be much better if the mine was laid off in districts or sections, each district being separate and distinct from the succeeding district, a solid rib or pillar being left in between them, the breadth of such pillar depending on the character of the coal and the nature of the overlying strata. By this method of working, the mine will be better adapted for splitting the air current and giving to each district or section fresh air direct from the intake. Less trap-doors would be required and the continual danger and expense of attending and maintaining such doors would be considerably reduced. For who has not heard the remark after an accident had occurred that such a door had been left open by the carelessness of some employe of the mine, or where is the manager or official who has charge of a mine that is generating fire-damp whose heart has not been filled with awe, and consternation, when he thought of the possibility of a main door being left open, and the air current diverted from its course. Whereas if cross-overs or air-crossings were used wherever practical and possible, these dangers would be obviated, the expense would be lessened, and the position of the manager would be made more comfortable than it is at present in such a mine as I have described.

In addition to giving each district of the mine pure air and the other advantages that I have already named, we would get a greater quantity of air than we have at present with the same pressure and with the same amount of power expended, or if we have already sufficient air by the present system of ventilation, less power will be required when the air is split to produce that quantity. If gas is generated by this system of working and ventilation it can be confined to that district where it is being given off and handled with much more efficiency than at present, and should an accident occur (which may under the ablest management, and under the best conditions) the force would be expended in a great measure upon the district where it took place, and as a result the loss of life would not be so great, and the destruction of property considerably lessened. Instead of the dangerous gases being swept around from one place to another, increasing in volume and in force, they can by proper management be carried direct to the return airway where no naked lights ought to be. When I think of this subject I am surprised that it is not more generally adopted, for its simplicity and for its many practical advantages over the coursing system of ventilation. I do not wish you to infer that this is any new system, or that I claim to be the originator of such a method, for air-crossings were used 60 years ago, and a knowledge of splitting the air was known to a few at that time. Pillars and ribs can be extracted much safer, where the air current is divided, for a separate split can be put on to such ribs or a current can be brought after it has done its work in ventilating the rooms in a district and made to circulate through the pillars; but on no account should air after it has passed over a gob, or a place where ribs are drawn, be made to circulate through a district where the men work with naked lights and where the new workings are in operation. For it may become charged with gas and catch by the light of a miner or of a driver as he passes along, not thinking of the danger or of the result should such an accident take place.

Or what advantage is it in giving the men that are working the pillars, and drawing the ribs, safety-lamps, if we allow the foul air to pass directly on to some other place where a naked light is in use? There is nothing practical about it, nor is it safe to adopt such a course as the most of you know. I am rather inclined to think that many who hold certificates of competency to-day, had they ventilated their mine plans in such a manner before the examining Board would have been found wanting. If such knowledge is necessary to satisfy an examining board surely its practical application is necessary to protect life and property.

Old workings can be kept comparatively clear of gas by coursing the air through them as it passes to the upcast, after it has done its work in the interior of the mine, or a fresh current of air can be admitted in order to prevent such places from becoming a pent-up magazine, which only needs a fall over a large area, or a reduction in the pressure of the atmosphere to force it out, and foul the main roads and traveling ways.

Another thing necessary to make mining as it ought to be—safe, healthy, and pleasant—is to remove the dangers as far as practicable. Coal-dust is one of these dangers, at least we believe it to be, and think our knowledge is not without foundation, for this subject has produced surprise, and startled us from time to time, for now and then an explosion takes place, resulting either in loss of life or destruction to property, and can only be accounted for by the ignition of coal-dust. The law by which this danger arises is that if the small particles of a combustible substance, such as coal-dust, are scattered diffusively in a volume of air, and if the proportion of air and dust are such, that the oxygen can burn up the dust, and produce a volume of flame equal to the space occupied by the dust and air then an explosion will ensue if the air contains a very small percentage of gas. In kindling a fire it will be observed that the sticks burn freely when the interspaces are such that air can freely circulate through them, so with coal-dust, it is coal in a fine state of division, each particle presenting a comparatively large surface to the air and is therefore easily burnt.

Therefore let us try to remove this cause and the direful effect will cease. Mining as it ought to be needs close att-ntion by men of keen intellect, quick judgment, and possessing a disciplined and well-trained mind. Not to be trying this plan to see how it works, and adopting that to ascertain how it pans out, but to weigh the facts in the particular case and when once your inference has been drawn, be firm in your decision and act on it. And as we heard at our last meeting that discipline is an important element to make a successful manager, it is just as essential to make mining what it ought to be. While you are firm and decided, be kind and ready to impart that knowledge which you possess.

If a miner asks why it is necessary to fence off a place where gas has suddenly made its appearance do not deceive him by telling him there is nothing in there to do any damage, but rather tell him what is there, and the properties of such a gas, and the consequence of it becoming ignited, strive to stir a spirit of emulation among your employes to become conversant with the properties of the gases and the laws that govern the ventilation of mines; by so doing a better state of things will exist, fewer accidents will take place, and then we will have the science of mining placed on an elevated platform where it ought to be.

Electric Mining Machinery.

On our advertising pages is announced the formation of a new corporation under the title, H. Ward Leonard & Co., whose principal office will be in New York City, and whose business will be that of Electrical Engineering generally, with special attention paid to electrical motor appliances, the transmission of power, the installation of Central Station lighting and power plants, the concealed wiring of large office buildings, hotels, etc., and plants in which advantages can be obtained by a combination of apparatus of various companies, such as alternating current systems, storage batteries, arc lights, etc.

A feature of the business of this concern which is entirely novel, will be the supplying of expert information regarding engineering matters, the operation of different plants and upon the best methods and system of accounts in connection with the operation of electrical plants. Such information will be supplied by correspondence at a very moderate charge per annum.

This Company will be actively in business before September 1st. Their offices will probably be in the Columbia Building, No. 29 Broadway, New York City.

Bittenbender's Improved Mine Drills.

Owing to the great capital employed in coal mining in the United States and particularly in Pennsylvania competition has been sharp, and consequently inventive genius has been very active in producing labor-saving machinery and devices to lessen the cost of production. Naturally enough, the mine owners were first to seek the advantages which labor-saving devices offered, and having the capital to buy whatever was of practical value, inventors, as a rule, naturally concentrated their efforts on producing machinery that would commend itself to them, and but little attention was paid to inventions that would tend to lessen the labor and make work easier for the miner. In fact up to a very recent date nothing better than the long heavy iron bar with a steel bit was in use for hand drilling, and many of these cumbersome and inconvenient tools are still in use. But they will soon be superseded by the drilling machines, which, though costing but little more, render the work of the miner much easier and enables him to accomplish much more work per day. For about six years, Mr. Fred. T. Bittenbender, of Nanticoke, Pa., was employed as an engineer at a coal mine, and he paid particular attention to the methods in vogue among the miners at their daily work. The old method of drilling with the old bar drill struck him as slow and laborious, and he at once set his inventive genius and practical mechanical skill to work to endeavor to prodsce a tool that would be more practicable and lessen the labor. The result was the invention of the "Improved Coal and Rock Mining Drill," a machine which will drill five or six holes with the expenditure of less labor and time, than will be expended in drilling one hole by the old method.

The miners were quick to appreciate the invention and the demand for them became so great that Mr. Bittenbender decided to give up his position as engineer and engage actively in the manufacture of his drills. This was about six years ago, and the little blacksmith shop which then constituted his "factory," has now grown into a building 110 ft. long by 30 ft. wide, supplied with engines and machinery capable of turning out over 200 drills per month, and as the demand is continually increasing further enlargements must soon be made.

The "Improved Drill" is bound to become very popular, owing to the superior advantages it possesses. It is cheap, simple, durable, and easy to operate. Every machine that leaves the shop is accompanied by a written guarantee against destruction within three months, and as a matter of fact, Mr. Bittenbender states that they have had to repair scarcely any of the drills within the past three years. With such a record it is easy to see how this drill has made its own reputation, and when it is understood that the trade is not "drummed" its sales show that real merit must exist. These drills are now in use in all parts of the country.

The drill is so perfectly shown by an illustration in Mr. Bittenbender's advertisement on another page that a further description would be useless. We will only add that the feed bars are made with 6, 8, 10, 12, and 14 threads per inch, a range which thoroughly fits the drill for all grades of hardness in coal or rock.

PERSONALS

Mr. W. S. Gresly, M. E., of Erie, Pa., has been to Saginaw, Mich., on professional business in regard to improving the mode of mining and other matters connected with the Saginaw Bay Coal Company's mines at Sebewaing, Mich. This month he proceeds to the mines of the Shawmut Coal Company, Elk County, Pa., to advise on a Longwall system for a three feet vein, in connection with electric undercutting machines.

Mr. C. A. Byers, of Williamsport, Pa., has succeeded Mr. M. E. Taylor as general manager of the Elk Coal and Coke Company, at Glen Fisher, Pa., and the title of the company has been changed to the Fisher Coke Company.

Baird Halberstadt, E. M., of Pottsville, Pa., who has been appointed assistant geologist on the Geological Survey of Pennsylvania will complete a Bituminous Map of Pennsylvania similar to the map of the Anthracite region already issued by the survey. All of the mines will be located on the map, and in the report to accompany it there will be a short account of each mine, section of the bed worked, together with other valuable information.

Mr. Austin King, Inspector of the Eighth Bituminous District of Pennsylvania, resigned the position on the first inst. to accept the superintendency of the Leisenring No. 3 shaft of the H. C. Frick Coke Company. Mr. King has been succeeded as Mine Inspector by Mr. D. H. Thomas, of Bitumen, Pa.

Mr. Bernard Callaghan, of Leisenring, Pa., ex-Inspector of Mines, has been appointed superintendent of the Leisenring No. 2 plant of the H. C. Frick Coke Company

Mr. H. C. Zacharias, Assistant Engineer of the Philadelphia and Reading Coal and Iron Company in charge of the Shamokin District, resigned on the 1st inst. to accept the superintendency of the Silver Brook Coal Company's colliery at Silver Brook, Pa. Mr. Zacharias has been succeeded by his first assistant Mr. K. C. Farrow.

PRIMARY EDUCATIONAL DEPARTMENT

FOR CANDIDATES FOR

MINE FOREMEN'S CERTIFICATES

AND FOR

STUDENTS OF MINING.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the sciences related to mining and to learn how to answer the questions in ventilation, surveying, and mechanics which are asked at the examinations for mine foremen's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine foremen and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and many calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

In referring to Figures 12 and 13, we will call the letters 1, 2, 3, and 4, beginning at the left. Letter 1, Fig. 12, represents the letter B drawn on ideal principles, that is to say, in this letter all the laws of penmanship are fulfilled. Letter 2 is intended to illustrate how the principal curves in the letter are generated; it will be seen that the two bottom scrolls consist of ellipses having their major axes parallel to the mean axis of the stem of the letter. This is easy enough to comprehend, but the ellipse that lends most beauty to the construction of the letter B is the large upper ellipse. Now in constructing the letter B, few persons give this ellipse its right inclination, they

FIG. 12.

either droop the axis of the ellipse too much, as in Letter 3, or incline it upwards as in Letter 4. By reference to Letters 1 and 2, and especially Letter 2, the right inclination of each ellipse is clearly shown. By paying attention to Letter 2 any person may in a few minutes be able to execute it with majesty and grace.

In Letter 3 it will be observed the large bottom scroll of the stem is an outrage on the first law of penmanship, namely, that all strokes should be parallel. In Letter 4, however, the deformity entirely arises from giving the upper ellipse the wrong inclination.

In Letter 1, Fig. 13, the bottom ellipse of the letter B has the wrong inclination, or in other words, it is not parallel to the mean axis of the stem, hence the deformity that is offensive to the eye. In Letter 2 the bottom ellipse is inclined in an opposite direction to the major axis of the bottom ellipse of Letter 1, hence these wrong inclinations have given to Letters 1, 2, and

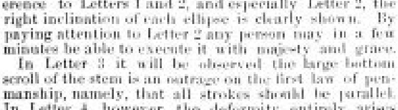


FIG. 13.

3, a positively uninviting appearance. In letters 2 and 3 the upper ellipses are a little too large, but in Letter 4 the ellipse becomes nearly a circle, and although the inclination of the major axis is correct, it nevertheless is a manifest deformity. Nothing is more important to a person in pursuit of knowledge than correct ideas of form, and nothing is more likely to refine and develop the observing faculties than a study of the letters of the alphabet as we are now presenting them.

ARITHMETIC.

It is important to be able to numerate or to operate with whole and decimal numbers, as rapidly as with whole numbers alone. We are afraid that to many beginners the strangeness of the language employed, beclouds the eyes of their mind more than the inherent difficulties of the subject; to speak of decimal fractions is to some people repulsive, and we honestly believe, that if our beautiful Saxon words had been compounded to express these terms and principles, the people of England would have been further advanced in elementary education than they are.

The word decimal means something relating to ten, therefore we might have said tenal fractions instead of decimal fractions, or fractions of tens or tenths. Perhaps the most accurate way of expressing what is here meant would have been to call them tenth fractions. Now the learner, to understand these fractions, cannot do better than to make use of his own hands and fingers. We have five fingers on each hand, or a total of ten fingers; now each single finger is one-tenth of the whole of our fingers and might be expressed as ·1 of our fingers; two of our fingers might be expressed as two-tenths, or ·2 of our fingers; three of our fingers might be expressed as three-tenths or ·3 of our fingers; and four fingers might be considered four-tenths of the fingers, or ·4. Operations with decimal fractions are performed in the same way as operations with ordinary whole numbers, the only difference arises out of the use of the decimal point. Now suppose a person to be required to add 333 to 22, he would certainly place the figures as

$$\begin{array}{r} 333 \\ 22 \\ \hline 355 \end{array}$$

Now let us suppose that instead of placing the figures as has been done in the example given, the operator was to place the figures representing 22 under the wrong figures representing 333, it would then be made to appear that 333 added to 22 were equal to a sum of 553, as below

$$\begin{array}{l} 333 \\ 22 \\ \hline 553 \end{array}$$

But say you, this is a mistake, you put the figures 22 in the wrong place. Most decidedly that has been done, and if the learner is acute enough to notice this false arrangement, he will be equally sharp enough to properly locate whole and decimal numbers for addition.

Supposing again we are going to add 33·3 to 2·2, now if no regard is paid to the value of the figures in relation to the decimal point, errors of the most startling kind must occur; for example, 33 is nothing more than 33 and 33·3 is 33 and a little more, that is to say, it is less than 34. Now 2·2 is only 2, and 2 tenths of another unit. Now, if these figures were properly located for addition, they would appear as follows:

$$\begin{array}{r} 33{\cdot}3 \\ 2{\cdot}2 \\ \hline 35{\cdot}5 \end{array}$$

But supposing now that fractions were added to whole numbers, what serious mistakes would occur

$$\begin{array}{l} 3\,3\,3 \\ 2\,2 \\ \hline 5\,5\,3 \end{array}$$

Now see what a mess this is, what is this 553? It really is nothing; because anybody's common sense can tell them if 33 be added to 2 the sum will be 35. Now add the two decimal parts together—two-tenths and three-tenths—and they will produce five-tenths; then when 33·3 is correctly added to 2·2 the result is 35 and a half, ·5 being five-tenths of 1.

To some of our advanced readers our explanation may appear somewhat playful, but in educating the judgment of a learner it is necessary that you should assume that he is beginning to learn from zero.

CHEMISTRY RELATING TO MINE VENTILATION.

An elementary body is one that is not reducible by any known process, into any other than the single or simple unity form of an element.

For example: Water is a compound body, and cannot be called an element; it is reducible into oxygen and hydrogen. Now oxygen and hydrogen are each of them elementary bodies, and therefore cannot be reduced.

The elementary bodies found in the gases of mines are five in number, and are as follows:

Oxygen.	Nitrogen.
Hydrogen.	Carbon.
Sulphur.	

Each of these elements can exist in a free state that is, uncombined with any other element.

For example: Sulphur can exist at ordinary temperatures as pure sulphur, which is a solid. Carbon can exist at all temperatures as a solid in a perfect vacuum. Nitrogen, hydrogen, and oxygen in a free state, are always found as gases.

Densities of the gases. Hydrogen is the lightest known element, and its specific gravity is always taken as unity, that is, if a cubic inch, a cubic foot, a gallon, or any other measure of capacity be taken, the one each measure of hydrogen would be one. Oxygen is sixteen times heavier than hydrogen, and its specific gravity is said to be sixteen.

The gases oxygen and nitrogen, and the vapors of sulphur and carbon are, volume for volume (at the same temperature), weighed against hydrogen, as follows:

Hydrogen, oxygen, nitrogen, sulphur, carbon (say one gallon of each).

Hydrogen	1
Oxygen	16
Nitrogen	14
Carbon	12
Sulphur	32

The elementary gases are, for expediency and brevity, designated in the language of chemistry by their respective initial letters, which are known as the symbols of the elementary gases.

Hydrogen	*H*
Oxygen	*O*
Nitrogen	*N*
Carbon	*C*
Sulphur	*S*

Combining proportions of the elementary gases. First. Water which is a liquid, and a gas as watery vapor. It is a chemical compound H_2O, that is, two volumes of hydrogen combined with one volume of oxygen.

Second. Carbon dioxide (commonly known as carbonic acid) is a chemical compound CO_2, that is, one volume of carbon (as gas) combined with two volumes of oxygen.

Third. Carbon monoxide (commonly known as carbonic oxide), is a chemical compound $C\,O$, that is, one volume of carbon (as gas) combined with one volume of oxygen.

Fourth. Methyl hydride (commonly known as marsh gas, fire-damp, and light carbureted hydrogen), is a gas, and is a chemical compound $C\,H_4$ that is, one volume of carbon (as gas) combined with 4 volumes of hydrogen.

Fifth. Hydrogen sulphide (commonly known as sulphureted hydrogen), is a chemical compound H_2S, that is, two volumes of hydrogen, combined with one volume of sulphur (as gas).

Atmospheric air is not a chemical compound, but a mechanical mixture of two elementary gases and three compound gases, the latter three in small quantities, viz., the elementary gases, nitrogen and oxygen, and the compound gases, watery vapor, carbon dioxide, and ammonia.

The quantities of the compound gases, carbon dioxide and ammonia, are very small (carbon dioxide 4 in 10,000 parts, and ammonia 1, in 1,000,000 parts), and may be here neglected, but not so with water gas or watery vapor, which plays a most important part in mine ventilation, as will be shown further on.

The relative values or "weights" of nitrogen and oxygen in atmospheric air are in 100 parts.

Nitrogen, 77 parts.
Oxygen, 23 parts.

Atoms and Molecules.—An atom is assumed by the chemist to be the ultimate indivisible condition of an elementary body, consequently two or more atoms combined would be a condition of divisibility; this condition of divisibility is called a molecule.

Relative weights, specific gravities, and absolute weights of the gases.—Relative weight is a term used in chemistry whereby it is shown that the specific gravity of a compound gas is not the mean or average weight of the constituent atoms in the molecule, but a weight resulting from the condensation of a group of atoms into a volume equal to the volume of two atoms of hydrogen. For example: Carbon dioxide is CO_2. Now here we have three atoms, and if no condensation resulted, the molecular weight would be

$$\frac{C+O+O}{3} = \frac{12+16+16}{3} = 14\tfrac{2}{3}.$$

The true relative weight, however, is

$$\frac{C+O+O}{2} = \frac{12+16+16}{2} = \frac{44}{2} = 22$$

relative weight.

From this we get the general law at once simple and easy to deduce. All the compound gases found in mines have a relative weight, which is found by dividing the sum of the weights of the constituent atoms by two.

$$H = 1,\ O = 16,\ N = 14,\ C = 12,\ S = 32.$$

Methyl hydride $= CH_4$.

$$\frac{C+H+H+H+H}{2} = \frac{12+1+1+1\times1}{2}$$

$= \frac{16}{2} = 8$, relative weight.

Hydrogen sulphide $= H_2\,S$.

$$\frac{H+H+S}{2} = \frac{1+1+32}{2} = \frac{34}{2} = 17\text{, relative weight.}$$

Carbon monoxide $= C\,O$.

$$\frac{C+O}{2} = \frac{12+16}{2} = \frac{28}{2} = 14\text{, relative weight.}$$

Nitric oxide $= N\ O$.

$$\frac{N+O}{2} = \frac{14+16}{2} = \frac{30}{2} = 15\text{, relative weight.}$$

Watery Vapor $= H_2\,O$.

$$\frac{H+H+O}{2} = \frac{1+1+16}{2} = \frac{18}{2} = 9,$$

relative weight.

To atmospheric air the above law does not apply, as air is a mechanical mixture.

The proportions of nitrogen and oxygen being by weight as previously shown, nitrogen 77, oxygen 23, and as $N = 14$ and $O = 16$, it follows that the specific gravity of air when weighed against hydrogen is

$$\frac{79 \times 14}{100} + \frac{21 \times 16}{100} = 14{\cdot}42.$$

which means that $\frac{77}{100} \times 14$ added to $\frac{23}{100} \times 16$ will give the specific gravity of air.

Note then, we find that in mine ventilation we have to deal with five elementary bodies: nitrogen, oxygen, hydrogen, carbon, sulphur, and seven compound gases, viz.:

Carbon Monoxide,	Methyl Hydride,
Carbon Dioxide,	Watery Vapor,
Hydride of Ethyl,	Hydrogen Sulphide,
Nitric Oxide,	

and one mechanical mixture, atmospheric air.

The specific gravities of gases are found by weighing them in equal volumes against hydrogen, thus $H = 1$, then

Carbon Monoxide	= 14	Watery Vapor	= 9
Methyl Hydride	= 8	Carbon Dioxide	= 22
Hydride of Ethyl	= 15	Hydrogen Sulphide	= 17
Nitric Oxide	= 15		

Atmospheric Air = 14·42.

The absolute weights of the gases may be found by a simple proportion, the weight of a given volume of air being known.

THE COMPOSITION AND CLASSIFICATION OF COAL.

Q. 1. What is coal ?

A. Coal is mineralized vegetable matter.

Q. 2. What is coal composed of ?

A. Coal differs very much in its composition, so far as the proportions of its constituents are concerned, but the essential elements are the same in all cases, namely, carbon, hydrogen, and small quantities of nitrogen, oxygen, sulphur, silica, lime, and alumina.

Q. 3. How may the constituents of coal be classified, so far as their solidity and fluidity is concerned ?

A. The constituent of coal, when burnt, assume two forms, first the solid, as coke or cinder; second, volatile matter, such as the gases and oils that are expelled by heat.

Q. 4. How may the constituents of coal be classified according to their value in the fuel ?

A. They may be classified under three heads—first, carbon and hydrogen, which supply heat and light; second, the constituents that reduce the value of coal, such as sulphur and nitrogen; third, the worthless constituents such as the silica, oxides of iron, magnesia, lime, and alumina, all the latter constitute the ash.

Q. 5. What is the average percentage of combustible matter, injurious or destructive matter, and ash in coal?

A. The proportions vary so much in different varieties that only an average can be given; carbon and hydrogen may be taken at 92 per cent., sulphur at 1 per cent., and ash at 7.

Q. 6. How may coals be classified according to their appearance when broken ?

A. They may be classified as indefinite in cleavage, such as lignite coal; cuboidal, as the Bituminous coal; and conchoidal, as the Anthracite, and some varieties of cannel coal.

Q. 7. How may coal be classified according to their relative age ?

A. They may be classified according to their relative ages, as lignite or brown woody coal, such as are found at the bottoms of peat bogs, or interstratified with the latest or newest rock formations, as found in all parts of the world. Lignite, by age, slowly changes into Bituminous coal, and cannel coal appears to be of the same age as the Bituminous seams.

Anthracite coal cannot be said to be older than the oldest Bituminous coals, because the same seam, as found in South Wales, will change from a Bituminous coal at the rise near the outcrop, to an Anthracite coal where it dips beneath a thicker cover of the rocks.

Graphite is the oldest variety of mineralized vegetable matter known, and is found interstratified with the oldest rocks, such as the Silurian group and groups of even greater age, such as the Laurentian, in Canada.

Q. 8. How may coals be classified according to their mode of burning?

A. They may be classified as flaming and non-flaming, Lignite, Bituminous, and Cannel coals, all belong to the flaming varieties, giving off much smoke. There is only one non-flaming variety, that is Anthracite.

Q. 9. How may coals be classified according to their commercial uses ?

A. They may be classified as household coals, gas coals, and steam coals.

Q. 10. How may coals be classified with regard to their condition when subjected to a high temperature ?

A. They may under these conditions, be classified as caking and non-caking.

Q. 11. How do you account for some Bituminous coals being non-caking ?

A. The non-caking variety seem to contain oils that are easily volatilized by heat, and contain a small percentage of tar, pitch, or resinous matter; the coking variety appears to be made up of mineralized vegetable matter that was originally very rich in solid resin.

Q. 12. Can non-caking coals be made to cake by artificial treatment ?

A. Yes; non-caking coals if broken into slack by a disintegrator, and mixed with about 5 per cent. of finely ground pitch, will cake in a coke oven.

Q. 13. Is lignite coal of much commercial value?

A. As a general rule it must be said that lignite is of comparatively little commercial value for two reasons, first, it contains a high percentage of water and neutralizes the heat which is largely consumed in converting the water into steam; second, in proportion to its weight it generally contains a higher percentage of ash than other coals.

Q. 14. What reason can you assign for the percentage of ash in lignite being greater than that found in ordinary Bituminous coal ?

A. Lignite, so far as we know, is found in the temperate regions of the earth where climatic conditions have not been favorable for a rich and rapid development of woody tissue, at the period of the formation of the seam. The rich coal seams afford abundant evidence of being composed of the remains of vegetable matter, which flourished during the period of its growth, in a warm moist climate. There, however, can be no doubt that some seams of lignite, characteristic of tropical regions, will be as rich as the best Bituminous coals, but climatic conditions render them at present inaccessible to civilized men.

Q. 15. How do you account for the cuboidal structure of Bituminous coals ?

A. The cuboidal structure of Bituminous coals is the result of planes of fracture in the coal at right angles to each other.

Q. 16. How do you account for the horizontal planes of fracture in Bituminous coal ?

A. The horizontal planes of fracture in Bituminous coal coincide with the planes of stratification; the coal has been increased in thickness by leaves or sheets sometimes called lamina. During the growth of a great peat bog there would prevail storms and tempests just as now; heavy rainfalls would develop water torrents carrying with them in suspension small particles of earthy matter, which deposited on the vegetable matter as a thin layer, made partings or partitions by which the coal has been split into leaves or sheets; in short, these partings have produced stratification. Sometimes storms had raged of a more violent character, and the flowing waters had carried into the bog an enormous quantity of earthy matter, and made partings varying from an eighth of an inch to an inch and more in thickness, and these partings are now known to the miner as bands in the seams.

MECHANICS IN MINING.

It is very important to understand with great clearness the relationship of circular and square measure. Suppose a square to measure 12 inches on each of its four sides, and a circle to measure 12 inches in diameter. Now it is clear that the space enclosed by the four sides of the square must be larger than the space enclosed by the circumference of the circle; consequently we speak of the contained spaces as 144 square inches for the square, and 144 circular inches for the circle. From this it must be clear that the value of a circular inch is less than that of a square inch in the proportion of 1 to ·7854; that is to say, if a square be 1 foot on every side, the four sides will enclose a square foot, or, if a square be 1 inch on every side, the figure will enclose a square inch. In the same way a circle 1 foot in diameter may be called a circular foot; that is to say, the circumference of the circle encloses a space equal to ·7854 of a square foot. The same contrast may be applied to square miles or square anything else.

Another matter must be carefully noticed, viz.: If the square be equal in square inches to the area enclosed by a square whose side is 12, 144 circular inches will be the area enclosed in circular measure by the circumference of a circle whose diameter is 12; but 144 circular inches are less in value than 144 square inches in the proportion of 1 to ·7854; therefore $144 \times {\cdot}7854 = 113{\cdot}0976$ square inches. From this we conclude that the square of the diameter of any circle is equal to its area in circular measure, and the circular can be converted into square measure by multiplying by ·7854. As a knowledge of circular relationship constantly is required we hope we have made the matter plain.

Q. What is the area in square measure of a circle whose diameter is 13?

A. We first find the area of a square whose sides are 13 inches, and multiply the result by ·7854, thus

$$13 \times 13 = 169 \times {\cdot}7854 = 132{\cdot}7326.$$

Q. The bucket of a pumping set is 15 inches in diameter, the length of the stroke is 5 feet; how many cubic inches of water does the pump lift in one stroke?

A. The square inches of the end of the bucket are found by squaring the diameter 15″ and multiplying the result by ·7854, thus $15 \times 15 \times {\cdot}7854 = 176{\cdot}715$ sq. inches. The length of the stroke is 5 feet or 60 inches, which multiplied by 176·715 sq. in. will give the number of cubic inches in the bucket, or the cubic inches of water the pump will lift in one stroke. Thus

$$176{\cdot}715 \times 60 = 10{,}602{\cdot}9.$$

Q. How many cubic feet are there in 10,602·9 cubic inches?

A. There are 1,728 cubic inches in one foot, and $10{,}602{\cdot}9 \div 1{,}728 = 6{\cdot}1359 +$ cu. ft.

Q. How many gallons are there in 10,602·9 cubic inches?

A. 45·9 gallons, there being 231 cubic inches in the standard U. S. gallon.

Q. How many square feet of rubbing surface are there in a circular shaft 18 feet in diameter, and 1,500 feet deep?

A. The circumference of the shaft is in this case called the perimeter. Now the perimeter in feet, multiplied by the depth of the shaft in feet, will be equal to the rubbing surface demanded. The diameter in feet multiplied by 3·1416 gives the circumference, or perimeter of the circle in feet, thus $18 \times 3{\cdot}1416 = 56{\cdot}5488$ linear feet, and $56{\cdot}5488 \times 1{,}500 = 84{,}823{\cdot}2$ square feet of rubbing surface.

Q. Suppose a brattice to be introduced in the former question, and that the brattice is 15 feet wide, how much will this increase the rubbing surface of the air?

A. As the air will rub on both sides of this brattice, the rubbing surface due to it will be found as follows: $2 \times 15 \times 1{,}500 = 45{,}000$, the rubbing surface due to the brattice; but the total rubbing surface due both to the shaft and the brattice will be $45{,}000 + 84{,}823{\cdot}2 = 129{,}823{\cdot}2$ square feet of rubbing surface.

Q. How many thousand bricks will be required to line a 14-foot shaft for a depth of 780 feet, the brick on the inside face or small side being 4 inches by 9 inches, the joints being made with ⅛ of an inch of cement?

A. First, find the square feet in the inside surface of the walling, as follows: $14 \times 3{\cdot}1416 \times 780 = 34{,}306{\cdot}272$ square feet. Now each brick will measure on the face $9\frac{1}{8} \times 4\frac{1}{8}$, that is allowing for cement in the joints, and the area of the face of each brick will be found in square feet as follows:

$$9\tfrac{1}{8} = \frac{73}{8};\ 4\tfrac{1}{8} = \frac{33}{8},\ \text{then}$$

$$\frac{73}{8} \times \frac{33}{8} \times \frac{1}{144} = \frac{2{,}409}{9{,}216} \text{ or } \frac{803}{3{,}072} \text{ sq. ft.}$$

Now, if this fraction of a square foot be divided into the surface of the shaft in square feet, the result will be the answer required:

$$34{,}306{\cdot}272 \div \frac{803}{3{,}072} = 131{,}244 \text{ bricks to line the}$$

shaft in question.

Q. A circular shaft is 16 feet in diameter, and during the course of sinking, from some cause the shaft feeder has flooded the shaft with water to a depth of 312 feet; how many gallons and cubic feet of water are there in the shaft?

A. To find the cubic feet of water in this shaft, we square its diameter 16, and multiply the result by ·7854, or

$$16 \times 16 \times {\cdot}7854 = 201{\cdot}0624$$

the square feet in the area of the section of the shaft. Now if the area of the section be multiplied by the depth of the shaft in feet, the result will be the volume of water in the shaft in cubic feet, that is to say

$$201{\cdot}0624 \times 312 = 62{,}731{\cdot}4688$$

cubic feet of water, which multiplied by 1,728 gives cubic inches thus

$$62{,}731{\cdot}4688 \times 1{,}728 = 108{,}399{,}978{\cdot}0864$$

and this divided by 231 the number of cubic inches in a standard United States gallon gives the required number of gallons, thus

$$108{,}399{,}978{\cdot}0864 \div 231 = 469{,}264 \text{ gallons.}$$

Q. How long would a pump be in pumping the shaft in the former question dry, supposing no feeder continued to run into it, the pump being 12 inches in diameter, and having a 5 feet stroke and making 6 strokes per minute?

A. If we knew the number of gallons the pump could lift per minute, we would only require to divide the gallons of water in the shaft, by the number of gallons the pump could lift per minute. Now in solving this question, we require first to find the gallons the pump can lift per minute. This can be determined in different ways. For example:

$$12 \times 12 \times {\cdot}7854 = 113{\cdot}0976 \text{ square inches.}$$

in the area of section of the pump. Now if the area of the section of the pump be multiplied by the length of the stroke in inches, the result will be the cubic inches of water lifted in one stroke as

$$113{\cdot}0976 \times 60 = 6{,}785{\cdot}856 \text{ cubic inches.}$$

Now, if the cubic inches be multiplied by the number of strokes per minute, the result will be, the cubic inches of water lifted per minute, which is equal to

$$6{,}785{\cdot}856 \times 6 = 40{,}715{\cdot}136 \text{ cubic inches per minute.}$$

Now, there are 231 cubic inches in a gallon, therefore,

$$\frac{40{,}715{\cdot}136}{231} = 176{\cdot}256 \text{ gallons per minute.}$$

But as no pump could lift this theoretical quantity an allowance of 10 per cent. ought to be made for leakage due to the bucket and the valves, therefore,

$$176{\cdot}256 \times {\cdot}9 = 158{\cdot}63 = \text{quantity actually}$$

lifted by the pump per minute. Now, if the total number of gallons in the shaft be divided by what the pump can actually lift per minute, the result will be the time in which the shaft without a feeder would be emptied, therefore,

$$\frac{469{,}264}{158{\cdot}63} = 2958{\cdot}2 \text{ minutes or } 49\tfrac{1}{3} \text{ hours.}$$

Answer required.

The same question can be answered by finding the cubic feet the pump can lift per minute, as follows: The diameter being 1 foot, then,

$$1 \times 1 \times {\cdot}7854 \times 5 \times 6 \times {\cdot}90 = 21{\cdot}2058$$

cubic feet the pump will lift in one minute. Now, if the cubic feet of water in the shaft be divided by the cubic feet of water the pump can lift per minute, the result will be the time in minutes the pump will clear the shaft,

$$\frac{62{,}731{\cdot}4688}{21{\cdot}2058} = 2958{\cdot}2 \text{ minutes.}$$

as before, or $49\frac{1}{3}$ hours.

How many cubic feet, cubic yards, and gallons of water are there in a 14 feet shaft, with the water 468 feet up the shaft?

A. We will first find the cubic feet by squaring the diameter, multiplying the result by ·7854, and this result by the depth 468 feet, thus

$$14 \times 14 \times {\cdot}7854 \times 468 = 72{,}043 \text{ cu. ft.}$$

Now 27 cu. ft. make one cu. yd., then

$$72{,}043 \div 27 = 2{,}668 \text{ cu. yds.}$$

To find the number of gallons we reduce the cubic feet to inches and divide by 231, thus

$$72{,}043 \times 1{,}728 \div 231 = 538{,}919 \text{ gallons.}$$

Q. There are 3,500 cubic yards of water in a shaft, the depth of the water being 480 feet, what is the diameter of the shaft?

A. There are 27 cubic feet in a cubic yard, consequently $3{,}500 \times 27 = 94{,}500$ cubic feet. Now 94,500 cubic feet divided by the depth of the shaft in feet, which is 480, will give the sectional area of the shaft in square feet, or

$$\frac{94{,}500}{480} = 196{\cdot}875 \text{ square feet.}$$

Now to convert square feet into circular feet

$$\frac{196{\cdot}875}{{\cdot}7854} = 250{\cdot}6684 \text{ circular feet.}$$

Now the square root of the circular feet will be equal to the diameter of the shaft or $\sqrt{250{\cdot}6684} = 15{\cdot}83$ feet, the diameter of the shaft.

Q. What are the contents in cubic feet and gallons, of a cylindrical boiler with hemispherical or egg ends, the total length is 40 feet and the diameter 5 feet?

A. The area of the circular section of the boiler will be found as follows: $5 \times 5 \times {\cdot}7854 = 19{\cdot}635$ square feet. The contents of the cylindrical portion will be found as follows: $19{\cdot}635 \times 35 = 687{\cdot}225$ cubic feet. Now if the two hemispherical ends be conceived to jointly make a sphere, then the cube of the diameter of the sphere, which is 125, multiplied by one-sixth of pi, or 3·1416 the result will be the contents of the sphere—thus

$$\frac{3{\cdot}1416 \times 125}{6} = {\cdot}5236 \times 125 = 65{\cdot}45.$$

Now if the contents of the sphere be added to the contents of the cylinder we have the contents of the boiler, or $65{\cdot}45 + 687{\cdot}225 = 752{\cdot}675$ cubic feet, or 5,630·4 gallons. There are 6·25 gallons in a cubic foot, therefore,

$$752{\cdot}675 \times 6{\cdot}25 = 4{,}704{\cdot}21875 \text{ gallons.}$$

Q. Suppose the boiler in the previous question to be built into its seat in such a way that half of its surface will constitute the heating surface for the action of the find how many square feet of heating surface will this represent?

A. To find the heating surface of the cylindrical portion proceed as follows: Multiply the circumference of the cylindrical portion by half the length of the cylinder, or the length of the cylinder by half the circumference, and the product will be the heating surface of the cylindrical portion, then

$$\frac{3{\cdot}1416 \times 5 \times 35}{2} = 274{\cdot}89$$

square feet of heating surface due to the cylindrical portion of the boiler.

Now if we calculate the two ends as a complete sphere, the half of the surface of the sphere will be the portion exposed to the heat of the fire. The surface of a sphere is equal to the surface of a hollow cylinder, whose length and diameter are equal to the diameter of the given sphere, consequently the surface of the sphere is found as follows:

$$\frac{5 \times 5 \times 3{\cdot}1416}{2} = 39{\cdot}27.$$

Now if half the surface of the sphere be added to half the surface of the cylinder the total will be the heating surface of the boiler, thus $274{\cdot}89 + 39{\cdot}27 = 314{\cdot}16$ square feet of heating of the boiler.

Q. Theoretically 9 square feet of heating surface generates steam capable of doing the work of one horse power. About collieries where coal is used extravagantly or wastefully, 6 square feet of heating surface is made to do the work of one horse pow r, but let the equivalent of a horse power in this case be 9 feet, what then is the equivalent horse power of the boiler in the previous question?

A.

$$\frac{314{\cdot}16}{9} = 34{\cdot}9 \text{ horse power.}$$

EXAMINATION QUESTIONS ANSWERED.

QUESTION 33.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

A mine employing 250 men and 10 mules is ventilated by two splits, each split receives the same quantity of air, what size would the airways have to be to pass the quantity of air required by law, the velocity being 5 ft. per second, allowing 500 cubic feet for each mule? What is the total quantity passing in the mine, the mine being located in the Connellsville Coke Region?

ANSWER.—The mine law requires a minimum of 100 cu. ft. per minute for each person employed, and as much more as the circumstances may require. As, in this region there is considerable gas evolved the minimum amount is not enough, and at least 200 cu. ft. should be furnished per employe. Then for the 250 men, there will be 250×200 or 50,000 cu. ft. required. Adding to this, the 500×10 or 5,000 cubic feet required for each mule, we have a total of 55,000 cu. ft. required, or 27,500 cu. ft. in each split.

A velocity of 5 ft. per second is equal to 300 ft. per minute. To pass this each airway will have to be

$$\frac{27{,}500}{300} \text{ or } 91{\cdot}66 \text{ sq. ft. area.}$$

Therefore, if square, the airway must be $\sqrt{91{\cdot}66} = 9{\cdot}6$ ft. square.

QUESTION 34.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

If the mine described in the preceding question was ventilated by furnace power producing a pressure of 4 lbs. per square foot, what would be the length of the motive column in feet, the weight of a cubic foot of air at the inlet to be 0·0686 lbs.?

ANSWER.—As the power produces a pressure of 4 lbs. per square foot, that represents a difference in pressure of 4 lbs. between the column of air in the downcast, and the column in the upcast, then as a cubic foot of air in the downcast weighs 0·0686 lbs., and as the motive column is the length of a column of air in the downcast shaft which would be equal in weight to the difference in weight of the air in the downcast and upcast shafts, we find its length by dividing 4 by 0·0686, which gives us 58·3 ft. as the length of the motive column.

QUESTION 35.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

Where and how should safety-lamps be used?

ANSWER.—Safety-lamps should be used by a competent fire-boss every morning, not more than three hours before the workmen enter the mine, to examine all accessible portions of the mine for fire-damp. They should be used by the workmen in all places where dangerous accumulations of gas are likely to occur. They should only be used by men of enough intelligence to under-stand their use, and should be kept locked when in use.

QUESTION 36.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

The units of work producing ventilation is 165,000; what is the horse power?

ANSWER.—The units of work represent the foot-pounds applied to circulate air, and 33,000 foot-pounds equal one horse power. Therefore $165{,}000 \div 33{,}000 = 5$ horse power.

QUESTION 37.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

How does a furnace produce ventilation, and in what class of mines are they most effective, and why? Show how to find the ventilating pressure arising from the use of furnace ventilation.

ANSWER.—A furnace produces ventilation by expanding the air in the upcast, and rendering it lighter than the cooler air in the downcast. If we suppose we have two shafts of equal depth sunk to a coal bed, with a communication between them at bottom by means of an underground channel, and the shafts and channel be filled with air of the same density and temperature, there would be no circulation and the air would remain stagnant. By imparting heat, however, to one of the shafts, the equilibrium will be destroyed; the effect will be to expand the air in the warmed shaft and render it lighter than that in the other, and, consequently cause a current down the colder shaft, along the drift, and up the warmer shaft; if the heat be continuously imparted, as in the case of a furnace, a constant current will be the result. Furnaces are most effective in deep mines. It is reckoned that the quantity of air produced by furnace ventilation, is as the square root of the difference between the temperature of the downcast and upcast shafts, and also as the square root of the depth from the surface, so the higher the temperature and the greater the depth at which the furnace is placed, the greater will be the quantity of air it will put in circulation.

The ventilating pressure arising from the use of furnace ventilation is found by ascertaining the difference in weight between the columns of air in the downcast and upcast shafts. The column of air in the downcast, which would represent the difference in weight between the air in the two shaf.s, is called the "motive column." Or, if the difference per square foot in the downcast and upcast be multiplied by the quantity of air passing, and divided by 33,000, we will get the horse power.

Thus, if the difference of pressure per square foot between the two shafts amounts to 4 lbs., and the quantity of air passing is 55,000 cubic feet per minute, the ventilating power is

$$\frac{4 \times 55{,}000}{33{,}000} = 6{\cdot}66 \text{ H. P.}$$

Again, if the temperature of the downcast be 50 degrees, and the temperature of the upcast be raised from 75 degrees to 150 degrees it will double the quantity. For we find that at first the difference in temperature is 25 degrees, and afterwards it is 100 degrees. Therefore, as the amount of ventilation effected is as the square root of the difference between the temperatures of the downcast and upcast we have

$$\sqrt{100} \div \sqrt{25} \text{ or } 10 \div 5 = 2.$$

To find the weight of the air in the two shafts, we use the following formula:

$$W = \frac{1{\cdot}3253 \times B}{459 + t}$$

where B = the height in inches of the barometer, and t = the temperature by Fahrenheit's thermometer. This rule is arrived at from the fact of 459 cu. ft. of air at 0 degrees Fahr. weighing 39·76 lbs. when the pressure is 30 in. of mercury, of the density due to 32 degrees, the weight being only $\frac{1}{30}$ of this or 1·3253 lbs. when the pressure is only 1 inch, and 459 ft. of air at 0 degrees expanding exactly one cubic foot for each degree of heat added. Then to find the difference of pressure per square foot in the two shafts of a mine, we proceed as follows:

Suppose the average temperature of the air in the downcast is 44 degrees, upcast 200 degrees, barometric pressure half way down say, 30½ in.; depth of shafts, 700 ft.

(1). In the downcast, the weight of one cubic foot =

$$\frac{1{\cdot}3253 \times 30\tfrac{1}{2}}{459 + 44} = {\cdot}08036 \text{ lb. and } 700 \times {\cdot}08036 = 56{\cdot}25 \text{ lbs.}$$

as total pressure per square foot.

(2). In the upcast, the weight of one cubic foot =

$$\frac{1{\cdot}3253 \times 30\tfrac{1}{2}}{459 + 200} = {\cdot}06138 \text{ and } 700 \times {\cdot}06138 = 42{\cdot}966 \text{ lbs}$$

as the total pressure per square foot. The difference of pressure is $56{\cdot}25 - 42{\cdot}966 = 13{\cdot}284$ lbs. or the pressure per square foot producing ventilation.

QUESTION 38.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania on October 28, 29, 30, and 31, 1889.

When an aircourse is of irregular form how do you determine the area?

ANSWER.—Divide it into a number of triangles, or parallelograms and triangles, and find the area of each of these simple figures. Then add these areas together for the total area of the airway.

The areas of the parallelograms = the base multiplied by the perpendicular height. The area of triangles is found by either multiplying the base by one-half of the altitude, or add the lengths of the three sides together, divide the sum by two; from the half sum subtract each side separately; multiply the half sum and three remainders continuously together, and take the square root of the product.

QUESTION 39.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

A mine makes 200 gallons of water per minute, said water being caught in a sump 200 feet perpendicular below the surface, and also located 2,000 feet from mouth of slope, the slope dipping 1 in 10, would you discharge the water up through a drill-hole perpendicular or up the slope, considering expenditure of power only, and what sized pump would you use, and what make of pump would you prefer?

ANSWER.—The vertical lift, via the slope would be

$$\frac{2{,}000}{10} \text{ or } 200 \text{ ft.,}$$

the same as by the drill-hole, and as by using the drill-hole, I would only have $\frac{1}{10}$ as long a pipe line, and consequently only $\frac{1}{10}$ the rubbing surface to cause friction, I would discharge the water through the drill-hole.

Regarding size of pump, we will assume that we have an average effective steam pressure of 40 lbs. per square inch, and the pumps would work 100 ft. per minute.

Then we have the formula:

$$D = \sqrt{\frac{G}{{\cdot}034\ L\ N}}$$

D = diameter of pump in inches.
G = number of gallons to be delivered per minute.
L = length of stroke in feet.
N = number of strokes per minute.
LN = speed of pump per minute.

Then as we have 200 gallons per minute, and we would use a double-acting piston pump each pump would have to handle 100 gallons per minute. Then

$$D = \sqrt{\frac{100}{{\cdot}034 \times 100}} = 5\tfrac{1}{2} \text{ inches nearly.}$$

As this formula gives the net diameter of the pump plunger; it is usual to increase the area of the plunger ¼ to allow for leakage etc.

Then the area of the pump plunger should be

$$5{\cdot}5 \times 5{\cdot}5 \times {\cdot}7854 = 23{\cdot}76 \text{ sq. in.}$$

and $23{\cdot}76 \times 1{\cdot}25 = 29{\cdot}7$ in. as area of each cylinder. Then as the area of a circle equals the square of the diameter multiplied by ·7854, we find the square of the diameter is

$$\frac{29{\cdot}7}{{\cdot}7854} = 37{\cdot}82 -.$$

Then $\sqrt{37{\cdot}82} = 6{\cdot}15 -$. Therefore the diameter of the pump cylinder should be 6·15 inches, or say 6¼ inches. Now, as to the steam end, the area of the 6¼ inch water cylinder is $6{\cdot}25 \times 6{\cdot}25 \times {\cdot}7854$ or 30·68 — inches. Then the pressure on each water piston due to a head of 200 ft. of water is equal to $200 \times {\cdot}434 \times 30{\cdot}68 = 2663{\cdot}02$ lbs. (See p. 102, COLLIERY ENGINEER POCKET-BOOK). Now as the effective steam pressure is 40 lbs. per inch, the theoretical area of the piston to balance this weight should be

$$\frac{2663{\cdot}02}{40} \text{ or } 66{\cdot}57 \text{ sq. inches.}$$

In practice we add one-half for resistance, and therefore the area of each steam piston should be $66{\cdot}57 \times 1{\cdot}5$ or 99·86 sq. in., and the diameters should be

$$\sqrt{\frac{99{\cdot}86}{{\cdot}7854}} \text{ or } 11{\cdot}28 \text{ in.,}$$

say 11¼ inches.

I would th refore use any standard duplex pump with 11¼ in. steam cylinders and 6¼ in. water cylinders, that was advertised in the columns of THE COLLIERY ENGINEER.

QUESTION 41.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October, 28, 29, 30, and 31, 1889.

A mine generating explosive gas has not been entered for some time, what means would you take to enable workmen to descend, and suppose furnace ventilation was proposed? Describe fully the method you would adopt in lighting the furnace and clearing the mine of fire-damp.

ANSWER.—I would allow no workman to descend until a competent fire-boss had examined the mine and ascertained how far he could enter with safety. I would then allow only enough men to enter to repair bratties, doors, etc., and would pick only cool-headed men that were perfectly familiar with the safety-lamp and working in gas for this purpose. I would restore ventilation as rapidly as possible and would not allow the regular working force to descend until the fire-boss had reported the whole mine in a safe condition. If furnace ventilation was used I would first endeavor to secure a fairly good current of fresh air through the mine by the temporary use of a steam-jet in the upcast or a waterfall in the downcast, and if the mine was a large one ventilated by several splits, I would shut off all but one from the current, until I had first cleared all gas out of that split with either the steam-jet or waterfall, and second had my furnace lighted and the air in the upcast shaft heated to a temperature sufficiently high to create a current strong enough to dilute and carry off the gas in all splits if the mine was in its normal condition. I would then divide the current and allow a portion of it to sweep through another split. When this had been cleared, I would add another split, until I had, upon careful examination, found the entire mine free of gas. As my furnace would work in connection with a dumb drift, the lighting of it, and the clearing of the mine of explosive gases, would thus be rendered a safe operation.

QUESTION 42.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

Describe the dangerous gases found in coal mines how they are produced, the dangers attending the presence of each and how each may be detected.

ANSWER.—This question was fully answered in our issue of December last, page 105.

MECHANICAL NOTES

An Ancient Lock.

An Egyptian lock has been found which was in use more than 4,000 years ago. The old Egyptian lock was not made of metal, like those we use nowadays, but of wood, and the key that opened it was wooden, too. On one side of the door to which it was fastened there was a staple, and into this staple fitted a wooden bolt that was fixed to the door itself. When this bolt was pushed into the staple as far as it would go, three pins in the upper part of the staple dropped into holes in the bolt and held it in its place, so that it could not be moved back again until the pins were lifted. The key was a straight piece of wood, at the end of which were three pegs the same distance apart as the pins which held the bolt firm. When the key was pushed into the bolt through a hole made to receive it, the pegs came into such a position that they were able to lift the pins that fixed the bolt, and when these were lifted, the bolt could be lifted out of the staple. The most modern locks work on a similar principle.—*Metal and Iron Journal.*

The Tool and Handle in One Piece.

The difficulty in making an effective strong joint between a tool and its handle has long been felt, and the disadvantages thus involved are well understood, not only in respect to looseness in the joint but to the positive lack of power. But the invention of the Mannesmann process for the production of tubes direct from metal blocks, would now appear to have rendered both possible and desirable the making of a tool combined with its handle; that is, by means of that process, tubes are produced having solid portions at one or more points of their lengths, and these tubular rods may be made in any convenient lengths, with solid portions at regular or irregular distances apart, so that by cutting through such solid portions the rod can, of course, be divided up to a corresponding number of blanks for tools. By cutting such bars through at convenient points, as the size or length will show to be best, each section will consist of a hollow part, which may be suitably shaped or bent to form the handle, and the solid part, which can be shaped into the tool head by forging or stamping. Various tools are so formed, and it is obvious that they possess a greater degree of strength and durability than tools of which the handles form a separate piece.

A New Rotary Engine.

In a new construction of rotary engine it is claimed that the motive power is utilized to the greatest possible advantage. In this arrangement the frame supports a cylinder made in the shape of a ring having an annular recess, closed at one side by a ring-shaped head, while the outer edge of a piston extends centrally into this recess on the inner side of the cylinder, the piston being made in the shape of a wheel on a shaft turning in suitable bearings of the frame. The wheel-shaped piston has recesses or bucket, in its periphery against which the steam is tangentially directed through angularly arranged inlet ports in the cylinder. The outer ends of these ports are connected by short branch pipes with a pipe extending almost entirely around the cylinder, this latter pipe being also connected at one end with the steam supply source and closed at its other end. The series of inlet ports follow each other at equal distances around the cylinder, and following them is an exhaust port connecting with a pipe leading to the outside. By this arrangement all but one of the buckets in the periphery of the piston are kept constantly filled with live steam, each discharging as it reaches the exhaust port. To insure the steam-tight rotation of the piston in the annular recess of the cylinder, packing rings are provided, to be pressed against the sides of the cylinder by set-screws at suitable distances apart in each outer side of the cylinder.

Maxim's Flying Machine.

Mr. Hiram Maxim, well known for his many ingenious inventions, who is, moreover, a very practical and successful mechanic, has for some time past devoted considerable study to the subject of aerial navigation. His practical experiments in this direction, which have been many and various, appear to have crystallized into the form of a machine which might be called a steam kite. The experimental device consists of a thin sheet or kite 4 feet wide and 13 feet long, which is propelled by a screw capable of 2,500 revolutions per minute. According to information given by Mr. Maxim this machine, when properly inclined and pushed forward by the screw at the rate of 30 miles per hour, will maintain itself in the air; if the forward speed is increased to 35 miles per hour, it begins to ascend; at 90 miles its rising power is quite strong.

Mr. Maxim says he has already expended $45,000 on these tests, and is now at work on a large machine of silk and steel, with a plane 110 feet by 40 feet, with two wooden screws 18 feet in diameter. A petroleum condensing engine will furnish the power. In his previous experiments he found that one horse power would carry 133 pounds 75 miles per hour. He had proved that the screw would lift forty times as much on the propelled plane as it could push. A motor he says has been built, weighing 1,800 pounds, which pushes 1,000 pounds, and will consequently lift 40,000 pounds. The estimated weight of his engines, generator, condenser, water supply (2 gallons), petroleum (40 pounds per hour) and two men is about 5,000 pounds. Thus with a steam kite weighing in all 6,800 pounds he calculates on having an ascending power equal to 40,000 pounds, or 23,200 pounds more than the dead weight, say eleven tons. It is devoutly to be hoped that Mr. Maxim will soon be able to demonstrate the success of his great passenger kite.—*Scientific American.*

How an Axe is Made.

The first step in the operation of making an axe, is the formation of the axe-head without the blade. The glowing flat iron bars are withdrawn from the furnace and are taken to a powerful and somewhat complicated machine, which performs upon them four distinct operations—shaping the metal to form the upper and lower part of the axe, then the eye, and finally doubling the piece over so that the whole can be welded together. A workman stands by, seizing the partially-fashioned pieces one after another with a pair of tongs, and hammering the lower edges together. Next the iron is put in a powerful natural-gas furnace and heated to a white heat. Taken out, it goes under a tilt-hammer and is welded together in a second. This done, one blow from the "drop" and the poll of the axe is completed and firmly welded.

When the axe leaves the drop, there is some superfluous metal still adhering to the edges and forming what is technically known as a "fin." To get rid of this fin, the axe is again heated in a furnace, and then taken in hand by a sawyer, who trims the ends and edges. The operator has a glass in front of him to protect his eyes from the sparks which fly off as the hot metal is pressed against the rapidly-revolving saw. The iron part of the axe is now complete.

The steel for the blade, after being heated, is cut by machinery and shaped with a die. It is then ready for welding. A groove is cut in the edge of the iron, the steel for the blade inserted, and the whole firmly welded by machine hammers. Next comes the operation of tempering. The steel portion of the axe is heated by being inserted in pots of molten lead, the blade only being immersed. It is then cooled by dipping in water, and goes to the hands of the inspector. An axe is subject to rigid tests before it is pronounced perfect. The steel must be of the required temper, the weight of all axes of the same sizes must be uniform, all must be ground alike, and in various other ways conform to an established standard. The inspector who tests the quality of the steel, does so by hammering the blade and striking the edge to ascertain whether it be too brittle or not. An axe that breaks during the test is thrown aside to be made over.

Before the material of an axe is in the proper shape, it has been heated five times, including the tempering process, and the axe, when completed, has passed through the hands of about forty workmen, each of whom has done something toward perfecting it. After passing inspection, the axes go to the grinding department, and from that to the polishers, who finish them upon emery wheels.—*The Manufacturer and Builder.*

ELECTRICAL PROGRESS

Electricity and Industry.

In the census taken ten years ago, a department was devoted to the subject of power used in manufactures, but its reports and tables dealt only with steam and water power, and made no mention of electricity. During the ten years that have intervened, the application of electricity to industrial purposes has been wonderfully rapid. About two years ago, *Electric Power*, a New York journal, printed a list of 150 industries to which the electric motor had actually been applied in this country, and one of the editors expresses the opinion that if a list were now prepared with equal completeness, it would show that the electric motor has found employment in connection with nearly 300 branches of productive industry. The electric motor has been successfully used to run the sewing machines of girls employed in glove making in their own homes, and with the reported result of enabling each worker to accomplish more and better work in less time, and under conditions more favorable to health and causing less fatigue.

With these facts before us, the introduction of electricity as a power applicable to a great variety of industries, and available in the private house and at the individual work-bench, is no longer a dream or a prophecy, but an actual realization, of which the possible future development and industrial influences cannot be foretold. One of the principal articles of belief of the cheerful economic creed so ably propagated by Mr. Edward Atkinson, is that natural forces are constantly tending to a distribution of population more favorable to individual welfare. That where men have been too much isolated on great farms and sparsely settled tracts of land, the tendency toward higher cultivation of smaller areas, is operating to bring them into closer and better relations with the world, and that, on the other hand, where population has become too closely concentrated, in crowded cities and towns and over-crowded tenements, the development of rapid transit is operating to secure a distribution over a larger area, and to correct the evils incidental to a congestion of population at industrial centers.

In the latter direction, nothing could be more efficacious than the gradual adoption, in many industries and at many manufacturing centers, of a form of power peculiarly suited to such distribution, as would do away with the necessity for crowding hundreds of operatives together in the work-rooms of great factories. Such a change could be made to bring with it an amelioration of many of the conditions which now occasion most complaint, and to secure for a great mass of workers, more wholesome and cheerful surroundings, less crowded and better lighted and ventilated. Such a change seems like a dream of a return to the days of the hand-loom and spinning-wheel, and its possibility is an answer to much of the sentimental lamentation constantly heard about the changes which time and development have wrought in the condition of the toiling masses. Progress in the application of electricity to the employments of men, is but one of innumerable evidences that an improvement in social and industrial conditions is to be sought in the higher development of mechanical invention, and in the advancement of science, rather than in vain regrets for the simpler life of the irrevocable past.—*N. Y. Commercial Bulletin.*

Underground Wires.

The greatest sufferers by the burial of the wires are the telephone companies whose system connect with the long distance lines. A short length of underground cable has little or no effect on telephonic transmission, but when a few miles of underground cable are joined on to several hundred miles of overhead line, the effect is very marked, the speech becoming muffled, thick, and indistinct. All cities ought to make allowance for this apparently insuperable difficulty, and allow the wires of the long distance system to be carried overhead. For local telephone work, underground wires work admirably. The telephone system of New York from the Battery to the Harlem River is entirely underground, and there are to-day under the streets of New York considerably more than 20,000 miles of wire used for telephonic communication.

The type of underground cable now in general use should have a very long life. The lead covering is practically indestructible; if laid in iron pipes it cannot be affected even by galvanic action, because iron is electro-positive to lead, and the iron would be attacked. As the insulating material is hermetically sealed within the lead covering, it is safe from deterioration as long as the lead remains sound. So that unless it is found that the insulating materials deteriorate by reason of the action of the current, the depreciation on underground cables of this class should be placed at a very low figure. In contrast, the depreciation of overhead lines is very considerable, especially in towns where the wires are exposed to the action of smoke and gases besides the influence of extremes of weather.

In large towns and cities the underground system is among the established order of things, while freedom must be conceded for overhead wires in the open country and on restricted routes.—*Herbert Laws Webb, in The Engineering Magazine for August.*

A Novel Electrical Bell.

The *Journal des Applications Electriques* for last month describes a novel form of electric bell, in which the vibrations are maintained, not by hammering, but by means of synchronically intermittent electro-magnetic attractions. The bell or gong itself, which is made of steel, carries upon its outer edge a very small plate of platinum; and this plate, when the apparatus is at rest, just touches another platinum contact, that is attached to a fixed spring. Within the bell, and almost touching its edge, is a short fixed electro-magnet, and this is put into electrical circuit with the platinum contact pieces. Now, when the current is passed, it is obvious that the steel bell will be successively attracted and released with great rapidity; similarly to the contact breaker of a Ruhmkorff coil. The amplitude of its vibrations will, of course, depend on the strength of the current, and upon the adjustment of the spring contact. The bell is so placed as that when in full vibration it does not quite touch the face of the bar magnet. Hence there is practically nothing to interfere with its vibration; and the disagreeable clashing of the ordinary electric hammer is replaced by a pure musical note. When the bell is mounted in a resonant box, it can be heard distinctly from a long distance, and the arrangement is highly recommended by our contemporary for adaption to orchestral music.

A New Application of Electricity in the Purification of Water.

Two new methods of softening water for industrial purposes have been recently proposed by M. Lahovski. One of these involves purely chemical reactions, and need not be noticed here; the other introduces an ingenious application of electricity.

Hydrated oxide lead is placed in a filter press which is traversed by the water to be purified, and this produces an effluent showing only one or, at most, two degrees of hardness. In this way all the carbonates, sulphates, and chlorides are precipitated.

Now, in order to work this process economically, it is necessary to produce the hydrated oxide of lead cheaply, and the following method has been devised by Villon for this purpose:

Sodium nitrate is dissolved in water, and the solution is placed in a vat divided into two compartments by a diaphragm; lead electrodes of large surface are placed in the solution, and the current from a dynamo then passed through. The sodium nitrate is decomposed, caustic soda being formed in the negative compartment and nitric acid at the positive pole, from which it dissolves a certain quantity of lead forming lead nitrate.

After the current has been passing through the liquid for a certain time, the solutions that result from the various decompositions are run from the two compartments into a second vat, and then mixed mechanically by means of an agitator. The soda precipitates hydrated oxide of lead, and itself forms sodium nitrate; the liquid is then filtered, and the sodium nitrate solution which runs through the filter is again subject to electrolysis.

When the hydrated oxide of lead has been in use for some time it is then replaced by fresh oxide; the proper time for replacing the contents of the filter press is indicated by the degree of hardness of the water.—*Electrical Review*, London.

Electricity vs. Steam Railways.

While electricity may not yet be able to take the place of steam as an economical motive power for railway trains, it is demonstrating its ability, when properly managed, of cutting into the business of existing steam railways. The illustration of this is to be found in the passenger travel between St. Paul and Minneapolis. Until recently the steam railroads have controlled this business, and, with the exception of the fares charged, have given a fairly satisfactory service but an electric road is now running between the two cities connecting with the street lines of both, and in the half year which it has so far served the public it has taken such a large portion of the patronage from the steam railway that the latter will probably withdraw from competition for the local passenger traffic between the two cities. The reason for this is plain. The steam railroads charged 30 cents for a single trip of ten miles, and 50 cents for a round trip, while the electric road has been put on a paying basis while charging but 20 cents per round trip. In addition to this difference in fares, the electric road runs its cars more frequently and gives transfers to other street railways in either city. The electric company is making preparations to handle a very extensive traffic and will soon be able to run trains under one minute headway. The 30-horse power motors first used will be replaced by new ones of 50-horse power, and the cars will be run at higher speed than at first. Similar conditions of travel in other places will doubtless be met in the same way, and before railroad men realize it, electric railways will be running, the character of whose traffic will bear a very strong resemblance to that of steam railways. In this growth the fact may be developed that a comparison between steam and electricity will not always lead to the results obtained in the experiments thus far made.—*Metal and Iron Journal.*

An Electric House at the World's Fair.

Some months ago we made the remark that there appeared to be no limit to the possibilities of electricity. We can now add that if men like Mr. Edison have their way there never will be. One of the wonders promised for the Chicago Exhibition is an electric home. A miniature home, worked entirely by electricity, will be shown with bells and lights, and doors and windows with burglar alarms, which will immediately illuminate the entire dwelling in the event of an attempted ingress. The rooms are to be warmed by electric radiators and cooled by electric fans. The cooking will be done in an electric range at the top of the house, and the food will be lowered to the dining-room by an electric dumb-waiter, and the dishes will be afterwards washed by an electric dish-washer, in which a child can wash 10,000 dishes a day without breaking them. If these little matters can be accomplished we shall quite believe the promises that are made, that the washing and ironing of linen, and the scrubbing of floors and the cleaning of windows will also be performed by electricity. We shall think none the less of this wonderful power if it does not fully accomplish all that is claimed for it. But if Edison has pledged himself to the programme, it certainly will be accomplished.—*Colliery Manager.*

The Suez Canal Too Small.

"The most important deduction," says the *Engineer*, "to be obtained from the annual report of M. Ferdinand de Lesseps to the shareholders in the Suez Canal is that the facilities of the waterway are rapidly falling behind the enormous increase of traffic, and that before long probably even the relief afforded by the recent diminution in the time required for transit, will be found insufficient. The report shows that during the year no less than 3,389 vessels passed through the canal, giving a total receipt of £2,637,000. The principal work carried on in the period covered by the report has been the widening of the maritime canal by 15 metres. This work has been carried from the tenth mile, from Port Said to the fifteenth, and it is intended during the present year to carry it as far as the twenty-second mile. The other widening works also in course of execution have been continued vigorously, and the new basin at Port Said has been excavated to its full width for a length of 300 m. The crowding of the canal is so severely felt that the engineers have determined to abolish the supply of stores, etc., by water to the stations of the company between Port Said and Ismaila. The boats and barges at present employed will therefore be displaced in favor of a steam tramway, which is now in active construction. The Egyptian government has entered into negotiations with the company for the employment of this tramway as a public line for the transport of passengers and merchandise. One other noteworthy feature of the report is the statement that the development in the petroleum commerce of Port Said has rendered it necessary to undertake the construction of an isolated dock at that place for the accommodation of this traffic. At the annual meeting of the company in Paris the whole of the resolutions presented by the committee of management were approved, and MM. Chabrieres-Arles, Boucard, Guichard, and Lord Brassey were elected directors."

The Romans as Engineers.

The Romans were the first great engineers, and in their own particular manner have never been excelled. Their genius was more of an engineering quality than architectural, and it is in this department they erected their most successful structures. Architecturally, though of wonderful variety and imposing magnitude Roman art was rich, too great a combination of diverse elements to be thoroughly artistic and in keeping with refined taste. The barbaric Etruscan element in the Roman character which found visible expression in their gladiatorial and bloody shows, was too strongly rooted to be eradicated even in the centuries of independent Roman existence. The many lands which Roman conquerors placed under their city's sway made them familiar with a great variety of architectural forms they did not hesitate to avail themselves of, and the result was a combination, wonderfully rich and impressive, but often violating the canons of architectural art. Measured by the faultless standard of the Greek, its immediate predecessor and the model it most closely followed, Roman art leaves much to be desired from the æsthetic standpoint. But however unsatisfactory the Romans were in architectural design, and it must not be forgotten that after all it is the purist who chiefly finds fault with them, they more than made up as constructive builders. Construction was the Romans' chief point of excellence, and they brought to this work a native genius and an insight into engineering requirements of a very high order.—*Barr Ferree, in the Engineering Magazine for August.*

The Suwanee and the Mississippi.

One of the latest proposed improvements in our national waterways is the connecting of the Suwanee River with the Mississippi. The estimated distance is 500 miles, and depth of water *en route* 9 to 12 feet at mean low water. The establishment of this connection with the diversion of traffic by the opening of the Florida canal would add to the commercial facilities of all the country tributary to the water courses, and would also be of vital importance as a means of coast defence. All obstacles are said to be removable in our present advance in engineering science and mechanical appliances. The distance from the Suwanee River to St. Marks is from 70 to 90 miles, according to the route selected, the one being a direct and the other a dredged line. From St. Marks to the Mississippi the water line is almost continuous, but requiring improvement. The Ocleckony and Crooked Rivers require straightening and the removal of sundry bars, which are not supposed to be difficult, and are entirely practicable. In St. George's Sound, near Apalachicola, an oyster bar needs to be removed, and then the Apalachicola River is reached with 12 feet of water on the bar. The distance from St. Marks, Florida, to Apalachicola, Fla., by the coast line, is about 61 miles; by the Ocleckony and Crooked Rivers, about 10 miles longer. From the Apalachicola River to the Mississippi the distance is about 400 miles, and it will require about 30 miles—possibly less—of canaling to make land-locked connection between the two rivers. This project is in unison with the spirit of modern enterprise, and though at present but a proposition, may be accepted as a possible future fact.—*The Age of Steel.*

The Era of Canals.

The American canal was inaugurated in the beginning of the present century. They were made for purposes of inland transport, and were in coincidence with the exigencies of the situation. Railways were immature, both in construction and service, and with the blind guess at natural advantages that is in every historic case the pioneer of better facilities, the utilization of waterways and the artificial corrections of geography were generally crude and temporary efforts. These canals were from 6 to 7 feet deep, and traversed the course of drainage up hill and down for some hundreds of miles. The canal barge furnished the modest navy, and the horse and mule the moving power. For a time these canals served their purpose, till the iron horse and the railway track relieved them of business and future service. To-day circumstances are changed and under new conditions of industrial development the ship canal is a stately sequence to the slow-going barge and the cumbersome lock. We are improving on geography. Where nature made an isthmus a Lesseps, a Menocal and a Miller are using science and a dredger to make a canal. Increasing population, rapid industrial development and the necessities of international commerce are making rapid transit an economic necessity.

The Suez Canal was in response to commercial exigencies; the Panama abortion was on the same line, and the Nicaragua is in coincidence with the same commercial necessity. The movement is not local, but general. The necessity is cosmopolitan. Germany connects the North Sea with the Baltic; Greece digs a channel across the Isthmus of Corinth; England leads the Mersey from Liverpool to Manchester, and proposes a deep cut through the peninsula of Malacca to shorten the ocean voyage between India and China. All these attempts converge in a reconstruction of international relationships, and practically illustrate what we have repeatedly stated in *The Age of Steel*, that the industrial and commercial affinities of nations are really the pivot on which swings the destiny of the human race.

In a home sense we are helping to fill out the divine programme. We have joined the Chesapeake with the Delaware, and have made the Great Lakes a chain of inland seas. It is but a question of time when ocean steamers can load at Chicago and discharge their cargoes in Liverpool, and New York have an unbroken waterway to Lake Michigan. Florida will yet be an island, and the vessels of the Gulf Stream pass through its everglades and orange groves. In short, modern engineering and commercial necessity will add the ship canal to the triumphs of civilization and the service of international commerce.

The Future Railway Map.

Railways are rapidly changing international relationships and the character of nations. Isolation and the prejudices it engenders is going, as feudalism and slavery have gone, into the ash-pit of history. Nations now are neighbors, and notwithstanding all political jingoism to the contrary, it is becoming an economic and historic fact that as we shorten distances and develop commerce we reduce the possibilities of misunderstanding and rupture. In this kind of evangelization the railroad has been one of the most vital and important factors. It has done much, and is destined to do more. The steel rail will yet be a planetary institution. It is annexing the globe, and when complete will radiate from the equator to the poles. It is just 24,000 miles round the waist of Mother Earth, and when the Bessemer girdle is complete some 20,000 miles can be traveled in a palace car. From New York and other Eastern points we can travel to San Francisco, thence to Alaska, can cross what will be but an ocean ferry to Siberia, and on to China and India. The gorges of Afghanistan will pass in panoramic grandeur before the traveler as he glides along to Russia in Europe; Berlin, Paris and London will be scheduled in the same time-table, and an Atlantic trip of five days will see the cosmopolitan American in sight of the Hudson. It is simply a question of time, and in less than two decades will probably be an historic fact. The Siberian railway is being pushed with vigor, and the American link, missing in Alaska, will, without a doubt, be supplied in a few years, and the railway map of the planet be complete.—*The Age of Steel.*

Romance of the Sky.

By the increased power of telescopes, the number of stars within our ken has been increased from 2,000, the number which may be seen in both hemispheres by the naked eye, to probably about 80,000,000. The star nearest to the earth, α Centauri, is about 275,000 times as far from us as the sun is, and Sirius is about twice as far away as that; if, however, we could view these bodies at an equal distance, α Centauri would appear nearly twice as bright as our sun, and Sirius 40 times as bright.

Star 61, Cygni, has a velocity of not less than 30 miles a second, or 3,000,000 miles a day. So far, then, we find that the stars are at different distances; that they are of different sizes, and that, instead of being fixed, they are all in movement.

Such bodies are masses of glowing gas, the materials of which are, for the most part, precisely the same as those of which our earth is built up, the great difference between such stars and the earth at the present time being that they are hot, while the earth is cold.

The sun is so hot at present that its outer atmosphere, instead of being composed of cool oxygen and nitrogen and water vapor, as happens with our own, consists of brightly shining hydrogen gas and iron vapor chiefly. The iron is not solid and it is not molten, but exists as iron steam at, perhaps, a distance of 200,000 miles above the shining orb that we see and call the sun. This, I think, may be taken as a fair indication that the sun is a very hot body, especially when we remember that as its center is approached, the temperature must always increase.

I have said this much about the sun, because it is very natural to ask whether all stars are like the sun. It used to be thought that they were, but I, for one, do not think that this is so. When we come to examine the bodies which shine in the sky, those dim patches of gray light called ne'ulæ, as well as many of the stars themselves, the prism tells us that the light which they send to us is very different from the light sent to us by the sun and by other stars, the light of which is exactly like sunlight.

A great deal of work recently done shows that probably many stars, instead of being like the sun, are built up, as the comets are, of enormous clouds or swarms of little bodies, some of them, perhaps, no bigger than grains of dust, the different quantities and qualities of the light given out depending upon the motions of these little particles and the average distance between them.

So, when we have a great many of these little masses closely packed together and moving rapidly, they will have an opportunity to strike one another and thus produce light and heat in a greater degree than can happen in those other so-called "stars," where the dust is sparser and the motion less rapid.

This is an idea which has lately been suggested, and I refer to it here because it appears to make clear a great many points on which children even of a larger growth have long been puzzled.

In this way, we pass from what we see in the heavens as patches of milk-white light, called nebulæ, to other bodies even hotter than our sun, and when the stage is reached in which we see specks of light merely, and deal with "stars," properly so called, we get a hot body which increases in temperature as all the little particles arrive at the center, until the motion of all of them has been changed into heat, and a ball of vapor results, very, very, hot.

As soon as the supply of heat ceases, the mass begins to cool. Our sun is such a cooling mass. The cooling goes on until at last a body such as our own earth is formed. This is why it is that the chemical composition of the sun and earth are so similar.

If this is what really happens we can easily explain the colors of all the stars. Each stage of heat in a star has its own special color. It is true that sometimes very nearly the same color is produced at two different stages of heat; but aside from this, we know that very white stars are at the condition of their greatest heat, and that yellow stars are cooler, though some are old, some young; and that very red, but especially blood-red stars, are tottering on the verge of invisibility, having run through all their changes.—*Norman Lockyer.*

The Improvement of Predictions.

The principal problem which the new Weather Bureau will try and solve will be the improvement of the predictions. If this can be done, the financial loss due to miscalculations regarding frosts, rainfall, droughts, and great storms will be much lessened as related to agricultural, marine, and commercial interests. Professor Harrington believes that the forecasts of local rain can be improved by greatly extending the number of local stations, and that observations taken high in the air will greatly aid the advancement of weather science. He is at present actively engaged in establishing local centers of weather prediction, it being part of his plan to especially emphasize the importance of local indications. It has been discovered during recent years, while carrying forward the signal service work, that the predictions at Washington for the country in general were not equal to the special predictions made at local centers. This was shown in the excellent results achieved by Sergeant E. B. Dunn, of New York, and J. W. Smith, of Boston. The admirable local predictions made by Mr. H. H. Clayton, of the Blue Hill Observatory—Mr. A. Lawrence Rotch, director—near Boston, Massachusetts, also emphasize the importance of these local stations. Washington is merely the executive office. New York and Boston are the most important stations for observation, owing to their vast marine and commercial interests and the widely diffused suburban population affected by the local weather forecasts for these cities. The investigation of local storms by the New England Meteorological Society—Professor William M. Davis, director—has shown that a line of rain a few miles in width but many hundred miles in length may steadily advance over an immense extent of territory. It is clear that when the Weather Bureau has increased the number of local centers of weather prediction the approach of rain will be announced with such an improvement in the verifications that the results will be of great value.

Under the Earth.

The workmen in the deepest mines of Europe swelter in almost intolerable heat, and yet they have never penetrated over one seven-thousandth part of the distance from the surface to the center of the earth. In the lower levels of some of the Comstock mines the men fought scalding water and could labor only three or four hours at a time until the Sutro Tunnel pierced the mines and drew off some of the terrible heat, which had stood at 120 degrees. The deepest boring ever made, that at Sperenberg, near Berlin, penetrates only 4,172 feet, about 1,000 feet deeper than the famous artesian well at St. Louis. While borings and mines reveal to us only a few secrets relating solely to the temperature and constitution of the earth for a few thousand feet below the surface, we are able, by means of volcanoes, to form some notion of what is going on at greater depths. There have been many theories about the causes of volcanoes, but it is now generally held that though they are produced by the intense heat of the interior of earth, they are not directly connected with the molten mass that lies many miles below the immediate source of volcanic energy. Every body knows that many rocks are formed on the floor of the ocean, and it has been found that a twentieth to a seventh of their weight is made up of imprisoned water. Now, these rocks are buried in time under overlaying strata which serve as a blanket to keep in the enormous heat of the interior. This heat turns the water into superheated steam, which melts the hardest rocks, and when the steam finds a fissure in the strata above it breaks through to the surface with terrific energy, and we have a volcano. We find that these outpourings that have lain countless ages many thousands of feet below the surface are well adapted to serve the purposes of man. Many a vineyard flourishes on the volcanic ashes from Vesuvius, and volcanic mud has clothed the hills of New Zealand with fine forests and its plains with luxuriant verdure. The most wonderful display of the results of volcanic energy is seen in the northwestern corner of our own land, a region of lofty forests and of great fertility.—*Goldthwaite's Geographical Magazine.*

A Useful Invention.

One of the most ingenious and at the same time practically useful among the automatic machines which have been introduced of late is a device which forms, fills, weighs, and seals packages in those establishments where large quantities of goods, such as fine-cut tobacco, soda, starch, &c., are constantly put up. The operation by which this result is accomplished, though decidedly novel, is not at all complex in any particular, the machine consisting merely of a series of forming blocks, receptacles, folders, gummers, and feeders, all working in mutual harmony, so that the packages are smoothly and continuously produced. The forming blocks successively size the paper, which instantly afterward is wrapped around them, folded and gummed at the end; the paper sacks are then plunged into receptacles filled with the commodity for which they are intended, finally folded on top and sealed.—*New York Sun.*

USEFUL INFORMATION

Kauri Gum and "Swaggers."

Kauri gum is an amber-like fossil resin, which is used as a base, instead of gum-mastic, for fine varnishes. Kauri gum digging is one of the industries peculiar to New Zealand. In former ages vast forests of the Kauri pine must have been burnt in the north part of the North Island, and the resin melted down into the ground and became deposited in lumps. These lumps vary in size from a thimble to an anchor, and can be dug up by any one able to handle a spade. Gum land is considered worthless for any other purpose, but as it yields to the value of nearly two millions a year for export, and the supply seems inexhaustible, it has an unquestioned worth of its own. As no apprenticeship is needed to make a gum-digger, and no capital but a shovel, the unemployed take to it when they have nothing better to do; waifs and strays also, because of the element of uncertainty in it that appeals to the gambling instinct. The regular army of labor looks down on the work, and classes the workers with the "sundowners," or "swaggers," who roam over the country in search of employment, terribly afraid lest they may find it. To run as little risk as possible, they take care not to appear at farmsteading or station till a little before sundown, sauntering then into the yard, swag or red blanket rolled into a pack on their back, requesting, in humble or insolent tones as may be, food and a night's lodging. The request is always granted, as the farmer or squatter has no wish to quarrel with men whose friends may drop accidentally a lighted match near his ricks on a dark night. They may be told to chop a little wood or do some chores in the morning, in exchange for their supper; but as a rule they feel that this implies a reflection on the hospitality of their entertainers, and before the household is astir, they have folded their swag and silently stolen away. It is only fair to add that I have heard of this class of the population not at first-hand. The "swagger" has probably a different story to tell from the squatter. So, doubtless, has the Kauri gum digger; but neither had I the good fortune to fall in with any member of that interesting profession. It is difficult to understand why in a country like New Zealand there should be so many tramps, but it is unnecessary to enter on social questions at present.—*From "New Zealand," by G. M. Grant, in Harper's Magazine for August.*

Increase of Suicide.

There seems no doubt that a notable increase of cases of suicide is in progress among civilized nations. Comparative statistics are hard to obtain and are often open to question, but that the present century has witnessed a steadily increasing proclivity to suicide in Europe seems indisputable. A recent writer computes the suicides of Europe at sixty thousand annually, and believes that while this number represents the recognized cases of suicide, we should require to double it in order to reach the true figure, and to include secret or unrecognized cases. Germany affords the largest relative proportion of cases, France and England follow next in this order, while Spain, Ireland, and Portugal are very little given to suicide. The Slavonic race is the least suicidal in Europe. As a general rule, suicide is relatively more frequent among the civilized and cultured than among the ignorant and barbarous. The list of notable suicides is a long one, and includes men in the very front rank of literature, science, art, politics, and war.

The causes of suicide are numerous and obscure. Probably no question opens up more diverse or more abstruse problems in sociology than the inquiry into the reasons that tend to make men weary of life. Racial idiosyncrasy (itself a very obscure subject, and capable, no doubt, of further analysis), degree and quality of the civilization attained, type of intellectual development, religion, the severity of the struggle for existence, disease—all these play their part in determining whether a larger or a smaller proportion of persons of unstable brains will elect "to bear the ills they have" or "fly to others that they know not of." Alcoholism is alleged to be the chief obvious cause of suicide in Northern Europe; but before we can admit this doctrine we should require to investigate the causes of alcoholism itself, to determine how far it is itself a symptom of nervous instability, or an index of misery, over-pressure or boredom. No error in sociological inquiry has been more wide-spread or pernicious than the tendency to accept alcoholism as an ultimate fact, requiring no further explanation or analysis, and to trace to the fact of alcoholism all the deplorable evils which follow in its train, without regard to the predisposing causes or the associated conditions. The same hereditary or racial peculiarities that incline one individual to alcoholism *minus* suicide, may incline another to alcoholism *plus* suicide.

It is very striking that absolute want and destitution do not seem to be frequent causes of suicide. The abjectly poor and the utterly ignorant do not in any considerable numbers seek to terminate their misery by self-destruction. To incline to suicide there would seem to be required a sharp disparity between either the present and the past social condition of the individual or between his desires and his attainments. The hereditary or chronic pauper, however miserable his state, rarely thinks of violently terminating his sufferings, probably because he has become accustomed to them, or has only a vague realization of the difference between what is and what might be. On the other hand, the man who has fallen from comfort and social consideration to utter need is in danger, because he vividly realizes the contrast between the present and the past. Somewhat parallel is the fact that it is the more intellectually gifted races that are most prone to seek refuge in suicide. The intellectual German or the sprightly Frenchman inclines to self destruction, whereas the phlegmatic Slav has no such inclination.

It is in this connection that the very unwelcome fact of the tendency of education and culture to increase the proclivity to suicide finds its explanation. Education, while immeasurably increasing the usefulness and enlarging the enjoyments of the individual, also multiplies his wants, and if those wants cannot be reasonably satisfied, irritation and unrest ensue and may predispose to suicide. We must recognize this fact, and it need occasion no surprise. The man whose mind has been expanded by science, art, or letters cannot be satisfied, like ignorant Hodge, with a hunk of bread and cheese, a pipe, and a quart pot. The former has aspirations which cannot be stilled without danger, and the gratification of which may be beneficial, not only to himself, but to his fellows. The enormous benefit of education is that the new wants which it creates are in the main intellectual, and that their legitimate satisfaction tends to wean the individual from the gratification of the senses. The conclusion to be drawn is, not that the perils of education outweigh or even seriously detract from its advantages, but that as education spreads, adequate provision must be made for the satisfaction of those new wants which this spread involves.

We are apt to attribute the growing tendency to suicide to the nervous wear and tear of an age of over-pressure, to the railway, the steamboat, the post, the telegraph. This has become one of the commonplaces of the day, but it is only one side of the question. Suicide is common in stagnant China, whether from religion, misery, boredom or that weariness of life which seems one of the inevitable concomitants of an ancient civilization. There is under-pressure as well as over-pressure. Legitimate and normal development is foreign to both.

We have mentioned religion, and no account of suicide could be at all adequate which neglected this essential factor. Every classical scholar knows how profound is the difference between the ancient and the modern mind on this subject, and this difference is due mainly at least to the teachings of Christianity. The ancient Greek and Roman saw nothing wicked, but rather everything meritorious, in voluntarily terminating a life which had been robbed of all happiness and value by domestic, personal or national calamity. Aristotle, Demosthenes, Cato, Seneca, and Hannibal sought refuge in suicide from overwhelming misfortune, and their example, so far from being condemned by heathen writers, was held up to admiration and imitation. Christianity, however, from the first put its darkest stigma on self-murder, and contributed powerfully to the dissemination of that sentiment of horror which now surrounds—probably very salutarily—the subject of suicide.—*Lancet.*

As to Thermometers.

The aperture in the tube of a thermometer is smaller than the finest hair. Though it appears to be round, it is not; if it were, the mercury could not be easily seen. It is, therefore, made flat, and then the glass magnifies it so that it seems to be quite large. To bring it out still more distinctly, a maker of Boston recently conceived the idea of backing the tube with a thin film of white sizing. This device is now generally adopted by the foreign makers.

Mercury is generally used in thermometers because it is more regular in its contraction and expansion. It is, indeed, impossible to make a spirit thermometer that will be as trustworthy as one in which mercury is used. In a mercurial thermometer the degree marks are all the same distance apart, because the expansion under all conditions is uniform; but in a spirit thermometer the degrees are wider apart at the top, because the expansion increases at a greater ratio after a certain temperature is reached. Though not so trustworthy, spirit thermometers are necessary, as mercury freezes at forty degrees below zero. Spirits of wine is generally used, and is colored red, so that it will be more visible to the eye.

In a correct thermometer, the scale is graduated to the requirements of the tube to which it is fitted, so that every correct thermometer must have a special scale of its own. That is to say, it wouldn't do to put the tube of one thermometer in the frame of another. Of course, in the very cheap grades of thermometers such accurate adjustments are not made, and, therefore, their records are only approximately correct. The best thermometer tube made will cost about five dollars; but a thermometer may be made to cost almost any price, according to the way in which it is mounted.

As every one knows, the Fahrenheit scale is that most commonly used in this country. Fahrenheit arbitrarily assumed a limit of cold which he termed zero. This makes the freezing point thirty-two degrees above zero and the boiling point two hundred and twelve degrees above zero. As a matter of fact, however, in northern latitudes the temperature in winter frequently falls below the zero point, so that there is no scientific reason why the zero point in the Fahrenheit scale should be where it is. A much more scientific scale is that known as the centigrade, which marks the point at which water freezes as zero, and divides the space between that and the point at which water boils into one hundred degrees. In the Reaumur scale zero marks the freezing point and eighty above zero the boiling point. Many self-registering thermometers are now used. These instruments mark the highest or lowest temperature reached, as the case may be, so that one may return at night feeling assured that the weather can play no pranks without his learning of them.—*Scientific American.*

The Value of Education.

The assertion of Charles A. Dana, in his speech on Horace Greeley, that he was a man of no education at all, except what he had acquired himself, and that this was a great disadvantage to him, has elicited considerable discussion pro and con. Mr. Dana recognized Greeley's remarkable abilities, and a fair construction of his language is that the subject of the oration could have made his abilities of far greater effect if he had started with the advantages of college training. Nevertheless such a sweeping declaration as, "there is no greater misfortune for a man of extraordinary talent than to be educated by himself, because he is of necessity a very poor schoolmaster," warrants some of the sarcastic retorts taking "the remarkably successful career of Greeley as an illustration of the disadvantages of self-education." The fact is that a great deal of dispute about the advantages or disadvantages of self-education is necessarily befogged by an uncertainty of terms. Taking the word in its broadest sense, all men who have earned eminence in any sphere of effort are self-educated. Whether in political or social philosophy, scientific investigation or commercial effort, every successful man knows he has gained his greatest knowledge and his most complete grasp of details of his special work by the thorough lessons of practical experience. If a man is not self-educated in the sense of learning for himself the lessons of life, the judgment of human nature and the complete mastery of the details of his special line of effort, he will never amount to much, whether he goes through college or not. Of course this is not the kind of education in dispute, but it is important in this discussion as showing what the training of colleges and books must have reference to. But the discussion of the value of college training must depend on the kind of education that obtains there. The college teaches its student that it will at best only give him a groundwork for beginning the greater education of practical experience. If it trains him in habits of mind that will digest the lessons of life most advantageously, and impresses him with the seeming paradox that the object of education is to teach us that at best we know comparatively nothing, then Mr. Dana is right in saying that even a man like Greeley would have been better off if he had started in life with that advantage. But if the preliminary education starts the graduate into actual life with an idea that the comprehension of the digamma, or theoretical familiarity with conic sections, places him on a plane of mental superiority above men who have learned the lessons of actual work, then Mr. Dana's critics are right. The first thing a student who has received such an education has to do is to unlearn his lessons, and it sometimes takes him all his life to do it.—*Pittsburgh Dispatch.*

HOW TO LIVE

The Value of Walking to Health.

Few things, if any, are so effectual in building up and sustaining the physical organization as walking, if resolutely and judiciously followed. It is a perfect exercise. It taxes the entire system. When you walk properly every member and muscle, every nerve and fiber has something to do. The arms swing backward and forward, keeping step, as it were, with the legs; the chest expands and contracts as the lungs fill and discharge; the drummer boy pulse beats a tune for the march; the legs curve and straighten; the feet rise and fall, while the head rides over all—but not as a dead head. Every sense it has is employed, every faculty alert. The nostrils expand to quaff the breeze; the ear turn to every sound; the eyes roll in their sockets, sweeping from left to right, from earth to sky; the brain is at work through all its parts. Progress under such conditions is the very eloquence of physical motion. What is the effect? The flesh is solidified; the lungs grow strong and sound; the chest enlarges; the limbs are rounded out; the tendons swell and toughen; the figure rises in height and dignity, and is clothed with grace and suppleness. Hunters, who walk much, are tall and straight, while sailors, who scarcely walk at all, are low and squat. The whole man is developed, not the body merely. The mind is broadened by the contemplation of creation's works, the soul is enlarged, the imagination brightened, the spirits cheered, the temper sweetened. The moral forces are strengthened equally with the physical. A loftier reverential feeling is awakened, if not a profound religious sentiment. No one who rightly walks the fields and groves, or climbs the heights beneath the heavenly dome, with its blazing sun by day and its moon and countless stars by night, but is irresistibly drawn toward the Infinite, as he "looks through Nature up to Nature's God."—*A Sexagenarian, in Belford's.*

The Summer Sea.

Commend us, at this sultry season, to a quiet spot on the margin of the sea. The fashionable bathing-places are delightful, no doubt, to persons who would consider it undignified to shake hands with the sea-gods except in kid gloves; but those who love the ocean for itself prefer to enjoy its buffets and its breezes where there is more elbow-room and less ceremony. When one reflects that the Atlantic sea-board extends from latitude forty-four almost to the edge of the northern tropic, it seems absurd that multitudes professedly in search of health and ease should consent to be penned up, season after season, like sheep in shearing-time, in five or six pet localities not a whit superior in natural advantages to hundreds of others that may be found within convenient distances of the great centers of population. But if the world of fashion were disintegrated, the fragments would be of small account; it is only when massed together that its gorgeous splendors provoke the envy which is so dear to its votaries.

Sea-air is somewhat too pungent for weak or unsound lungs; but where there is no pulmonary disability or disease, it is the finest invigorant in the world. And how gloriously the Atlantic bath supplements the Atlantic breeze. *Elixir vitæ* passes into the system through every pore. The circulation is quickened and a salutary chemical change is wrought in the blood itself.

Nothing in nature presents such an endless variety of forms and phases as the sea. The earth changes its aspect only with the seasons, but the ocean is more changeful even than the clouds. Its lights and shadows shift momently, and of all its myriads of acrobatic billows, no two perform their somersaults alike. How glorious to stand on the yellow beach and see, rank on rank, the white knights of Neptune, with foam-plumes streaming from their emerald helms, come charging in! What is the shock of armies to the collision between raging sea and rock-bound shore! What are all the trumpets that ever pealed defiance in the field to the shout of the multitudinous waves as they dash themselves against the gray ramparts that have baffled their onset since time began! "Calm or convulsed," the sea is a perpetual poem.—*New York Ledger.*

Hot Weather Suggestions.

At the opening of the heated term a few good resolutions should be made. Among the first should be one to cultivate tranquility of mind. Nothing more conduces to comfort of body. In hot weather a fiery argument is almost as productive of a raised physical temperature as is a brisk walk in the blazing sun. Moreover, its effects are less rapidly dissipated, for it is easier to sit down and get cool after bodily exertion than it is to so subdue the perturbed mind that it will not cause a series of "hot flushes" for possibly hours after a vehement discussion.

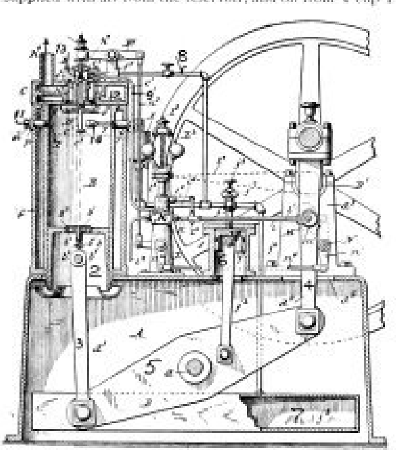
The same rule that applies to undue exercise of the tongue and temper should be observed in intellectual pursuits conducted in the dog days. Do not attempt to shirk steady work in this line, but let all you do be done methodically not spasmodically. Adherence to the German motto, "Without haste, without rest," relentless as it seems, is really less wearying than a series of violent efforts resulting in a fatigue which can be relieved only by utter repose.

So much for the mental attitude in hot weather. The bodily condition is of equal importance. Many people seem to think that ease in summer can only be obtained by laziness, that employment of any sort is the mortal enemy of *bien-être*, and so devote the whole of the long days to what is expressively termed "loafing." What wonder if for them the weeks drag drearily, and that they hail the return of shortened days and frosty nights as a release from ennui?

There is no better way to keep cool than to have some regular occupation, be it never so trivial, that will serve to divert the mind from the bodily condition. No matter what this employment may be, whether the charge of certain branches of housework, the doing of the family mending, the conducting of a course of reading, the studying of a language or a science—whatever it is, let it be made a duty, and followed conscientiously.

OIL ENGINE.

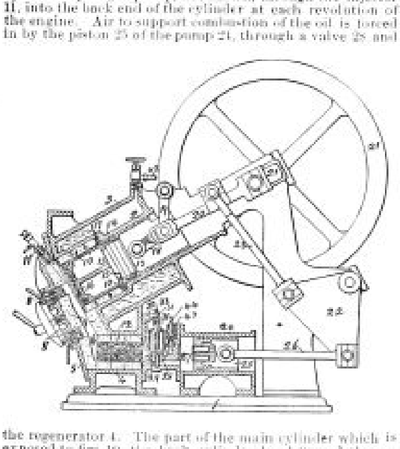
No. 432,260. George B. Brayton, Boston, Mass. *Patented July 15, 1890.* This engine burns a fine spray of oil, in a chamber full of compressed air, and the resulting expansion furnishes the power. The working cylinder B, is vertical, and the long piston 2 is connected to the main crank by the rods 3 and 4, and beam 5. An air pump 6, driven by a rod from the main beam 5, compresses air and stores it in a reservoir 7. A small plunger pump K, on the governor stand, is worked by an eccentric on a shaft M below the main crank shaft. Shaft M is driven by gearing at one half the speed of the main shaft. In this pump the usual clack valves for supply and discharge are not used, and their place is supplied by a small slide valve driven by another eccentric on shaft M. The connection between the plunger of the pump K and its eccentric rod is loose, to permit great lost motion. The governor moves a tapering key up and down between them, varying the lost motion and consequently the stroke of the plunger—thus regulating the amount of oil forced into the working cylinder, through the pipe 9. A burner 10 is kept constantly glowing in the top end of the cylinder, to fire the charges as they come in. This burner is a small metal shell filled partly with asbestos and loose spirals of platinum wires, and is supplied with air from the reservoir, and oil from a cup I.



This burner is lit by a torch inserted through a window 11 in the side of the cylinder, when starting engine, and remains incandescent as long as the engine runs. The inlet valve 13 and exhaust valve 12 in the top of the cylinder are operated by the lever F, which is moved by suitable rods and a cam on the shaft M. When valve 13 rises it allows a gust of compressed air to blow the oil supplied by pipe 9 down the hanging tube to the deflector shown at its lower end, which throws it upward toward the cylinder head in fine spray, past the burner 10 which fires it. This occurs when the piston is near the top of its stroke and the air in the cylinder is greatly compressed. The instantaneous heating of this body of air produces a powerful pressure which drives the piston B downward. As it rises the exhaust valve 12 is opened and the spent air and gases are expelled. During the next downstroke the valves 12 and 13 remain closed, and the cylinder fills with fresh air through the poppet valve in the piston. As it rises again it compresses the entrapped air, and at the top of the stroke another charge of oil spray is blown in and fired as before. It will be seen that the engine is independent of gas works, and can be used anywhere that oil can be procured, and produces no dust, no ashes, or danger of explosion.

HEAT ENGINE.

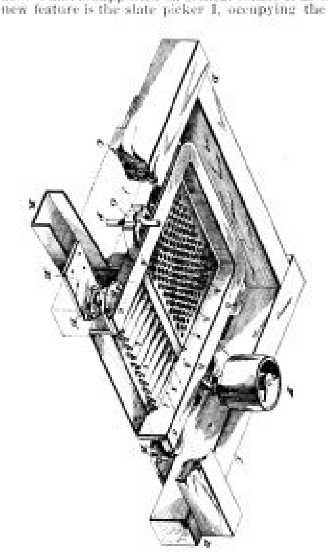
No. 436,781. James Hargreaves, Farnworth, England. *Patented Sept. 23, 1890.* Oil or other liquid is forced by a small plunger-pump, not shown, through the injector 11, into the back end of the cylinder at each revolution of the engine. Air to support combustion of the oil is forced in by the piston 25 of the pump 24, through a valve 28 and



the regenerator 4. The part of the main cylinder which is exposed to fire 10, the back cylinder head 9, and the regenerator 4, are all lined with non-metallic refractory lining, which is kept at a high temperature by the flame. The piston is composed of two parts, a shell 16, which is in contact with fire, and the piston proper 13, which is provided with packing rings 14. The lining of the cylinder is made to fit the piston shell 16 as closely as possible without touching it. The regenerator 4 is filled with small spiral pieces of refractory material, which absorb heat from the burnt gases as they are pushed out by the main piston, through the exhaust-valve 29, and give it out again to the air pushed through the valve 28 by the air pump piston 25. The amount of oil injected at 11 is governed by a common centrifugal governor. The main cylinder is provided with a jacket 3, and the space between them is filled with water. Owing to the high temperature of the cylinder the water is made into steam, and it passes out by the pipe 42 to a valve 44. At each stroke of the engine this valve is opened and the steam blows into the regenerator along with the air driven in by the air pump. There is no explosion in the cylinder as in common gas engine, but a very rapid combustion, which greatly expands the air and products of combustion, and produces pressure upon the piston. The lining of the cylinder head quickly becomes red hot, and ignites and gasifies the injected oil, and no firing burner is needed after the engine is started.

SLATE PICKER.

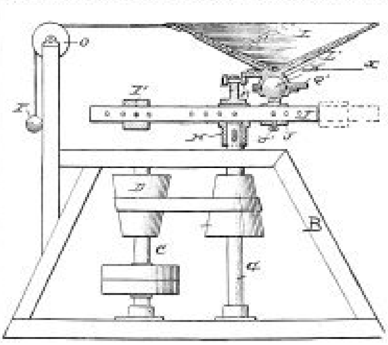
No. 450,482. Eckley B. Coxe, Drifton, Pa. *Patented April 14, 1891.* The screen frame A and screen plate H is the same as that previously described in The Colliery Engineer for January, 1891. The screen is shaken by the cranks G G and is supported on conical rollers E as before. The new feature is the slate picker I, occupying the front



half of the pan. It is composed of a series of parallel bars *i* set with their top surfaces inclined, and the edge of each bar lapping under the next, but leaving a narrow slot between them. The flat pieces of slate either pass through these slots, or are caught by them and prevented from passing off into the next screen with the coal. The slate which passes through passes off by the trough K.

ORE CONCENTRATOR.

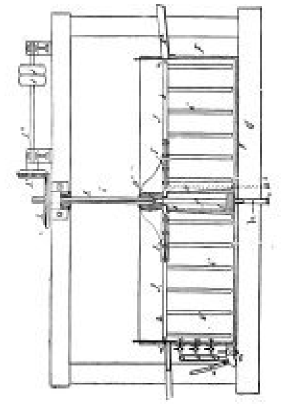
No. 450,013. Walter J. Hammond and John Gordon, Rio De Janeiro, Brazil. *Patented April 7, 1891.* The construction of this ore concentrator is based on the fact that if particles of ore are placed in a vessel containing water and the vessel is revolved, its center of gyration lying between the center of gravity and the outside edge of the vessel, they



will arrange themselves in the order of their specific gravity. Water in motion will lift and carry substances of much greater specific gravity than its own, the velocity of the water determining how heavy a body can be carried. The motion of the particles in the vessel among themselves is greatly facilitated by turning the vessel at the same time that it is rotated on its own axis. On the upper end of the shaft G is secured a carrier H, on which is held adjustably a horizontally extending bar I, carrying at one end a counterbalancing weight I^{3}, and supporting at its other end a sleeve J, held adjustably on the bar I by a set screw J^{1}. On the top of the sleeve J is a ball K carrying a vessel L, having the shape of an inverted cone, shown in figure. The outer edge of this vessel L extends beyond the axis of the shaft G, so that the latter is located between the outer edge of the vessel and its axis which is in the center of the ball-joint K L^{1}. A rope N is connected by one end with the outer edge of the vessel L, the said rope passing over a pulley O to a weight P. Now, when the shaft G is rotated from the main driving shaft C the vessel L revolves and at the same time it is turned on its own axis by being connected with the rope N, carrying the weight P, so that the vessel turns once on its own axis while revolving once. The belt is shifted on the cones to impart a faster or slower rotary motion to the vessel L while revolving as above described. It will be seen that the sleeve J, supporting the vessel on the bar I, can be adjusted on the latter, so as to increase or diminish the distance between the axis of the vessel, and the axis of the shaft G, said distance never being greater than the distance between the outer edge of the vessel and its own axis.

SETTLING AND AMALGAMATING PAN.

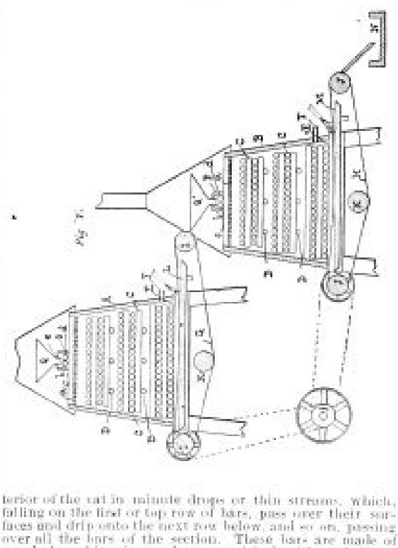
No. 440,552. William A. Merralls, Kansas City, Mo. *Patented March 31, 1891.* This pan is provided with a revolving stirrer J which is turned by gearing L L^{1} as shown. The stirrer is lifted out of the pan, and lowered down to its work as gradually as desired, by means of steam or water pressure in the cylinder H. The center spider I, of the stirrer, turns freely on the top end of the piston rod f^{1}, and by regulating the pressure applied through the pipe *h*, the stirrer can be made to operate at any depth. Instead of the



stirrer shown, settler plow shoes, or mullers can be used equally well. In case of accident—say at the moment of a belt breaking—by one turn of the cock in the pipe *h*, the spider and its adjuncts can be raised out of the quickly settling pulp, and thus the danger of its becoming stuck in the mass avoided, and as compared with the old styles of pans operated, say by right and left hand screw, with which much time and labor are consumed in turning the screw for the purpose of raising and lowering the spider and its adjuncts, this invention is a great improvement.

LIXIVIATION APPARATUS.

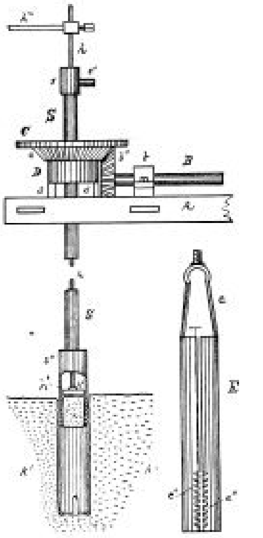
No. 449,814. Samuel W. Cragg, Baltimore, Md. *Patented April 7, 1891.* The gold and silver bearing ore if ground or pulverized and subjected to a chloridizing roasting. It is then introduced into the hopper of the vat A, from which it passes to the trough O. On entering the said trough it is divided into two streams, one falling in front of each of the pipes *c* and *d*. At the same time leaching water is admitted into the trough from an elevated tank (not shown) through the said pipes, and meeting with the finely ground ore carries it in opposite directions in the trough. The effect of these reverse currents is to thoroughly mix the ore and the water. The pulp thus formed overflows the sides of the trough or through the aperture *e* and falls on the wooden grating *a* and passes through it into the interior of the vat in minute drops or thin streams, which, falling on the first or top row of bars, pass over their surfaces and drip onto the next row below, and so on, passing over all the bars of the section. These bars are made of wood, dry white pine, and are varnished with asphaltum. It then falls through a current of atmospheric air circulat-



ing between the sections and strikes the first row of bars of the second section, and, passing over these bars, drips from one row to the next one below, and so on, from one section to the next one under it until it falls on the filter. The passage of the pulp over these round surfaces, which are separated from each other, greatly facilitates the breaking up of the chlorides and the salts of the base metals. All the globules of gas formed in the water are broken and all deleterious gases generated by the decomposition of the chlorides or salts of the base metals—such, for example, as sulphureted hydrogen—which would precipitate gold, are diluted by the currents of air circulating in the vat and are carried off. The pulp drips onto the endless cloth or apron G, which is carried forward by the horizontal rollers I, around which it is stretched. Both aprons G and H are driven continuously forward by belting as shown. There is thus a continual renewal of the filter surface under the vat, and as a very small quantity of pulp not exceeding a sixteenth of an inch in thickness, is deposited at any one place on the cloth, the liquor is soon filtered and passes into the trough L. As the filter-cloth carrying the pulp passes out from under the vat A the pulp may be sprayed with water to wash out any of the leaching water or soluble salts remaining in it. This wash water is also collected in the trough. As the apron G advances and passes over the roller L the pulp falls or is scraped off into the hopper Q, from which it passes through the mixer P into the second vat B, where it is treated in a similar manner, with a solution of sodium or calcium hyposulphites supplied from an elevated tank, not shown. The tailings are sluiced away in the trough N. Each tank is covered by a hood and has a pipe to carry off the gases liberated below.

CORE DRILLING APPARATUS.

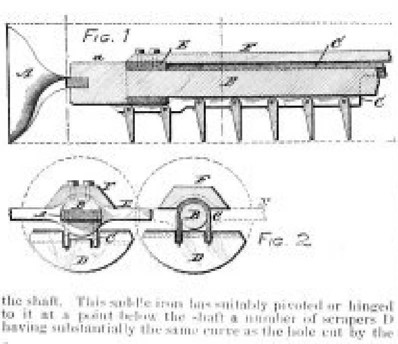
No. 450,656. Moses Beal, Elyria, Ohio. *Patented April 21, 1891.* The drill employed is a steel tube S[11], with teeth at its lower end. It is attached to a tubular drill-rod S in the usual manner and is rotated by the bevel gears C and D[11], by power applied to the shaft B. Water is supplied to the drill through the tube S and stuffing-box *s* as usual. To keep the core from breaking, a rod *h* runs down inside the drill-rod S and ends in a point which engages the top end of the core. The rod carries a loose collar h^1 which touches the inside of the drill, and is centered by it. The



core is steadied by the point of the rod *h*, and prevented from fouling with the drill—thus securing long sections of unbroken core. The extractor E is a sheet-metal tube open on one side, of somewhat smaller diameter than the core, and is provided with teeth e^{11} bent inward. It is easily forced over the core, but as soon as force is applied to lift it, the teeth e^{11} take hold and tear the core loose, and retain it within the tube, and it is raised to the surface. The loose collar h^1 has large notches in its edge to pass the water and borings.

SCRAPER FOR COAL-DRILLING MACHINES.

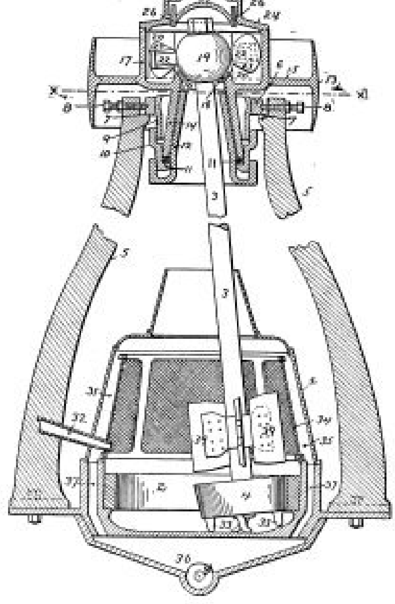
No. 448,829. Horace B. Wyman, Dover, N. H. *Patented March 24, 1891.* This scraper is designed to clear away the chips from machines which use a gang of drills for undercutting coal. The drill-shaft B has a saddle C, which rests upon said shaft and is of such shape as to partly inclose the shaft back of the drill and extends down below



the shaft. This saddle iron has suitably pivoted or hinged to it at a point below the shaft a number of scrapers D having substantially the same curve as the hole cut by the drill, said scrapers being free to swing on their hinged connections in the path of the drill, and not to one side. The saddle C, as before mentioned, rests upon the drill-shaft B and is reciprocated lengthwise with the shaft by the usual mechanism, and the scrapers being directly below the shaft and on the same line therewith, the cuttings will be cleaned from the path of the drill. When two or more drills are used, they are connected together by a suitable frame, the front end of the frame being shown at E, Fig. 2 of the drawings, the drill shafts passing through holes in the end of the frame, as more clearly shown in Fig. 1. To this frame at its front end is bolted a shield F to prevent the coal-dust from falling on the saddle and working in between it and the drill-shaft. When two or more drills are used, they are so placed with relation to each other that the cutting-path of one drill laps into the cutting-path of the adjoining drill, as shown in dotted lines, Fig. 2, of the drawings, thereby removing the partition between the two drills and making a continuous mortise in the coal, of a length equal to the space occupied by the gang of drills used.

GRINDING MILL.

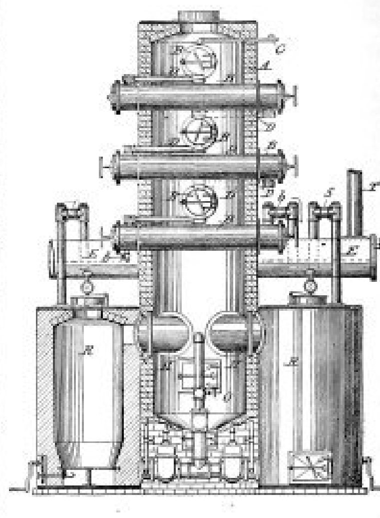
No. 449,118. Edwin C. Griffin, West Newton, Mass. *Patented March 31, 1891.* The ore is ground between the ring die 2 and the gyrating roll 4. The roll is thrown out and held against the die by centrifugal force. The ore is fed into the grinding chamber by the spout 32, and is stirred up and thrown against the die by scrapers 33 on the bottom of the roll. Fan wings 39, attached to the roll shaft 3, blow the finely ground stuff through the screens 34 into the casing 35, and from there it passes down holes 37 to a conveyor 36. The roll shaft is supported by a circular bearing ring 18 under the ball 19 which is fast to the shaft 3. The ring rests on the hub 14 of the pulley 13 and turns with it. The ball has two trunnions 22 provided with gibs or brasses 23 which



play in vertical grooves 20 in the enlarged upper part 17 of the pulley hub. This arrangement makes a universal joint, and permits the shaft to stand at any angle. The roll is turned positively by the pulley, at the same time that it is swung around against the whole face of the die. The pulley turns on a hollow bearing 12, which is screwed onto the collar 10. This collar carries washers 11 which afford a bearing for the lower end of the pulley hub, and it is adjustable by screwing it upon the sleeve 9, which has trunnions 6 resting on the lugs 7 of the main frame. Set-screws 8 serve to center the sleeve and shaft bearing. The suction produced by the fan blades below draws the dust and grit away from the bearings.

GAS APPARATUS OPERATED BY WASTE HEAT.

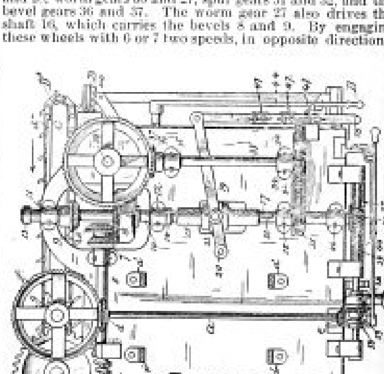
No. 437,315. John McKay, Titusville, Penna. *Patented Sept. 30, 1890.* The main flue A receives the waste heat from furnaces of any kind—or as shown in the drawing, from the generators R, of a water gas producer. Across the flue or hollow interior of these stack retorts B are arranged alternately at right angles to each other. An oil-pipe C extends in through the wall of said stack and supplies the uppermost of said retorts. The ends of the latter extend through the wall of the stack and allow connecting pipes D to be conveniently attached. Every retort, except the lowest, is connected by one of these pipes to the retort next below. In every instance the connecting pipe D is wholly outside of said stack. The lowest retort discharges gas through a pipe *b* at one end, and liquid with other residual material through a pipe b^1 at the other end. The oil in descending from the uppermost retort to the lowest is exposed, of course, to successive increments of temperature, and by the arrangement and connections of said retorts is compelled to travel in a circuitous course, repeatedly crossing the blast of the products of combustion, each time nearer to the source of heat. The gas which finally issues through the pipe *b* contains nearly all the volatile elements of the oil. There is no loss on the way by the oil coming suddenly in contact with an incandescent surface and being charred to an unserviceable form of carbon. The heat, though quite sufficient, increases so gradually that the oil is not injured thereby, and in each transition from one retort to another through a pipe D outside of the stack the oil is necessarily somewhat cooled by way of neutralizing any excess of heating action. It has been found in practice essential to vaporize the oil by gradual increase of heat in order to secure the greatest yield. It has further been found impracticable to have all the vaporizing surfaces and con-

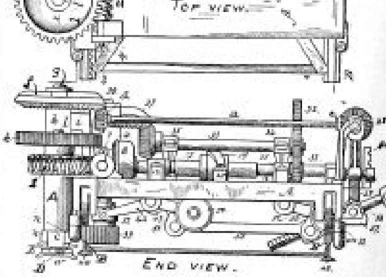


nections within the stack, as the smaller connections are liable to clog up, thus lessening the yield and causing considerable delay. The gas thus produced may be used by itself or employed for enriching coal gas, or, as illustrated in Fig. 3, for carbureting water-gas.

COAL CUTTING MACHINE.

No. 450,971. James H. McEwen and Burr E. Cartwright, Ridgway, Penna. *Patented April 21, 1891.* The cutters are attached to an endless chain D^1 which runs around an arm C, and is driven by a sprocket-wheel E on the lower end of the vertical shaft *l*. An electric motor, not shown, rests on the pads a^1 shown on the top view, and turns the shaft *a*. The motion is conveyed to the shaft *l* and cutter chain by the bevel gears *d* and *f*, and by a spur pinion (not seen) on the shaft *g* which drives the gear *k*. The machine runs on two rails B B, of any desired length. The front rail is provided with a rack which is engaged by the pinion 39 on the lower end of shaft 38. Motion is conveyed to it from the motor shaft *a*, by bevel gears *e* and 28, worm gears 30 and 27, spur gears 31 and 32, and the bevel gears 36 and 37. The worm gear 27 also drives the shaft 16, which carries the bevels 8 and 9. By engaging these wheels with 6 or 7 two speeds, in opposite directions,





can be given to the worm 2 which turns the worm wheel 1. The cutter bar C is attached to a long hub or sleeve which runs through the boss A on the main frame. The wheel 1 is keyed on the top end of this sleeve, and by turning the worm 2 the cutter bar and chain is swung around as desired. In starting work, the machine is placed on the rails B B close to the face, with the cutter bar in the position shown. The motor is started, and the bevels 6 and 9 are thrown into gear by the handle 18 and lever 19. The cutter chain is swung slowly against the face and it cuts its way into the coal until it stands at a right angle to the tracks. The lever 19 is moved to middle position leaving the worm 2 idle. The feed-gears 31 32 are now started and the whole machine feeds forward along the rails B B to any desired distance. When the end of the cut is reached, the gears 7 and 8 are engaged and the cutter bar is rapidly swung out of the cut.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 2. SCRANTON, PA., SEPTEMBER, 1891. WITH WHICH IS COMBINED THE MINING HERALD.

AN ELEMENTARY TREATISE ON THE PRINCIPLES OF COAL-MINING.

For the Use of Candidates for Mine-Foremen's Certificates, Mining Students, Mine-Foremen, Mine-Superintendents, Mining-Engineers, etc.

BY A. A. ATKINSON, DURHAM, ENG.

The last series finished with a paper by the late Mr. T. J. Taylor, and the following is another unpublished paper by the same gentleman, and it has some reference to the former one:

1. It has been shown that there are two distinct conditions of the existence of fire-damp in mines; one consisting of liberated gas, the emission of which is influenced by the state of the barometer; the other, and really dangerous condition, consisting of gas of a tension greatly superior to that of the atmosphere.

2. The receptacles of the fire-damp are the cellular tissues of the coal, and the cavities which are found to a greater or less extent in mines, more particularly along the lines of disturbance and fracture of the strata.

3. The emission of gas from the cellular tissue of the coal is slow and gradual, and such is the usual and manageable form of issue; it being neither by this form of its emission, nor by that of the liberated gas, that the great explosions of the mines of the North of England have been occasioned.

4. In the mines of class three, described in the first paper (the deeper mines with fire-damp at a great tension), a state of high tension is not casual nor accidental; but it is the natural condition in which fire-damp subsists, provided there are no means of spontaneous drainage. The cavities mentioned under head two, are filled with gas, the minimum tension of which is 4½ atmospheres, but the actual tension probably much greater; and when the intervening strata are compact enough to act, entirely or partially, as a dam, or when the rate of excavation is faster than that of drainage, the gas of these reservoirs will be discharged into the mine in a state, the tension of which has an indication in the displacement from the face of a block of coal of six tons at Jarrow, in 1830, and one of eleven tons at Walker, in 1845.

5. There are numerous ascertained instances of the discharge of high pressure gas into mines, and other cases in which it was obvious that such issue had been the cause of explosion; but in the majority of cases it is difficult to discover the source of issue when explosion ensues, and as no living witness remains of the fact, a peculiar degree of obscurity generally hangs over the immediate cause of these accidents.

6. Cases are cited in which air currents of 4·39 and 6½ feet per second were quite inadequate to dilute a stream of gas; and it is further shown by calculation from experiment, that our existing ventilating agencies are extremely feeble in comparison with the antagonist they have to contend against; and that if we were enabled to increase even tenfold the efficiency of these agencies, the ventilation would still be quite inadequate to meet the danger.

7. The cases of heavy explosions in the North of England have occurred, without a proved exception, in the whole mine, where the ventilation is the most perfect, but where the occurrence of eruptions of gas is most likely to be met with.

8. While good ventilation is, and will continue, essential for removing the ordinary and manageable gaseous products; and while it may be looked to as a security against the gases of mines of the first and second classes (first paper) it is yet manifest from the premises that we require some further means of protection, in the case of mines classed under the third head (the deeper mines); and though further research may lead to yet undiscovered measures of safety we are yet bound, in the meantime, to use the means in our power, and already devised, as a safeguard against explosions in those mines.

9. These means consist of the universal employment of the safety-lamp in the mines of the third class. Without giving a preference to any particular lamp, the experience of above thirty years in the mines of the North of England, has proved the principle of the Davy lamp to be an inestimable boon.

10. The expense of lighting mines with safety-lamps is, on the whole, less than that of lighting with candles; and though it is desirable to exclude naked lights as much as possible, yet the use of explosives, under proper regulations, is not inconsistent with that of safety-lamps.

11. With the safety-lamp exclusively in use throughout the mines of the third class, it is a legitimate conclusion that we should, in future, be as free from explosions in the whole mine as we now are in the pillar districts.

In the occurrence of an explosion of fire-damp the high temperature to which the explosive gases are raised, causes them to immediately assume a volume nearly double of that which they occupied before explosion; it checks the circulation of the air through the mine, and often destroys all obstacles opposed to its expansion. Immediately afterwards, the greater part of the water-vapor or steam condenses, and forms a relative vacuum, into which the atmospheric air rushes, and restores the equilibrium of pressure. These phenomena ensue so rapidly, that the workmen feel the shock and immediately experience the passage of the flame.

The following tables show the complete combustion of 100 cubic feet of fire-damp, and the resulting products:

MIXTURE BEFORE EXPLOSION.

		By Volume.		By Weight.	
		Cubic Feet.	Per Cent.	Pounds.	Per Cent.
Air.	Nitrogen...	740	71·15	56·03	72·21
	Oxygen...	200	19·23	17·85	22·23
	Total.....	940	90·38	73·88	94·12
Fire-damp..........		100	9·62	4·18	5·88
	Total.....	1040	100·00	80·36	100·00

MIXTURE AFTER EXPLOSION.

	By Volume.		By Weight.	
	Cubic Feet.	Per Cent.	Cubic Feet.	Per Cent.
Nitrogen	740	71·15	56·03	72·21
Carbonic Acid Gas..	100	9·62	12·29	15·29
Water-vapor(steam)	200	19·23	10·04	12·50
Total	1040	100·00	80·36	100·00

If the mixture of air and fire-damp is not in the proportion to cause an explosion, its ignition may not be attended with danger, and may only produce a flash. But the most terrible cause of destruction to life is the after-damp, which may spread through the whole mine, and kill more victims by its poisonous effects than the explosion itself.

If in the mixture to be exploded, there is present any excess of air or fire-damp, above the quantity necessary to ensure the complete combustion, the excess will remain in an unchanged state after the explosion, and be mixed with the after-damp. But there can never be such an excess of air before explosion as to render the after-damp fit to breathe, because the limits are such that, if there is an excess of air, no explosion can take place.

The following tables show the products of the extreme cases of explosion, with an excess of either gas:

MIXTURE BEFORE EXPLOSION.

		Excess of Air.		Excess of Fire-damp.	
		Cubic Feet.	Per Cent.	Cubic Feet.	Per Cent.
Air,	Oxygen	298	19·86	85	17·00
	Nitrogen	1102	73·47	315	63·00
	Total	1400	93·33	400	80·00
Fire-damp		100	6·67	100	20·00
	Total	1500	100·00	500	100·00

MIXTURE AFTER EXPLOSION.

	Excess of Air.		Excess of Fire-damp.	
	Cubic Feet.	Per Cent.	Cubic Feet.	Per Cent.
Oxygen	98	6·53	.....	.....
Nitrogen	1102	73·47	315·0	63·0
Carbonic Acid Gas	100	6·67	42·5	8·5
Water Vapor.........	200	13·33	85·0	17·0
Fire-Damp	.....	.....	57·5	11·5
Total	1500	100·00	500·00	100·00

Either of the damps resulting from the explosion of the above mixtures of fire-damp and air, are wholly unfit for and incapable of supporting life and combustion. As the water-vapor produced by the explosion, is almost wholly condensed in a very short time, it leaves as a residue, at the most of only 98 parts of oxygen to 1,202 parts of nitrogen and carbonic acid gas, or say 7·54 per cent. of oxygen. Relatively, the after-damp resulting from the explosion of a mixture containing an excess of fire-damp is much more poisonous and injurious in its effects than that resulting from an excess of air; but they are both incapable of supporting life or combustion.

The following are some short and clear instructions for the recovery of suffocated persons:

ASPHYXIA.

Miners are exposed to asphyxia when the circulation of the air is not sufficiently active, when the substance exhales a quantity of deleterious gases, when they imprudently penetrate into old and abandoned workings, and when there is an explosion, or when the air is deprived of its oxygen.

The symptoms of asphyxia, always easily known, are sudden cessation of the respiration, of the pulsations of the heart, and of the action of the senses; the countenance is swollen and marked with reddish spots, the eyes are protruded, the features distorted, and the face is often livid.

It is necessary to succor an asphyxiated person with the greatest promptitude, and to continue the remedies with perseverance as long as there is not a certainty of death.

The best and first remedy to employ, and in which the greatest confidence ought to be placed, is the renewal of the air necessary for respiration.

1st. Promptly withdraw the asphyxiated person from the deleterious place, and expose him to pure air.

2d. Loosen the clothes round the neck and chest, and dash cold water on the face and chest.

3d. Endeavor to make him swallow, if it be possible, cold water acidulated with vinegar.

4th. Clysters should be given, two-thirds of cold water, and one of vinegar; to be followed with others of a strong solution of common salt, or of senna and epsom salts.

5th. Attempts should be made to irritate the pituitary membrane, with the feathered end of a quill, which should be gently moved in the nostrils of the insensible person, or to stimulate it with a bottle of volatile alkali placed under the nose.

6th. Introduce air into the lungs by blowing with the nozzle of a bellows into one of the nostrils and compressing the other with the fingers.

7th. If these means do not produce the effects expected, the body of the asphyxiated person remaining warm, as that generally occurs for a long time, it will be necessary to seek the aid of Doctor Sylvestor's method of producing artificial respiration, as follows: Place the patient on his back, on a flat surface, inclined a little upwards from the feet; raise and support the head and shoulders on a small firm cushion or folded article of dress placed under the shoulder blades. Draw forward the patient's tongue and keep it projecting beyond the lips; an elastic band over the tongue and under the chin will answer this purpose, or a piece of string or tape may be tied round them, or by raising the lower jaw the teeth may be made to retain the tongue in that position. Remove all tight clothing from about the neck and chest, especially the braces. Then standing at the patient's head, grasp the arms just above the elbows, and draw the arms gently and steadily upwards above the head, and keep them stretched upwards for two seconds (by this means air is drawn into the lungs). Then turn down the patient's arms and press them gently and firmly for two seconds against the sides of the chest (by this means air is pressed out of the lungs). Repeat these measures alternately, deliberately, and perseveringly, about 15 times a minute, until a spontaneous effort to respire is perceived; immediately upon which cease to imitate the movements of breathing, and proceed to induce circulation and warmth.

8th. To promote warmth and circulation rub the limbs upwards with firm, grasping pressure and energy, using handkerchiefs, flannels, etc. Apply hot flannels, bottles of hot water, heated bricks, etc., to the pit of the stomach, the arm-pits, between the thighs, and to the soles of the feet.

9th. On the restoration of life a teaspoonful of warm water should be given; and then, if the power of swallowing has returned, small quantities of wine, warm brandy and water, or coffee, should be given.

10th. These remedies should be promptly applied, and, as death does not certainly appear for a long time, they ought only to be discontinued when it is clearly confirmed. Absence of the pulsation of the heart is not a sure sign of death, neither is the want of respiration.

The following are some definitions and technical explanations of some of the leading phenomena in connection with mining ventilation, and may prove useful to any who have an examination to pass on the subject:

NATURAL VENTILATION.

Natural ventilation is ventilation taking place without the aid of artificial means; it is due in a coal pit to the increasing heat of the earth as we descend. This natural heat rarefies the air in the pit, which thus becomes (in winter especially) lighter than the atmosphere. This warm air finding itself at the bottom of one of the shafts, gradually ascends, and causes to flow down the other shaft a slow current of cold air; this alters the barometric balance of the column of air in the two shafts, and a slight current is established, passing through the galleries and workings, which is liable to be reversed, or stopped by the slightest disturbance; in fact, it is trusting the ventilation of a pit to the caprice of the winds.

FURNACE VENTILATION.

In furnace ventilation, a furnace is placed at the bottom of the upcast, which heats and rarefies the air, thus increasing the difference of weight in the two columns in the upcast and downcast shafts. This of course acts in assistance of the natural warmth of the earth; this kind of ventilation is much less liable to disturbance from atmospheric changes, although far from exempt from their influence.

THE STEAM-JET SYSTEM OF VENTILATION.

The steam-jet acts in a manner totally different. It is a mechanical force applied to propel the air through the shaft. When a jet of high pressure steam is blown into an atmosphere at a state of rest, it produces a violent disturbance in that fluid. The particles of steam are in rapid motion; and since the first law of motion is, that a body in motion continues to move for ever or until stopped by something else, when stopped it communicates its force to the body stopping it. The force of the jet of steam is expended on the air on which it strikes and through which it passes; and this force is applied to the air as fully as if it were applied to a piston in a steam engine. Thus by this method we have the steam power applied directly to the object we require to move, avoiding all the friction of an engine. The force thus obtained is used in forcing the air up or down the pit, or both, according to the requirements, and is under more perfect control, and is a more powerful agent when properly employed than the furnace; the furnace not producing above three inches of disturbance of the water-gauge level, the jet has been shown to produce fifteen inches of mercury, which is equal to 15 feet of the water gauge. It requires no machinery, but a simple pipe in connection with the steam.

SPLITTING THE AIR.

Splitting the air is to divide the original trunk or column of air into separate branches, proportioned to the extent and nature of each particular working district. It is arranged by doors and stoppings sufficient to admit and regulate the quantities supposed necessary for each. Some of these splits, or branches, run a course of only a mile or two, or perhaps less, and others as far as perhaps eight or ten miles. They are "coursed" in the working places up and down the boards or workings, and are directed against the face of the works in each working place by "brattices," which take the air close up against the solid coal, or by allowing it to fall short of the coal by shortening the brattices. These currents dilute and sweep away any fire damp that may come off and keep the mine safe and healthy. The air used to be "coursed" up to the year 1813, through the whole passages and galleries of a mine, as if through a tortuous pipe. From the time of its entrance to its exit, it sometimes ran thirty miles, carrying all the impurities of the mine with it. In that year Wm. Buddle introduced "splitting the air," by dividing it into several great streams that swept each particular district, as just stated. It requires judicious management to direct proper quantities to each of these districts, for while the more splitting is practiced, the stream will be fresher and purer; yet when done to a very great extent, the small columns become so weakened as, like small streamlets of water, scarcely to be able to struggle forward and do their work amidst the obstructions and difficulties in their courses. This is the present mode of carrying air through the workings. The doors, stoppings, and regulators act as valves, and, like those in the vessels of the vital fluid of the body, they direct, curb, and regulate the vital fluid (*i. e.* the air currents), in the mines.

Upon this internal machinery, in addition to a full and healthy supply of air at its source, the entire safety of the mine depends. If any part of it falls into disorder or is neglected, congestion and accumulation in some district takes place; this diseased locality being then accidentally, or negligently touched by flame, bursts forth in its whole mass into instant explosion.

Thus abundance of air well directed is the source of life and safety to a mine.

FURNACE LIMIT.

The quantity of heat generated by the furnace is directly as the fuel that can be consumed in a given time. The amount of rarefaction or power of the upcast will always be directly as the temperature of the column of air passing up in a given time, which temperature will vary in proportion to the quantity. The amount of heat of the furnace is a constant quantity, which will be spread over a more or less quantity of air. The power of the upcast rises in "an arithmetical ratio;" the friction or drag of a current of air through the workings of a coal mine, offers a resistance equal to the squares of its velocity. Now it is manifest there will soon be a point where the resistance overtakes the power. The power being as an arithmetical ratio; while the resistance increases in a geometrical ratio, the "furnace limit" will be the point where these two powers balance each other. This limit coincides in practice much earlier than would appear on calculation, which seems never to have been noticed. This element is the resistance offered to the air going through a mine by the "vena contracta." It amounts to a serious quantity in the workings of an ordinary coal mine. This amount of extra resistance, added to the friction arising from the rate of current, adds considerably to the rate of increase of the drag. I believe it is to Mr. Goldsworthy Gurney we are indebted for pointing out this important fact for the first time.

NATURAL BRATTICE.

The resistance or drag of a current of air passing through the workings of a coal mine is, as stated before, as the square of its velocity. When this resistance is so great that the proper quantity of air cannot come through the galleries of a mine to fill the exhaustion produced at the bottom of the upcast shaft, it will come down through the shaft itself, as the easiest channel. It will come down on one side, leaving room on the other for the hot air to ascend; the stationary particles of air between the two moving currents forming an imaginary aerial plate; this plate has been called "the natural brattice."

FURNACE PARADOXES.

The amount of resistance of currents of air coming through the workings increase as the squares of their velocity; the power of exhaustion by the upcast shaft is *directly* as its temperature. If the quantity of air passing through a mine be reduced by increased friction or obstruction, that smaller quantity of air will be raised to a higher temperature by the furnace in the upcast shaft, and the exhaustion arising from its increased temperature will produce a greater amount of "force." The water-gauge is a measure of this force of exhaustion or power of the furnace. Under the above circumstances the water-gauge will rise and indicate a *greater power*, while the *amount* of ventilation is reduced. This is a seeming fallacy; it is not a fallacy; therefore, is called the "Furnace Paradox."

THE WATER-GAUGE.

The water-gauge is a tube of glass bent in the form of the letter U, one end of which communicates with the upcast and the other with the downcast or intakes by a pipe; it contains a little water at the bottom of the bend, and is an indicator of the *amount of power*; its extent of break of level in the two legs is a measure of the actual *force* which is necessary to overcome the "drag of a mine." When this force is known, its rise or fall indicates whether proper ventilation is going on in the extreme workings, or not; thus if the air comes through the workings by a shorter passage than it ought to do, the water-gauge will immediately fall. In an explosion, occasioned by leaving a door open between the downcast and upcast shafts, the water-gauge would have pointed it out. If the water-gauge rises above its working point, it shows obstruction existing somewhere in the workings. If it stands at its working point, it shows that ventilation is going right. It is a most useful instrument; it is a measure of the actual power required for ventilation, and in the possession of a practical man, will tell him nearly where, and how, ventilation is going on by simple inspection. In connection with the anemometer, the water-gauge is most valuable.

GAS DRIFTS.

A system of gas drifts along the *rise* of the coal deposit, intersecting its cleavages, banks, and interstices, and taken to the upcast shaft, might be, and in some cases has proved to be a practical and scientific means of removing the light carbureted hydrogen gas from the coal, without permitting it to descend into the workings.

EFFECT OF SEASONS ON FURNACE VENTILATION.

In winter the atmosphere is colder than the air of a coal mine; consequently the air in the mine forms of itself a natural upcast, and a certain amount of disturbance, or power, is thus produced. In summer, when the temperature of the air equals that in the mine, this power will cease; this generally occurs in spring; ventilation often ceases in naturally ventilated mines, and an explosion may follow in consequence. If a furnace be used for ventilation its power in winter is increased by the weight of the cold air in the downcast; but in summer this weight is taken off. In case no extra care and watchfulness are taken to meet the change, disagreeable results may ensue at this season of the year. If the furnace at its maximum power in the winter, with this assistance, is but just sufficient to prevent the fire-damp arriving at its explosive point, it will be unable to do it in summer, when its power is thus weakened.

THE BAROMETER.

This instrument is useful to show any change of weight of the atmosphere.

THE DIFFERENTIAL BAROMETER.

This is more delicate in its movement than an ordinary barometer; it may be made almost to any ratio of delicacy. It would show a change taking place in the weight of the atmosphere long before it could be seen in the ordinary barometer, and therefore be more valuable in a coal pit. On the fall of the barometer fire-damp issues out of the goaves and recesses of the coal in larger quantities than usual, so that ventilation requires to be increased under such circumstances. The barometer is said to be more useful in a coal pit than in a ship. It indicates impending storms, or change of weather; and the more delicate it is the better. The index of the differential barometer can be made to range easily from 50 to 100 times through a greater space than the ordinary mercurial level; and therefore slight changes in the weight of the atmosphere can be read off by this instrument, which are inappreciable in the common barometers.

THE ANEMOMETER.

The anemometer is a valuable instrument for measuring the *quantity* of ventilation; it shows the exact rate of currents and registers them by an index like a gas meter; by this instrument the *actual quantity* of air passing may be known; and at the same time by the water-gauge, the *absolute force* or *power* required to move or pass that quantity may be known; so that by these two instruments the amount, power, and probable state of ventilation may be ascertained.

THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.*

BY W. S. GRESLEY, M. E.

[Written for the Colliery Engineer].

Fig. 31 is a plan of a couple of breasts in an Anthracite seam of a tender nature and with a bad top, where the pitch is such that the coal after being mined will slide of its own weight to the gangway. Narrow headings or "chutes" are worked up (in the bottom benches of the seam) at right angles to the gangway and an air heading a few yards above it, to the full height of the lift, say 270 to 300 ft., holed through for air about every 60 ft., and with a sheet-iron trough or spout about 4 ft. wide, laid on bottom between the props. When the full distance has been attained the places are widened out on one side and worked backwards down hill, as shown in cut, the coal rushing down the iron chute to the wooden platform at foot where it is shoveled into cars. The miners get up and down the places behind the props. Half-inch plate-glass has been used in place of sheet-iron for floors of coal chutes in the mines containing acid waters which destroy iron very rapidly. The floors of many Anthracite seams are, however, often nearly as smooth and slippery as glass or sheet-iron. For preventing too much leakage of air between the gangways and headings above wooden brattices or canvas checks are erected in the lower part of the chutes just above the platforms with a trap door in them (if of wood) for men to pass through.

Figs. 32 and 32a are illustrative of another Anthracite mining method, or rather a variety, in detail of breast-work. It is devised to meet the difficulty of dealing with the falling top-slate, bony-coal, or other refuse made in mining, by keeping the same in the mine where the pitch is heavy (shown 45° here). As the plan, Fig. 32, shows, the coal is thrown down the timbered manways or side-chutes, and the separated refuse and fallen top accumulates and is cast into the gob or space between the coal-chutes, suitable timber platforms being fixed at intervals as the work goes on near the face for the miners to stand upon. The system has its special dangers as well as advantages which will be apparent to every practical mining man. The direction of the ventilation is shown. The profile, Fig. 32a, is taken on lines A B C D, Fig. 32.

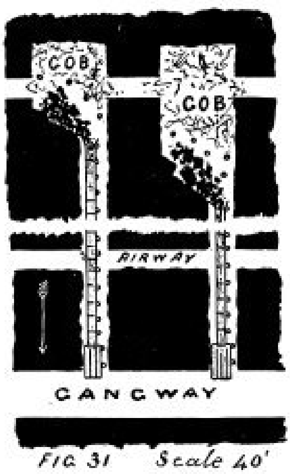

FIG 31 Scale 40'

Fig. 33 requires but little explanation. It is a profile up the center of an Anthracite mine breast where the pitch becomes too steep for the mule to take the wagon to the face and yet not steep enough for the coal to slide of itself in sheet-iron chutes to gangway. The plan illustrated is to use small cars called "buggies" (they hold about ¾ of a ton) in manner shown, *i. e.*, to chute or dump the coal several times from one level to another until the gangway is reached, the refuse being employed for carrying the buggy-track upon from dump to dump. Where refuse is scarce timber trestles may be used. The very frequent and rapid changes of dip or pitch of Anthracite seams in Pennsylvania may be such that in one single lift of say 300 ft. from gangway to gangway (see Figs. 15, 16, and 19,) nearly all the different modes of mining a breast may come into play one after another. At starting, for instance, the coal may be nearly flat, but commence rising a few yards in and the pitch increase more and more until verticality may be approached; or *vice versa*.

Fig. 34. Plan and cross-section showing a method of working a thick heavy-pitching coal seam on the plan of close stowing or complete packing as the coal is cut out and taken away. It has been successfully applied to very soft semi-Bituminous coals in China, and probably in other quarters besides. The preliminary or opening up work consists in sinking shafts, or making slopes on the vein or veins, and driving tunnels to intersect them; cross sections of the latter being shown on plan at T T. Gangways G G, both illustrations, are then driven to form "lifts" with chutes R R driven full pitch connecting them for air, etc. In the drawings given it will be seen that the second or lower of the two lifts is being worked. Between and above tunnels T T large solid pillars are left to protect them and other openings. I I are inclined planes connecting the upper or middle gangway with the surface, and these are used for taking stone, etc., from quarry or other convenient source into the mine by gravity, for filling the gob up solid in manner to be described. On each side of shaft or tunnel pillars a heading is driven parallel with and a few yards above the bottom gangway or water level, and when through from chute to chute, and batteries and loading places, etc., have been fixed, then regular coal digging commences on the high side and is carried on regularly and methodically up the pitch as shown in figure, the refuse for filling the excavations being dumped at upper gangway down every alternate chute marked R R. From the bottom of these chutes the rubbish is taken and spread layer upon layer as each skip or slice of coal is cut away and removed. The coal is drawn off through timbered or rock-built spouts or chutes in center of each panel or stall-face, as at E. Access for men to working places is had through the ladderways or manways previously put through for the purpose; the coal-chutes being made where the manways were driven. When the upper gangway is worked nearly up to, the faces are stopped, leaving the "chain pillar" stumps to be got out the last thing before abandoning the lifts. In this way of working many advantages are derived, which, briefly stated, are these: (*a*) The coal seam is thoroughly proved before the bulk of the coal is mined. (*b*) Nearly all the seam is worked and sent out. (*c*) Refuse in the coal is kept in the stalls and not run out with the coal. (*d*) Squeezes or crushes cannot take place, because every place is completely filled up solid as the work advances. (*e*) Practically there are no "fast ends," and every advantage can be taken of the cleat or cleavage-places to save labor and produce the maximum quantity of lump. (*f*) Suits thin as well as thick seams. (*g*) Overlying seams are not injured by working beneath them, and the surface is kept intact. (*h*) All the coal may be taken out beneath important buildings on surface, rivers, etc., without fear of damage, etc. The length of the stalls or working faces, *i. e.*, between each rock chute R R is, of course, set out to suit the conditions of each seam; and the distance one stall or room advances in front of its neighbor may be regulated at will of the superintendent. The coal is removed from the place where it is cut to the dump either in small mine wagons, in barrows, or slid down sheet-iron on a suitable grade and shoveled into chutes. It seems probable that this system of coal-mining, or modifications of it, will come much more into use in the future in localities likely to favor its adoption. The leading feature of it lies in substituting or replacing the coal, as taken out, with material put in compact and solid from floor to roof as the work advances.

THE DURATION OF THE ENGLISH COAL SUPPLY.

An Abstract of the Address of President Henry Hall, Inspector of Mines, in the Transactions of the Manchester Geological Society, Volume XX., by J. H., Mining Institute of Scotland.

Twenty years have passed since the Royal Commission reported on the coal supply of the country. How far has the estimate then made been verified by experience during these years? The main questions the Commission had to consider were (1) The available quantity of coal, and (2) The rate of consumption. The report fixed the quantity of coal available in the known coal-fields, at depths not exceeding 4,000 ft. (which the Commission considered the limit of practicable working), at 90,207 millions tons. In addition to this quantity, it was estimated that 56,273 millons of tons, covered by Permian rocks, lie above the 4000 ft. limit, making a total of 146,480 million tons. The quantity of coal between 4,000 and 6,000 ft. deep is estimated at 29,000 millions of tons. The Commission considered the question of the possible existence of coal under the Cretaceous rocks of south-eastern England, where it was recently reported that the coal measures had been pierced by a bore-hole, and came to the conclusion that the evidence was not sufficient to justify any credit for coal therein being taken in the report. It is obviously the more difficult problem to estimate the duration of the estimated coal supply. Two bases of calculation were used by the Commissioners—first, that the consumption would bear a fixed relation to the population, which was estimated at about 4½ tons per head per annum. On this assumption, they estimated that the 146,736 millions of tons would last for 360 years. The second method was to allow an annual increase in production of three million tons, being the average rate of increase during the preceding fourteen years. On this basis, the coal would be exhausted in 276 years.

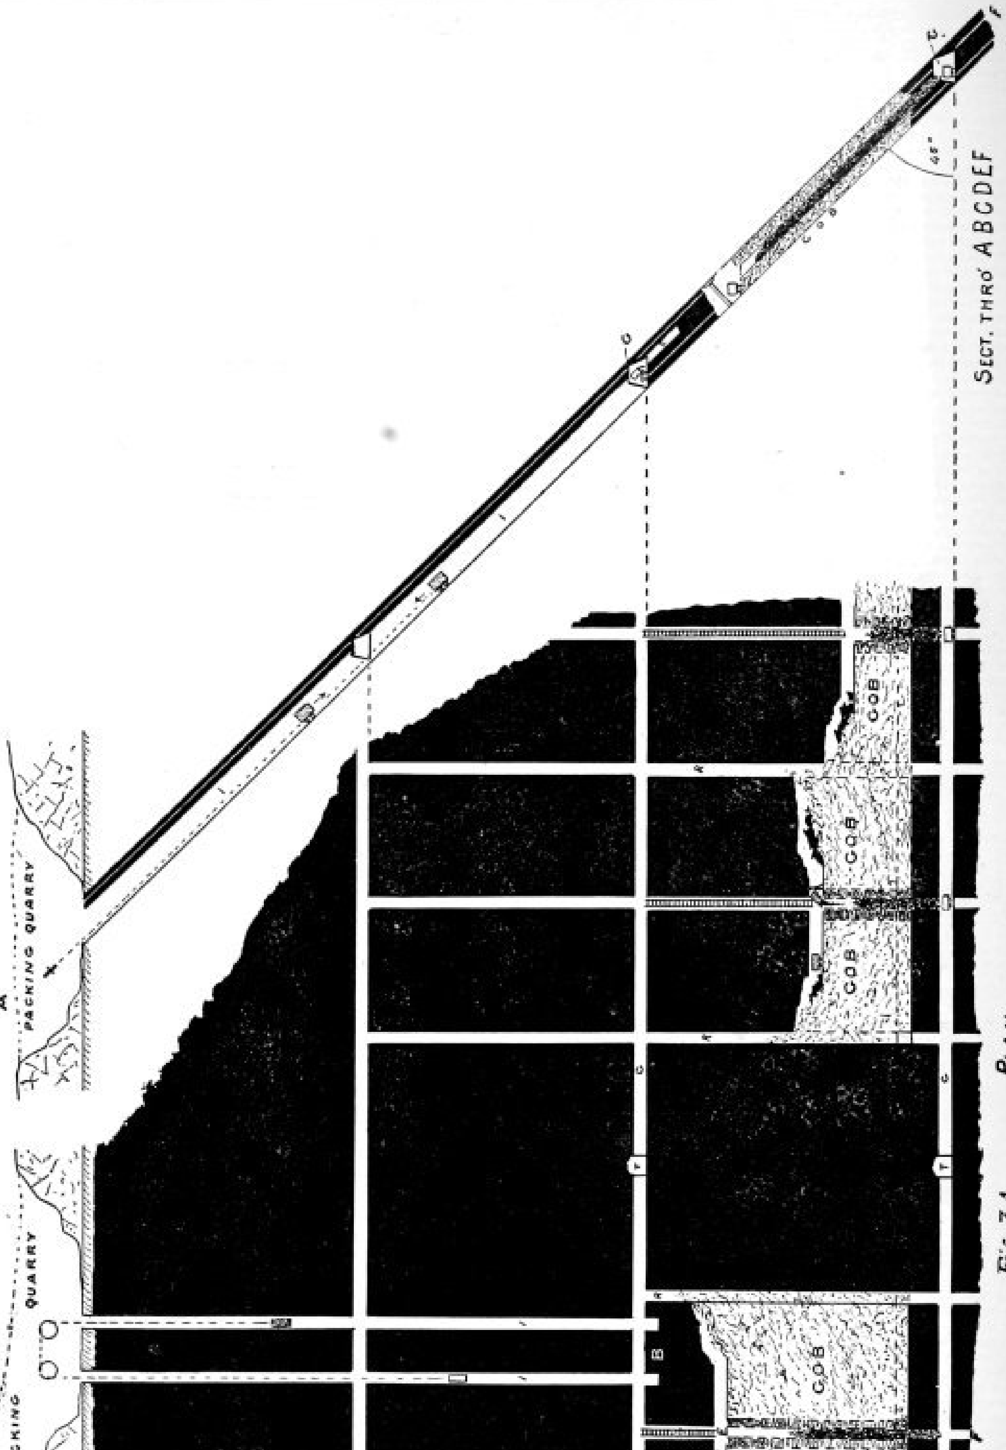
Taking the first method of calculation, Mr. Hall calculates that the consumption estimated by the Commissioners for 1891 is 10 per cent. less than the actual consumption in 1888. According to the second method the output of 1888 was estimated at 164 million tons, and the production was really 170 million tons—a difference of only rather more than 3 per cent. During the past ten years, the annual increase in production has been, on the average, four million tons in place of three-and-a-half millions—the average of fourteen years immediately prior to 1869. If this rate of increase be continued, the 276 years of the Commissioners will be reduced to 240. All these calculations are based on the assumption that workings may be carried to a depth of 4,000 ft., where the estimated natural temperature is 116° Fahrenheit. This, Mr. Hall believes, ought to be 130°, and he places the reduction of natural temperature possible by ventilation at 15°, against 7° mentioned in the report of the Commission, and so makes the probable temperature of the workings at 4,000 ft. 115°. Now, workmen complain of heat where temperature rises above 80°, and the conclusion reached is that, with our present appliances, coal can only be worked at great expense, if at all, at greater depths than that which gives a natural temperature of 100°.

It may fairly be questioned whether any considerable quantity of coal can be got from beneath permian rocks, and consequently the available supply is reduced to 90,207 million tons, if coal worked beneath the permian be set against what may be found unworkable at depths less than 4,000 feet, and on this assumption there will be no more coal workable in 171 years from the present time.

From particulars furnished by certain mine owners, it appears that the cost of coal in 1889 has been only 9d. per ton above the cost in 1869, while the costs in 1879 and 1869 are about equal. The difference in the former case is probably due to increased cost in labor.

AMMONITE.

Recently a series of experiments with a new explosive (Ammonite) were made at Risca, Wales, under the auspices of Sir George Elliot, M. P., and The Miners' Safety Explosive Company, Limited. The *South Wales Daily News* describes the experiments as follows: "A large section of a boiler was mounted on a gravel bed near the Risca Artillery shed. The boiler was 16 feet by 5 feet, and each end was closed by a heavy tarpaulin sheet, such as are used in collieries. Coal gas was admitted into this from a 2-inch main, and the bottom of the boiler was strewn to the depth of several inches with coal-dust. The dust was agitated by a flapper, worked by a chain, which mixed it well with the gas and the air into what ought to have been a terribly fiery condition. A small aperture in the middle of the boiler, also closed by a colliery sheet, was provided that the mass might be tested with a safety-lamp. When this had been done the cartridge of ammonite, buried in the 6 inches of coal-dust in the bottom of the boiler, was fired by electricity from an adjacent building. The spectators had all withdrawn to a safe spot on the sloping hill side, and witnessed again and again the sheets fly from either end as the explosion took place. In all nearly a dozen exhibitions were given with the boiler, and in these the explosive energy was varied by the use of dynamite, securite, stonite, and tonite. Then, after a half a dozen experiments, the coal-dust was cleared out, and the cartridge merely tamped, or covered with small coal, and gas introduced to the proper admixture. The last shot was with carbonite—an explosive used at the wish of one of the visitors. This gave the nearest approach to ammon-



THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.

ite, namely, no flame as far as could be seen. Dynamite gave lurid red tongues of flame from either end of the boiler, fringed with black, carbon-laden smoke. Tonite was even more fiery in the moment of its discharge than dynamite, and the sheets were ignited, and also the rope used to fasten them on to the ends. Ammonite showed to great advantage, and no appearance of flame could be detected in the smoke and dust which belched forth from the ends. In each instance the test of the safety-lamp was applied to the mixture in the boiler to prove that it had arrived at the explosive point. The experiments were considered to be conclusive and satisfactory. Then the value of ammonite in withstanding concussion was illustrated. A 60-lb. steel block was suspended over an anvil and dropped through guides from heights varying from 8 ft. to 23 ft. Dynamite, tonite, stonite, carbonite, gelignite, and the most recent of all, arthurite, all exploded; but although the height of the fall was increased from 10 ft. to 23 ft., ammonite declined to explode either in the cartridge or placed as loose powder on the anvil. Arthurite also did not explode the first time the hammer fell, but this was owing to the weight becoming hitched. When raised a second time on the arthurite, a faint explosion took place. This series of experiments was held to be conclusive and satisfactory, and here ammonite clearly scored. In some other experiments, however, where a lighted fuse was used, fire certainly was generated—whether from the fuse itself, from the cartridges of ammonite, or from the concussion causing sparks to fly from stones or pebbles, it is not allowable to say, seeing that doctors differ. The presence of fire was distinctly evident to several gentlemen when two stockades of sleepers were cut down by a line of ammonite cartridges. Probably better results would have been obtained had the cartridges been fired by an electric spark. The other experiment included the destruction of a section of railway by four 6-ounce cartridges, the smashing of two wrought-iron plates ⅝″ and ¾″ thick, respectively, by 6-ounce and 8-ounce cartridges, the exploding of a bundle of cartridges under water creating a good sized geyser, firing bullets at ammonite, immersing it in ice, burning it in a brazier, and firing 16 ounces of gunpowder, surrounded by a case of ammonite cartridges without exploding them. Proof up to the hilt was afforded when the fragments of the cartridges were collected together and fired in the approved fashion to create a big concussion, which shook the ground, loosened the plaster of the walls, and reverberated like respectably loud thunder amidst the neighboring hills."

Subsidence Due to Coal Working.

(From the Journal of the British Society of Mining Students.)

In a communication to The British Society of Mining Students, Mr. W. S. Gresley, of Erie, Pa., writes as follows regarding the subsidence due to coal working in the Anthracite regions of Pennsylvania:

"Now, in the Anthracite regions of Pennsylvania, the character of the coal measures is so peculiar, both in hardness and position, that the effects of working out the coal seams are peculiar and very different from those of ordinary coal fields.

"Where you have a seam, say 40 feet thick, outcropping at an angle of 70° to 80°, the working away of the coal in chambers or narrow stalls in the mine below will very frequently cause the whole seam and surface over it at the outcrop, to run in, form 'caves,' or 'crop falls,' as they are termed, and leave great yawning chasms all along the hill sides. I measured one that was 150 feet wide the other day, there having been 55 feet thick of coal run in from it. On another occasion the spot was pointed out to me where a miner's house and two men in it went down bodily with one of these 'caves-in,' and were lost.

"I was informed by a Mining Engineer of reputation, that at 600 feet deep, 50 feet thick of the 'Mammoth' seam on a dip of 25° were taken clean out, and the surface went down about 8 feet.

"At another colliery I was told that taking out 12 feet of Anthracite in one seam, at 150 feet to 200 feet deep, only lowered the surface 8 inches as proved by railway tracks on top.

"It is the opinion of many mine superintendents in this Anthracite field, that the clearing out of a seam, say 7 feet thick at 200 feet below another workable seam, will not affect the latter or the surface above in the least. These gentlemen claim, that the fall of the roof and strata above, take place in such a manner that the broken rocks, &c., soon fill up the excavations and 'choke themselves' as the saying is. But, notwithstanding, the binds are about as hard as roofing slates, the sandstones as strong as granite, fire-clay so hard it won't soften with water or 'weather' on top—the coal almost as hard as plate-glass; and that very thick beds of compact quartz conglomerate are interstratified with the other measures; so that the fallen roof, &c., can't become much compressed by top weight; there is something in what they say, though I can hardly believe that no surface subsidence goes on even in the case of the thinner seam workings. The wild and rough character of the mining regions of course makes it difficult and unnecessary to find out what subsidence does take place."

A new plummet for use in deep shafts is described in the *Lehigh Quarterly*. It consists of a vertical core 12 in. long, with eight radiating flanges, 9 in. high by 3 in. wide, of ¼ in. metal. At the bottom there is a circular disc acting as a web. This bob weighs 20 lbs., and has a surface area of about 630 square inches. An ordinary bob of equal weight would have a surface area of about 90 square inches. In an ordinary dry shaft 500 ft. deep this form of plumb-bob will settle, under usual conditions, in about one hour, instead of five or six hours as with the older form.

PREVENTION OF ACCIDENTS IN MINES.

A Prize Essay on Practical Means to Ensure Safety in Coal Mines.

BY AUSTIN KING, PHILIPSBURG, PA.

[Shortly after the disastrous explosion at the Mammoth Mine, the *Pittsburgh Times* offered a prize of $100 for the best essay on the above subject. The judges were Messrs. M. P. Kane, John F. Farrell, and Thos. Lynch. Of the 272 essays submitted, they considered that of Mr. King, the best, on the grounds that the ideas suggested were cheap, certain, and practicable.]

The services of a superintendent and of a mine boss should be secured, both of whom are possessed of a practical and theoretical knowledge of mining in all the phases likely to be presented or circumstances likely to occur in the particular coal field operated in; and combined with this they should be men of integrity, sobriety, tact, and executive ability, to enable them to manage successfully any difficulty that might arise in the operation of the mines, whether it was one of engineering of mines—other than professional work—or one of handling or dealing with men and enforcing obedience to such rules and regulations as the best practice and theory suggested for their personal safety and safety of the property. The superintendent should be a man of superior attainments, if possible, to the mining boss, so that should an unusual occurrence arise in the mine he could, if unable to cope with it alone, seek his superintendent's counsel and implicitly rely on his judgment when he gave instructions relating to it.

The mine boss in a gaseous mine should pay special attention to the reports of the fire bosses and note in his travels through the workings whether the places showed evidence of the regular visits of the fire boss, whose duty it was to daily examine them. He should also give particular attention to any violations by those under him of the regulations or laws governing the working of the mine, and administer the proper penalties for such violations as had been prescribed by the mine rules, or deemed advisable by consultation with the superintendent or mine inspector of the district when not already provided for. He should be unceasing in his vigilance and endeavor to foresee any possible danger, and thus be prepared to prevent rather than remedy the evil.

ACCIDENTS IN SHAFTS.

Prevention of accidents in shafts should be guarded against by the use of the different safety appliances now prescribed by law, (1) such as safety-gates at top landings, safety-catches on cages and good cover overhead on them, good ropes and chains, and in addition (2) by timbering shaft from top to bottom with timber of suitable size, strength and durability; (3) by using a reversible fan for ventilating purposes and making the hoisting shaft the upcast so that ice could not form in it. If ice formed in downcast or fan shaft, the fan could be reversed long enough to thaw it out; (4) by careful daily examination of hoisting machinery, and of ropes, and by shortening the latter at proper intervals so as to remove that part of rope bearing most strain, because resting on the pulley and by daily examination of clevices and bridal chains and the annealing of same at proper intervals; (5) by prohibiting the carrying of mining tools on cages by persons ascending or descending; (6) by the construction of safety-blocks so arranged that cars could not be pushed into shaft accidentally; (7) by keeping copy or code of signals printed in large type in engine-room and top and bottom of shaft, and so placed as to be always in full view of persons required to use them, and by employing no person at top or bottom of shaft who did not understand English "as she is spoken;" (8) by refusing to employ any person as hoisting engineer unless well and favorably known; (9) by using an automatic steam brake on winding drum, safety-hooks and catches fixed to head frame to prevent over-winding.

ACCIDENTS IN SLOPES.

There are but few slopes in Bituminous coal mines of Pennsylvania where persons are lowered into or hoisted out of slopes; but where this is done, (1) the same careful examination of ropes and chains and hoisting machinery, as suggested, for shafts; (2) and in addition, persons should be carefully lowered and raised, the tracks should be kept clean and in good order; (3) roof and timbers should be regularly and properly inspected by mine boss; (4) whitewashed shelter holes, not exceeding thirty feet apart, should be provided for the use of those whose labor required their presence on the slope; (5) the same precautions as to signals and safety-blocks should be adopted as at shafts. Where persons are not lowered into or hoisted out of slope mines a separate traveling way should be provided, which should be well drained and free from all steam or discharge pipes.

ACCIDENTS IN DRIFT OPENINGS.

These may be guarded against (1) by compelling inspection of roof and sides in all hauling roads and pillars if known to be weak—at least three times a week; (2) by providing a separate traveling way where hauling is done by machinery or inclined planes are used. Where this is not feasible, white-washed shelter holes should be provided every thirty feet. Where mules or horses are used for hauling purposes shelter holes should be provided at distances not exceeding sixty feet apart; the shelter holes in both cases to be made in the rib regardless of the distance of the rib from the track; (3) by refusing to permit the use of a steam locomotive where it was necessary for persons to travel into or out of a mine.

ACCIDENTS WHILE WORKING.

Having gone over the accidents likely to occur, to persons going into or out of the mine we will now consider the dangers persons are exposed to when working in mines, which for our purpose may be generally classed under six heads, namely: (1) Falls of roof and coal; (2) injuries by mine wagons; (3) explosions of fire-damp; (4) miscellaneous accidents; (5) explosions of coal-dust; (6) drowning by water.

A list of fatal accidents which have occurred in the Bituminous coal mines of Pennsylvania, and which were compiled from the reports of the inspectors of mines for the years of 1884 to 1889 inclusive, is here given to assist us in forming a correct idea regarding their number and the causes producing them:

Character of Accident.	Number.	Per Cent.
Falls of roof and coal	340	64·2
Mine wagons	74	14·1
Fire-damp explosions	51	9·7
Miscellaneous causes	46	8·7
Dust explosions	17	3·2
Total	528	99·9

If we only take the accidents that happened in districts in which fire-damp is generated, and also leave out the number killed at Kettle Creek explosion, which was attributed to coal-dust, the list will appear as follows:

Character of Accident.	Number.	Per Cent.
Falls of roof and coal	227	61·68
Mine wagons	56	15·22
Fire-damp explosions	51	13·84
Miscellaneous causes	34	9·24
Total	368	99·98

EXPLOSIONS OF GAS.

We will consider first the explosions of fire-damp in mines, because this form of accident is particularly dreaded on account of the large number almost instantly killed by them. The cause of fire-damp explosions, or explosions of any kind, should receive greater attention and consideration than any other for the reason that no matter how intelligent, careful, or circumspect a man or number of men may be who work in a mine generating explosive gases (and when such gas may be present in such quantities during working hours in working places, roads, and airways as to be ignitable) they are always liable to be the victims of some foolish or overt act that would cost them their lives, and as the strength of the weakest link in a chain measures the strength of the whole chain, so their safety is measured by the probable misconduct of some ignorant, vicious, or semi-idiotic person who cannot realize the awful consequences of his misbehavior.

To avoid such disasters, (1) ample means of ventilation should be furnished, always preferring it in the form of a fan, which should be placed at a safe and convenient point; (2) the work should be laid off in separate ventilation districts, giving each district a separate current of air and having a separate return therefrom to bottom of upcast, said return to be maintained solely for that purpose and only to be traveled by mine officials for inspection purposes. The objects attainable by this method of ventilation would be to increase the total volume of air circulating in mine to insure purity of air current (as far as practicable in mines) on its entrance to each particular district and to limit the extent of an explosion, should one occur afterward; (3) the overcast or air bridges should be constructed in the natural strata if the material was suitable for this work; if too expensive to construct in this way, then they should be constructed of iron in segments which should be of a known or calculated strength so as to resist being collapsed or blown out in case of an explosion; (4) no crosscuts should be made in main heading pillars or boundary pillars of a ventilation district, except at such points as were necessary for hauling purposes; the headings should be aired as they advanced from cross-heading to cross-heading, or from flat to flat, by means of incombustible brattice put up for that purpose. This precaution would greatly reduce the number of stoppings to maintain air-tight, or to be blown out (in case of an explosion) and would thus greatly facilitate a rescue under such circumstances. By a judicious use of this brattice in cross or flat headings the number of stoppings in them would be reduced one-half or more, with the before mentioned advantage, and with little or no extra cost where pillars are large and yardage is paid for cross-cuts.

Next the services of one or more fire bosses should be secured, whose qualifications should come up to the following standard: He should possess a good practical knowledge of mine gases—and especially of fire-damp—know their composition and specific gravities in order to be able to know where, under ordinary circumstances, to find them, to be able to form a good idea of the amount of air required to dilute any explosive gases he might encounter in his daily examinations; should be acquainted with the method of ventilation used in the mine and the direction of and distance traveled by any explosive gases that might be generated in his examination district or in the mine. He should be a total abstainer from all intoxicating drink, should not be shortsighted or color-blind, should be cool and courageous under all circumstances connected with his duties.

The fire bosses should be provided with a type of safety-lamp that would combine sensitiveness in testing with the quality of resisting the passage of flame through the gauze in currents passing at high velocities. It should also be provided with a shut-off to aid in extinguishing the flame in case a large body of gas was suddenly encountered. There should also be a small key fixed to the side of safety-lamp, near the top to unlock a device fixed to roof of working place by a small wooden plug driven in a hole one inch in diameter bored in the roof with a small auger. The device would consist of an ordinary clock face, say four inches in diameter, with a circle on the outside on which the numbers 1 to 31 inclusive were marked and three pointers. After the workman entered his room or heading he could see that the fire boss had been there (the cover being open) from the position of the pointers on the dial. If the fire boss had examined the place on March 20 at 3.30 in the morning the long pointer on the dial would be over the figure 20, the hour finger between the letters 4 and 5, indicating at minute finger at letter indicating six as on an ordinary clock face. The object to be attained by this is to furnish absolute proof that the fire boss' safety-lamp has been in such a position that if any gas was near the roof he could not help seeing it. This device could be moved forward as the work advanced, according as the coal seam inclined or the condition of the roof might suggest. The fire boss could, under ordinary circumstances, make the examination and fix figures of dial in 30 seconds (the dial should always be placed in the highest point practicable in the working place.) He should not be required to travel between places to be examined faster than two miles per hour. After an examination of the working places and also of those not worked in for the time being that are in any way contiguous to them or are ventilated by any air current that may afterwards pass in any place that may be worked or traveled in by workmen in the mine and all has been found safe, the fire boss should remain at the "station" and should see that no lamp passed him that did not satisfy him as to its safety.

No men should be hired to work in a mine generating explosive gases who did not possess some practical knowledge of the use of the safety-lamp. If men were needed and men possessed of this practical knowledge could be had, pains should be taken by those in charge of mines to explain to them the reason why the light was so guarded and try to impress on their minds the great danger of tampering in any way with the lamp, and the awful things that might happen to themselves and fellow workmen if the lamp was handled or damaged in such a way as to make the passing of the flame through the gauze possible and also show them how to shield their lamp in air traveling at a high velocity. The lamps furnished to workmen should be examined and tested before giving to workmen to enter the mine, and should be able to withstand safely a strong current of air and at the same time give a light equal to the Clanny. No common Davy, Clanny, or Stephenson (Geordie) lamp, or lamps of like character should be allowed to be taken into the mine, because they have been proven time and again to be unsafe and unreliable. Blasting should also be prohibited in any portion of the mine where fire-damp existed or was likely to be liberated by the blast or in the vicinity of gobs and falls that were not easily accessible to examination for the detection of gas, or where coal dust was deposited in any material quantity on the floor and sides as the flame of the shot might be propagated by it into inaccessible portions of mine. Tamping shots with coal should also be prohibited for the same reason. The laws forbidding the taking of matches, fuse, smoking pipes or any other combustible material into mines where safety-lamps are used, or the propping open of or doing damage to any door, regulator, or overcast used to direct the air currents in the mine, or tampering in any way with any safety-lamp, removing danger signals, etc., should be fearlessly and rigidly enforced.

ACCIDENTS BY FALLS OF ROOFS.

The best preventative for this class of accidents would be to (1) employ special or selected workmen to work or timber places where roof is "full" of slips, seams, or cracks, men known for the care exercised by them in their daily work; (2) to provide ample and suitable timber, proper caps and collars, which should be delivered on short notice to where it was required; (3) to compel workmen by rigid enforcement of rules to properly set their timber and keep it propped sufficiently close to the face of working place to secure safety under all ordinary circumstances and to withdraw the workmen from place if it shows signs of any approaching cave-in; (4) where drawing props is a necessity, either from an economical standpoint or to avoid squeezes or creeps, the work should be performed by one thoroughly acquainted with the character of the work and nature of the roof, and he should be provided with a "timber-bar" and chain to draw post in very dangerous positions.

ACCIDENTS BY FALLS OF COAL.

The accidents under this head may be prevented very materially (1) by increased vigilance on the part of the miner in looking for smooths, slips, and crevices in the coal, but where undercutting is required; (2) coal-cutting machinery should be put in to perform that labor. If this could be done in all coal seams the accidents under this head would be reduced fully 80 per cent. Where machinery cannot, with profit, be so used, miners should be compelled to set sprags to coal face at a distance not exceeding seven feet apart, whether it appears necessary or not, and the mine boss or mine inspector, if able to prove negligence in this respect (or in properly posting and securing his working place) should make complaint at once to the nearest justice of the peace—who should be given jurisdiction in such cases—and fined the sum of from $5 to $25; the fines so paid to be turned over to the miners' hospital fund of the district in which the misdemeanor was committed. Observation shows that about 50 per cent. of the accidents from falls are owing to carelessness or indifference on the part of the persons injured.

ACCIDENTS FROM MINE WAGONS.

These may be very largely prevented by the adoption or putting into practice the suggestions made with reference to drift openings, together with the provision (where condition of roof will permit) that the headings, or hauling roads be made sufficiently wide, so that with tracks placed to one side of the center there would be two to three feet of space between the loaded cars and one side of heading all along. The hauling roads should always be made wide enough to allow a driver to pass a moving trip of cars safely to put on or take off brakes or for the use of sprags, where the grade requires it; then having roads properly cleaned and well drained there would be little or no inducement to ride on or between cars. No persons should be permitted to ride on cars on any incline unless special provisions have been made for that purpose.

DEATHS FROM DROWNING.

Deaths from drowning by holing into old or abandoned workings containing large bodies of water have fortunately been small in number, but the danger is a fast increasing one from the fact that mines are being worked deeper each succeeding year, and that lakes of water, many acres in extent, surround some coal properties and overlie others. This is all the more alarming when we consider that in many cases no maps of these water-filled workings are to be had and if some maps are preserved their accuracy is not to be trusted or relied on, because there is good reason to believe that working places were advanced more or less after the survey had been made or probably some portion filled with water at the time and not on the map at all. To provide against disasters a large margin should be allowed for the correctness of the maps of old workings that contained either water or gas in dangerous quantities. A law should also be enacted compelling engineers of mines, mining engineers, and mine surveyors to sign and date maps or portions of maps made by them, after their surveys, and hold them responsible for any loss of life or property that was occasioned by any defect or inaccuracies proven as theirs. This would give a stimulus to intelligent, accurate engineering, and would relegate botches or barnacles of the profession.

ACCIDENTS FROM DUST EXPLOSIONS.

A comparatively newly discovered or newly demonstrated cause of explosion has made itself manifest in our Bituminous coal mines. I refer to that of coal-dust. It was the chief agent of destruction in the Kettle Creek explosion, and in that case the mining world was furnished the best proof of its deadly character when once raised and ignited, for at this mine no fire-damp was ever seen before or since, and had only been opened a few months, and had a score or so of working places. [These facts are merely cited for the benefit of your readers should it be my good fortune to merit the publication of them.] That coal-dust caused the death of a large number of persons at Mammoth was everywhere apparent to the rescuers and to the experts who visited the scene afterward. This source of danger is present in all dry, or partly dry mines, and should be guarded against by the prohibition of blasting in localities where dust has accumulated in dangerous quantities until the dust has been removed and the place and vicinity thoroughly moistened by sprinkling water thereon. Sprinkling should also be regularly practiced on roads where dust accumulates.

MINE FIRES.

These may be prevented by prohibiting naked lights from being taken into stable or feed rooms or where timber is very tinder-like, by keeping pump rooms and cabins in pits clear of all oily waste, and where cars are oiled at bottom of pit some absorbent should be used and the floors cleared from time to time and fresh absorbents scattered on floor of mine. Sand or gravel is suitable for this purpose. Where a place is in danger of being set on fire from ignition of gas blowers by shots, as near clay veins, for example, holes should be drilled ahead and the gas allowed to drain off. If the necessity of driving the heading will not permit this delay, then the place should be driven through the danger point by picks. Only such brattice as is incombustible should be allowed to be used in mines.

NATURAL GAS PIPE LINES.

The location of these lines should be accurately determined and plotted on mine maps of mines over which they pass. The strata under them should be left intact by leaving ample pillars of coal in for support.

OIL AND GAS WELLS.

The General Assembly should authorize the appointment of a competent corps of engineers to survey and accurately locate the position of all oil, gas, or salt wells, as far as can be ascertained from deeds, leases, or information gathered from other sources, that have been drilled in the coal measures of the State. The maps should be drawn to a scale not exceeding 400 feet to one inch, and they should be deposited with the recorder of the respective counties represented on them as public documents, so that ready reference may be made to them at any time. Mine managers can thus guard against striking them unawares and prevent the mine from being deluged by water or gas.

In conclusion, I would say that the greatest preventative of accidents in mines is the use of ordinary caution on the part of workmen and the rigid enforcement of rules, and the infliction of due punishment by the mine officials. This last may seem harsh, but my experience of 30 years in mines only serves to strengthen my opinion as to its necessity. It is much better to suspend or discharge a man for violation of rules providing for his safety than carry him home on a stretcher, crippled perhaps for life, or dead. Operators, too, should give their subordinate officials a standing order to do all possible to avoid accidents and see that their mines were well ventilated. When not entirely taken up with other business they should visit the mines in person, enter them and see that their workmen are cared for as he desires they should be.

SINKING THROUGH WET GRAVEL AND QUICKSAND NEAR NORWAY, MICH.

BY WILLIAM KELLY, VULCAN, MICH.

[Cleveland Meeting, June 1891. American Institute of Mining Engineers.]

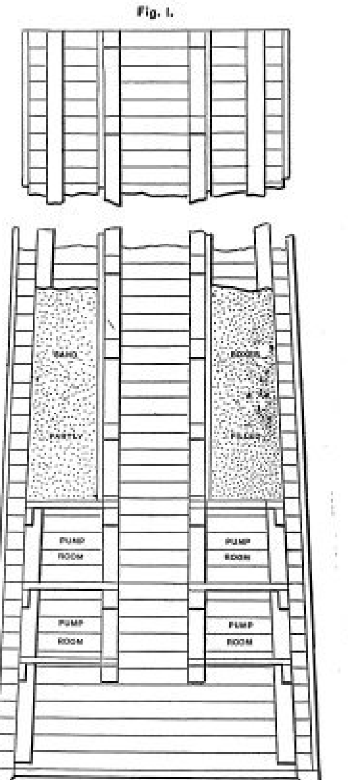
An extensive swamp covers a large part of the town-site of Norway and adjacent land. Through this swamp run two parallel ore formations. In the north one is the Aragon Mine. The south one passes into the swamp on the Harrison property. On the edge of the swamp, about 1,000 feet from the Aragon Mine, a diamond drill, in the fall of 1889, located the ore-bearing formation and a probable ore body. To explore further and develop this ore, the Penn Iron Mining Company proposed, in the Spring of 1890, to sink a shaft.

The drill had shown the depth of the glacial drift to be more than 60 feet. A test pit near the location of the proposed shaft had struck, at a depth of 20 feet, an amount of water which a 200 gallon pump was unable to lower. At the Aragon, a few years before a shaft had been sunk to hard pan with great difficulty and many delays by the usual method of driving laths.

Under the conditions it was decided to sink a caisson or drop shaft. Two 40-horse power boilers, a Lidgerwood engine with 4-foot drum, and a good derrick were set up; and two No. 10 Knowles pumps rated at 400 gallons a minute, were brought on the ground. The pumps had been purchased for another purpose, and, being brass-lined, were not well suited for the work intended, but they were available.

The dimensions adopted for the top of the shaft were 6 feet by 13 feet inside. To give sufficient space for pumps and working, and to aid the shaft to settle, it was made 4 feet larger each way at the bottom. The shaft was divided, to within 12 feet of the bottom, into three compartments, the middle one uniformly 4 feet wide. This compartment was used for hoisting, a ladder-way and pipes. The pumps were placed one

Fig. 1.



LONGITUDINAL SECTION.

Scale ⅛ in. to 1 foot.

HARRISON SHAFT.

in each end-compartment. Above the pumps the end-compartments were planked up to be filled with sand to increase the weight. A ventilation box was put in one corner. The bottom of the shaft was left unobstructed for working purposes, and sufficiently high to allow two additional pumps to be put in under the first. (See Fig. 1).

The bottom pieces, made of oak and constituting what is called the shoe (see A A Fig. 4), were 15 inches square, but the bottom inside was beveled off to 6 inches. Above the shoe, white pine timbers (B B), 12 inches square, framed in sets, were laid close and bolted together and to the shoe with eight 5-foot bolts. The successive sets were reduced 1 inch in length and width, until at 48 feet above the bottom their dimensions corresponded with the top. Corner posts, 12 inches square, of unequal lengths so as to break joints, were bolted to every other side piece and end piece. The bolts, being put in from the inside and having the nuts countersunk, were easily unscrewed and recovered when the corner posts were removed. Like the corner posts, side posts (D D) were put in, one at each corner of the middle compartment. Twelve-inch dividers (E) were used every 5 feet.

After the ground had been leveled the timbers were built up and bolted as far as the derrick and bucket would permit, nearly 30 feet. The seams were then carefully caulked outside, and 3-inch planks (C) in unequal lengths were spiked on, to protect the caulking and timbers and to strengthen the shaft. A shaft of this character is liable to be pulled apart if not very strong.

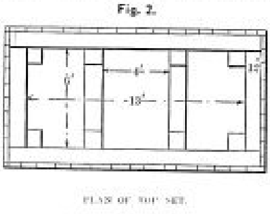
Steam hose was used at first to connect the pipe on the ground, coming from the boilers, with the pipes in the shaft. But afterwards lengths of pipe with double elbows were substituted. Two lines of steam pipe from the ground to the pumps were necessary, in order that one could be used while the the other was being altered in building the shaft up.

The shaft erected, the pumps in place, and everything ready, ground inside the shaft was broken Monday morning, June 2, 1890. As the top was dry the buckets came up fast, and by next morning the shaft had gone down 6 feet. On Friday, the fifth day, at 15 feet, the pumps had to be started. The first week's work resulted in 18 feet sunk. During the first three days of the second week 9 feet more were sunk. It was now evident that both our pumps had to run fast to keep the water out, and if one should break down or the water should increase, we would be drowned out. Therefore, before sinking the pumps below the water-level, we stopped to get more power.

Two portable boilers of 35 and 100 horse power respectively were bought, delivered, and connected, and two No. 10 Cameron pumps without air-chambers were placed 4 feet under the Knowles pumps. During the stop the shaft was built up again as high as possible. We lost thus 15 working days, but started afresh Monday, June 30th, with doubled power. During the next three days we sunk 7 feet. Then the Knowles pumps gave out. Eight days of sand and gravel had completely worn out the brass linings. It was necessary to take out the linings and put in larger pistons, which repairs consumed two days.

On Saturday, July 5th, we started again, and to the end of the following week we sunk 16 feet in 7 work-

Fig. 2.



PLAN OF TOP SET.

Scale 1/8 in. to 1 foot.

HARRISON SHAFT.

ing days, during which time everything went well. The pumps were kept busy; three running constantly and the Knowles pumps often making 100 strokes a minute. The quantity of water was estimated at 1,500 gallons a minute. During the week the sand boxes were filled to keep the shaft down to the bottom of the excavation. The sand and gravel came in under the shoe, and the surface about the shaft settled into a large pit which continually grew larger.

July 12th, the shaft was down 50 feet, and it became necessary again to build it higher. This took 3 days. A drill in the bottom gave us some encouragement, as at 10 feet it struck something hard. During the next 3 days we sunk 7 feet and found hard pan in a corner of the shaft. At this point the shaft did not settle regularly. Sometimes it would hang, and then it would drop with a great inrush of sand and water, even when the ground was out a foot or more from under the shoe. To increase still farther the weight of the shaft 30 tons of rails were laid on the top; and props had to be placed against the shaft at different times to keep it straight. It took 18 days to go through the 14 feet of hard pan; but parts of two days were spent in weighting the shaft and one day by an accident which bade fair to stop proceedings summarily.

Some difficulty with the water supply of the boilers cut down the steam pressure so low as to stop the pumps, and before steam was raised again they were completely drowned and could not be reached. An anxious quarter of an hour was passed before first one, then another, and then a third pump started of their own accord under water.

The ledge was struck August 7th, and two days later the slates were exposed all across the shaft. Four days more were spent getting the shaft down 2 feet further into solid rock.

The time spent in sinking may be summarized as follows:

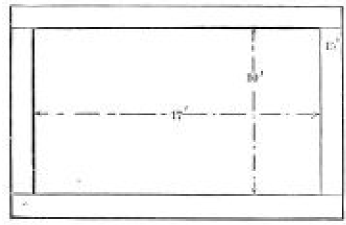
4 days sinking 15 feet above water-level;
17 days sinking 42 feet through wet gravel and quicksand;
16 days sinking 14 feet through hard pan;
4 days sinking 2 feet in slates; making a total of
41 days sinking 73 feet.
To this must be added:
6 days required to build up the shaft and
2 days weighting the shaft with rails; making a total of
49 days, or one day over eight weeks actual working time. In addition to this we lost
12 days in increasing our power and
2 in repairing pumps; making the time consumed
63 days, or ten and a half weeks.

We now, August 14th, had the shaft down firmly in the ledge; but the most delicate part of the operation was still to come, namely, stopping the flow of water.

Before that could be done, however, many things were necessary.

The rails had to be removed from the top and the sand from the boxes, the pipes changed and the shaft built up to the surface. There was now a sink-hole about the shaft, 65 feet in diameter and 20 feet deep,

Fig. 3.



PLAN OF SHOE.

Scale 1/8 in. to 1 foot.

HARRISON SHAFT.

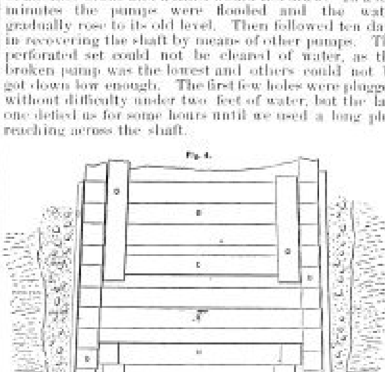
and the top of the shaft was about 6 feet below the original surface level. The shaft was but little out of plumb, the top set having to be raised 2 inches at one end to level it. The corner posts were taken out, the bolt-holes plugged and the shaft caulked on the inside. This work took 8 days.

The next 14 days were spent in sinking 11 feet further into the ledge. It was unsafe to make heavy blasts, and the pumps, after their severe strain with lengthened suctions were barely equal to their task. The bulk of the water from under the shoe was gathered together by troughs of boards and clay, but still water was falling everywhere.

The work of sealing up the bottom of the drop-shaft was now undertaken. A set, 6 feet by 13 feet inside, of 12-inch square timber, was carefully placed in line with the top set of the shaft, about 6½ feet below the shoe. This was thoroughly blocked against the rock all around with wedges. Six sets (F F) of the same size were placed on top of the first and each bolted to the next. Behind the sets as they were built up, was put a thin layer of clay over the wedges and then concrete of equal parts of sand and Hilton cement. The middle of the top set (G) was about opposite the bottom of the shoe. Through this set, twenty 2-inch holes had been bored. Behind the holes a layer of gravel and broken stone, 4 inches deep, was laid, leaving a free passage for the water. Upon this perforated set were put three other sets (H H) of increasing inside dimensions, so that the top set was against and bolted to the drop shaft. The space behind these sets was filled with concrete as before. This timbering and cementing in such a flood of water was a tedious process and took 18 days.

It was all done, and we were ready to plug up the holes, when the pumps failed. One had been removed to make room for lowering the timbers. The piston-rod of another broke and a third would not draw. In a few minutes the pumps were flooded and the water gradually rose to its old level. Then followed ten days in recovering the shaft by means of other pumps. The perforated set could not be cleared of water, as the broken pump was the lowest and others could not be got down low enough. The first few holes were plugged without difficulty under two feet of water, but the last one defied us for some hours until we used a long plug reaching across the shaft.

Fig. 4.



CROSS SECTION, SHOWING METHOD OF CLOSING THE BOTTOM.

Scale 1/6½ in. to 1 foot.

HARRISON SHAFT.

The result was entirely satisfactory. The water at once fell to about 200 gallons a minute. After the pumps and side posts had been removed and the interior had been thoroughly caulked, the water was decreased to about 90 gallons. After the shaft had been sunk farther and bearers put in, a small station was cut at one end and the water was gathered to a No. 8 Cameron pump. Below this the shaft was sunk with a No. 4 Cameron which now works about an hour and a half a day.

The time taken for sealing up the bottom may be summarized as follows:

8 days to alter shaft after it rested;
14 days to sink 11 feet in slates;
18 days to timber and cement;
16 days to remove pumps, caulk, and arrange shaft for regular sinking; making a total of 56 days.
To this we must add:
10 days lost by failure of pumps; making a total of
66 days or eleven weeks.

This makes the total of both periods of the work 129 days, or 5 months. At the end of this time, November 1st, the shaft was 84 feet deep and in shape for sinking in the regular way.

SINKING APPLIANCES AT LLANBRADACH.

By W. Galloway, in the Proceedings of the South Wales Institute of Engineers, Vol. XVI., Abstracted by J. H., of the Mining Institute of Scotland.

The shaft sunk by the Cardiff Steam Coal Collieries Company (Limited), at Llanbradach, was put down for the purpose of ascertaining the exact depth to the coal, and to gain such information as to pumping requirements, &c., as would enable the engineers to determine with some degree of certainty the fittings of the future colliery. It is also intended to form the upcast when the winding shaft has been sunk. It was known that a considerable thickness of the Pennant sand-stone series, which is invariably found heavily watered, required to be passed through, and surrounding collieries have heavy pumping fittings. The absence of any means of determining the probable quantity of water to be dealt with in sinking led to special provision for winding the water to the surface. The contract provided for certain allowances whenever the water exceeded 4,000 gallons per hour, whether pumps were provided, or not. The largest quantity met with was 7,500 gallons an hour in the shaft bottom. Down to a depth of 135 yards the total growth was 9,000 gallons an hour, of which 5,000 gallons was walled out by brick and cement walling. It would have been impossible to proceed with the sinking without pumps had it been necessary to fill the water into the kettle by the ordinary means of bailing. This bailing the author says he has long regarded as a disgrace to the art of mining, and so he devised what he calls the "Pneumatic Water Barrel." It consists of a cylindrical vessel of sheet-iron, 4 feet 2 inches in diameter, and 8 feet deep, closed at the top by an air-tight man-hole door. The bottom is 5 inches above the lower edge of the cylinder, and has a circular hole in it 18 inches in diameter. This hole is closed by a faced valve of cast-iron, mounted with a sheet of leather, capped and tightly clasped by an iron hoop. The valve is attached to a spindle by a ball and socket joint, by which it is kept in position, but allowed a certain amount of play so that it may readily accommodate itself to its seat. The cylinder is thus an air-tight vessel, the interior of which has communication with the exterior atmosphere only by means of a pipe, extending from close to the top of the cylinder in the inside, to the outside of the vessel half-way down. The outside end of the pipe is fitted with an instantaneous coupling identical with that used on the vacuum railway brake. In use the pneumatic water-barrel is lowered into the shaft till its lower edge is under water in the shaft bottom. The interior is put into communication with a condenser air-pump on the surface by attaching a flexible tube connected to the vacuum pipes in the shaft to the instantaneous coupling of the barrel. A vacuum equivalent to 20 to 22 inches of mercury is thus obtained inside the barrel, and the water rushes in through the bottom valve. A glass gauge tube on the outside of the vessel shows when it is full. The tube is detached, and the signal given to raise the barrel. When it reaches the surface a bogie is run under it, and it is lowered on a conical block of wood, which raises the valve, and the water escapes. With 7,500 gallons of water an hour thus raised, the rate of sinking was 4 yards a week. When the growth was only 500 gallons an hour, the progress attained was 6½ yards per week.

Two winding engines were erected and used in sinking—the principal engine for winding water and material from the shaft bottom, and an auxiliary for lowering walling material, and latterly used to raise the water collected by a cistern, first at 135 yards, and afterwards at 190 yards deep. The latter engine was a compound one, built to the specification of the author, who wished to try experimentally a contrivance he had desired to meet the difficulties already experienced in applying compound engines to winding. His solution is to introduce a reducing valve between the feed pipe of the high-pressure cylinder and the pipe connecting the high and low pressure cylinders with the object of maintaining the pressure in this connecting pipe when the engine is standing about equal to the average pressure therein when the engine is at work. The result has been entirely satisfactory. The guide ropes in the shaft are used to suspend the walling stage, which is always in the shaft, thus affording protection to the sinkers, and permitting the winding of water through a central opening 6 feet 6 inches square, while walling is going on. This stage is double the walling stage proper, having a roof 10 feet above it. The guide ropes are bound on drums of a steam crab, and can be wound or unwound simultaneously or separately.

ENGINEERING PHOTOGRAPHY.

A Paper Read Before the Lancashire Branch of the National Association of Colliery Managers, Eng.

BY MR. T. HOUSE, OF WIGAN.

I think it will perhaps be better to offer some explanation, and to describe the reason why it became necessary to introduce engineering photography. As an example take an engineering establishment where it is first necessary and essential at the commencement of an undertaking, say in a mechanical arrangement, to make a general drawing showing such arrangement in its entirety, thereby enabling the designer to assemble such mechanism to the best advantage for accomplishing the desired objects. Now from this general drawing the details for pattern, smiths, turning, fitting and erecting shops are got out on a larger scale so as to facilitate the manufacture and manipulation of the several parts of the mechanism forming such arrangement. And taking into consideration that the different parts or details of such arrangement must all be in a state of progress at the same time, it is requisite that a general drawing should be in the hands of the foreman of each department at the very commencement of the operation of manufacture, thereby enabling him to see at once if necessary for what part of the arrangement the details that he has in hand are for. A general drawing has to be kept in the drawing office for the draughtsman's reference, and perhaps a similar drawing to be sent to the customer for whom we are making the arrangement, so as to enable the necessary provisions being made for the erection of such arrangements, say such as excavations, foundations, framework, &c. Taking these circumstances into consideration, it is apparent that necessity compels us to have a multiplicity of these drawings, which would take, say in the case of a pit heapstead, with tipping, shaking, sorting, and picking arrangements, with all necessary provision made for reception of same, a considerable length of time to complete, say a drawing in the first place, and six *fac simile* tracings on either paper or cloth. These six tracings would take one man from three weeks to a month to complete, as much care having to be taken in one as in the other. Now it became apparent from this, that there was a considerable amount of expense incurred in the multiplicity of drawings as here described, which might be curtailed by a more rapid production of copies from any drawing. These remarks of course, not only apply to engineering establishments, but to colliery surveying, architects, and others who also require to have a multiplicity of copies from the same drawing. Now, to make a multiplicity of drawings or copies from any drawings the cheapest, most accurate, and most rapid method is undoubtedly by means of photography, of which there are several processes. Six effective and invaluable processes I will here enumerate: First, F. P., Ferro Prussiate Process, which produces white lines on blue ground, requring nothing but a developing bath of cold or tepid water. Second, Rolland Rapide, Ferro Prussiate Process, printing in any light. Third, B. L. process (invented by a French chemist, Prof. Pellet), known as the Cyanotype process, and produces blue lines on white ground under any conditions of weather during daylight, requiring two acid baths. Fourth, Ferric Cyanide process, produces blue lines on white ground, requiring one acid bath only. Fifth, B. W., black white produces black lines on white ground, requiring one acid bath only. Sixth process, Black Cyanotype process, black lines on white ground under any conditions during daylight, requiring three acid baths. Of the processes enumerated, the three principal ones at present in vogue in engineering and other establishments are the F. P., Ferro Prussiate, the L. B. blue line, requiring one acid bath only, and the B. W., black white, requiring one acid bath only, or namely the first, fourth, and fifth enumerated. These three processes being mostly in demand, I purpose explaining the mode of procedure and manipulation of these three processes fully, which, I think, will be sufficient and quite within the scope of this paper. Perhaps I had better here mention, for the benefit of the uninitiated, that it is still necessary to make a pencil drawing of the subject arrangement we desire to photograph, from which we make a tracing on either clear tracing paper or cloth. Those papers with bluish-white lines are preferable, and give the best results. Yellowish-tinted papers or cloths should therefore be avoided. The lines on the tracing should be made of well-rubbed Indian ink, with a little Prussian blue added. This latter takes out the brownish cast. Center and dimension lines, of course, should be dotted or broken, and made with either raw or burnt sienna, as these latter colors always give the best results. This tracing is called the negative, from which an *ad infinitum* number of copies can be made. The negative is made in precisely the same way for all the processes. Printing is done in every respect in the same way as the ordinary photographic silver-print, the tracing forming the negative. The papers on which we take the impression or copy from the negatives are called sensitised papers, having a chemical solution on the prepared surface. Sensitised papers for any of the processes can be bought from whole-sale producers, who have special mechanical appliances for the sensitising of papers, consequently their purchase from manufacturers will come in cheaper for consumers than if they bought paper made and put on their own solutions. As an illustration of the mode of sensitising paper in a primitive way, I will describe the preparation of paper for the F. P. Ferro Prussiate process, as was in vogue at engineering establishments who made their own for the particular process. Sensitising solution: (*a*) Citrate of iron and ammonia 100 grains, water 1 oz.; (*b*) red prussiate of potash, 70 grains, water, 1 oz. These solutions will keep indefinitely before mixing, but when mixed they should be used at once or left in the dark. Preparing the paper: Mix equal quantities of *a* and *b*, and apply to one side of paper with a sponge. The sponge should be well filled with the solution, which should be liberally applied to the paper for about two minutes. Then squeeze out the sponge and wipe off all the solution from the surface of the paper, care being taken to use the sponge lightly and judiciously, without abrasing the surface. The paper, which is now of a bright yellow color on the prepared side, should be hung up to dry in the dark. Manipulation of the F. P. Process: The sensitised paper should be cut rather larger than the negative tracing. The tracing is now placed face downwards in the printing frame; on the back of this is placed the sensitised paper; prepared side next to tracing, folds being carefully avoided. A piece of felt, pad, or cloth covreing is placed on both, for equalizingthe pressure. The hinged crossbars are now pressed down upon an intervening board, the board receiving the pressure of the crossbar springs, the crossbars being secured at the free ends by catches. It is essential that the tracing be in uniform contact with the glass. The printing frame is taken out of doors and the glass turned towards the direction of the sun so that a clear light falls upon the printing frame glass, intervening shadows to be avoided. The frame is left out until the margin of the sensitised paper shows a grey metallic color. Exposure: The fuller the exposure the darker the blue tint of the copy when completed. When the fine lines on the tracing appear blue on the copy, the exposure will be sufficient. If the lines appear yellow the exposure should be continued. Under exposure results in a light milky blue background. Over exposure results in the lines being indistinct and of a bluish-white color. Time of exposure: In clear sunshine, 4 to 15 minutes, in fair weather 15 to 30 minutes, in dull weather up to one hour, and even more. Developing: After sufficient exposure the copy is taken out of the frame and immersed in a basin or trough of cold or tepid water, and left there until the blue lines come out perfectly white. Copies should be fully immersed, and if several are washed together the water should be changed once or twice. After a final rinsing in clear water the paper is hung up over a roller to dry, or, if necessary, dried by blotting paper. All the operations should be executed in a darkish or subdued light, and except when exposed to the action of the sun in the printing frame no direct daylight should fall upon the paper, as it is apt to disfigure the copy by producing a yellowish brown cast. Corrections or additions in white can be made with a drawing, etching, or quill pen dipped in a solution of 40 grains of carbonate of potash to one ounce of water, or by means of an acid ink specially prepared. After using this solution or ink the line put in should be dried by blotting paper, or the lines will spread and become blurred and unsightly. A white line may be taken out by going over with a small camel hair brush dipped in the sensitising solution, exposing to the sun and washing as before. This process is about the oldest extant, and is much in use, and it can be safely claimed for this process that it is the easier to manipulate than any other process, as only two distinct operations are necessary, namely, exposure and development. Cost of Ferro Prussiate outfit, £5 10s. Printing frame glass view 40 by 27, superior water bath 42 by 30 foot, roll of 32 inches, sensitised paper. Cost includes carriage. As supplied by J. Halden and Co., Manchester. Manipulation of B. L. Blue Line process (blue lines on white ground): One chemical bath only required. Exposure is made in exactly the same manner as the Ferro Prussiate, great care being taken to shield the paper from the light before it is in the printing frame, the cutting and framing to be done of course in a subdued light. Sufficiency of exposure is led up to by various changes in the appearance of the sensitised paper. When the lines appear a distinct yellow on gray ground exposure is complete, withdraw from frame, and float on salt developing bath. The time of exposure depends on intensity of light available. In bright sunshine from one to two minutes, in fair weather from three to six minutes, in dull weather from ten to twenty minutes, and even more. Development: It is necessary before taking the print to the bath to turn up the edges all the way round for about half an inch from face to back. This forms a kind of tray, thereby preventing the developing solution from getting on the back, which would disfigure its appearance. The print is then floated on the developing bath, with its face down upon same, and to ensure the whole of the surface being in contact with the solution a dry, soft brush should be applied with slight pressure over the entire back of it, or the print may be drawn and agitated across the surface of the developing solution, the print to be raised from time to time for purposes of examination during the progress of development. The drawing will, in a minute or two, appear in distinct bluish-green lines on a ground of yellowish green. Washing: The photo is now laid face upwards in a trough of clean water, and a brush or soft sponge passed gently over it until the lines stand out well and clear, dark-blue lines on white ground, and every other trace of blue has disappeared. Then leave the photo for about five minutes in the water trough to soak, and renew the water once or twice as may be required, after which it is taken out and hung up over a roller to dry. Care should be taken that no finger marks are made on the photo, and that the surface of the paper is not cracked or broken. Spots and stains can be removed and corrections made in the drawing when necessary by blue solving. Bath consists of equal parts of red and yellow prussiate of potash, 10 P. C. solution dissolved in tepid water. It will be seen that only three distinct operations are necessary by this process, viz.: exposure, development, and washing, and is undoubtedly a great improvement over the other B. L. process, No. 3, enumerated. As for that process five distinct operations are necessary, namely: First exposure in printing frame to light. Second, floating of copy on yellow prussiate solution (development). Third, immersion of copy in first water tray. Fourth, immersion in acidulated bath of either sulphuric or hydrochloric acid (bleaching). Fifth, brushing and flushing in second water tray, and finally drying. It will therefore be seen the B. L. process (one acid bath) has dispensed with a somewhat tedious manipulation that was necessary formerly for the production of a blue line on white ground photo drawing. A recommendable feature of this process over the Ferro Prussiate is that coloring is permissible. Cost of Blue line process outfit £8 8s. to print copies 40 inches by 27 inches, which outfit includes printing frame, glass view 40 inches by 27 inches; lined bath for salts, 42 inches by 30 inches, water bath 42 feet by 30 feet; felt roll of 30 inches. Blue line paper, developing salts ½ pound mixed blue solving. B. W. Black White Process, producing black lines on white ground (one acid bath only required). Manipulation: Exposure as other processes. The point of sufficient exposure is led up to by various changes in the appearance of the sensitised surface. Its color before exposure is yellow. Under exposure the color gradually fades. Exposure is sufficient when the sensitised paper is white under the blank parts of the tracing, and the lines appear yellow on the prepared paper. Development: After taking from the frame, immerse the print in a gutta percha lined bath containing acid and water until the yellow lines become black. The print is then taken out, and immersed and rinsed in a bath of clean water. The print can be gently brushed to get rid of the superficial mucilage, and should be washed copiously with clean water to remove all traces of the chemical solution, or the print may be left to soak in the clean water bath for about ten minutes. If the print be hung up before a thorough washing, the acid on the lines will run and smear the copy. After a thorough washing the print is hung up to dry. Contents of acid bath should be three-quarters of an ounce of acid to one gallon of warm water. The acid is a mixture of gallic and oxalic acids with a little alum. It is essential in this process that the exposure should be well watched, as the paper is very sensitive; a little over exposure results in the lines being taken out, and in other cases left ragged. Under exposure results in a back ground of more or less violet hue or tint. Time necessary for exposure similar to B. L. process. The B. W. process, as compared with most processes, is very modern, being perfected in France about 1880. The simplicity of manipulation necessary, the clearness and utility of its results, and its very moderate cost, have placed this process far in advance of all others. The following advantages can be safely claimed: First, it is the nearest approach that can be got in appearance to an ordinary or original drawing, the only difference being that we should perhaps draw center lines in red and dimension lines in blue. In the photo., of course, these lines would appear black. Second, copies can be colored and treated in every respect like an ordinary drawing. This latter facility can not be over estimated, as for instance, in large drawings on a small scale, the great assemblage and intersection of lines make the drawing to one unaccustomed to dealing with them very intricate, but when colored in the various colors known as different materials, it makes the drawing easier to understand and more explicit throughout. As far as coloring is concerned, this can be done in the B. L. process, but the appearance is not near so good as in the process last described. It may be added that the great value of this process has been recognized, and its adoption accomplished by the leading engineers in Great Britain, Australia, the Continent, and the United States of America. Cost of B. W. outfit, £8 15s. 0d. Printing frame glass view 40 inches by 27 inches, lined bath for acid 42 inches by 30 inches, water bath, felt, roll of B. W. paper 30 inches wide, B. W. acid ½ pound (as supplied by J. Halden and Co., Manchester). Of course the cost of any of the outfits will vary a little, and be subject to fluctuation in cost of material. Hints that should be known: Sensitised papers should be kept in a dry dark place, where the sensitising will remain good for several months. The contents of acid baths will, when kept covered, last for a fortnight's operations. The liquid should be an inch and a half deep in the bath. There should always be a good supply of water, which should be led into the trays or baths by india-rubber tubes, about one inch diameter, the overflow, or emptying pipe, to run into a drain, when the supply pipe can be regulated in accordance with the discharge, thereby enabling fresh water to be constantly running into the washing trays or baths. Copies should be laid to dry across semi-circular rollers, about three inches diameter, in preference to suspending them from horizontal boards by wooden pegs. Copies should not be dried by steaming before a fierce fire. It turns the copies yellowish and renders the paper brittle. Chemical stains can be removed from the hands by a very weak dilution of caustic potash. When a pair of india-rubber gloves or finger stalls are used these stains are avoided. The zinc baths to be occasionally scoured with fine sand, and a weak solution of caustic potash, or soda. The gutta-percha lined trays should never be allowed to remain empty; if not in use they should be filled with water.

A considerable number of questions were asked Mr. House, and were satisfactorily answered. Mr. Mehers proposed a vote of thanks to Mr. House for his valuable paper, which had been an intellectual treat. Mr. Broome, in seconding, said the association was made the more valuable when they had such papers read before it. The paper combined both the theoretical and the practical, and the information contained in it was all the more valuable coming as it did from the head draughtsman of a well known and active firm in Wigan. The motion was heartily passed and acknowledged, and, a similar compliment having been paid to the chairman, the meeting terminated.

Correspondence

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to "E. R. S.," of Winburne, Pa., whose question appeared in the June issue:

In an airway of the following dimensions what quantity of air in cubic feet per minute will be obtained when there is a water-gauge of 1·85 inches; 6′ × 8′ × 1,000′, 9′ × 3½′ × 1,100′, 5′ × 7′ × 1,500′, 3′ × 8′ × 1,550′?

This question may be answered in several different ways of which I submit two.

First, by finding the relative amount of pressure absorbed by each section of the airway and then finding the quantity that the pressures will pass in their several sections.

The relative pressure is found thus:

$$\text{formula}: \frac{s}{a^3} = \text{relative pressure},$$

because $k\,s\,q^2 = p\,a^3$, and as the same quantity must pass through each section, k and q will cancel and we will have

$$\frac{s}{a^3} = \frac{p\,a^3}{a^3} = p.$$

$$\text{First section } \frac{28{,}000}{48^3} = \cdot2532 = \text{relative pressure.}$$

$$\text{Second section } \frac{27{,}500}{31\tfrac{1}{2}^3} = \cdot8830 = \text{relative pressure.}$$

$$\text{Third section } \frac{36{,}000}{35^3} = \cdot8396 = \text{relative pressure.}$$

$$\text{Fourth section } \frac{34{,}100}{24^3} = 2\cdot4667 = \text{relative pressure.}$$

$$4\cdot4425$$

W. G., 1·85 × 5·2 = 9·62 = the sum of the pressures due to each section.

Then

4·4425 : ·2532 :: 9·62 : ·548 true pressure.
4·4425 : ·8830 :: 9·62 : 1·912 true pressure.
4·4425 : ·8396 :: 9·62 : 1·818 true pressure.
4·4425 : 2·4667 :: 9·62 : 5·341 true pressure.
9·619

Then by the formula:

$$a\sqrt{\frac{p\,a}{k\,s}} = q.$$

$$\text{First section } \sqrt{\frac{48 \times \cdot548}{\cdot0217 \times 28{,}000}} \times \overset{a}{48} = \overset{\text{Quantity.}}{9{,}987}$$

$$\text{Second section } \sqrt{\frac{31\tfrac{1}{2} \times 1\cdot912}{\cdot0217 \times 27{,}500}} \times 31\tfrac{1}{2} = 9{,}988$$

$$\text{Third section } \sqrt{\frac{35 \times 1\cdot818}{\cdot0217 \times 36{,}000}} \times 35 = 9{,}989$$

$$\text{Fourth section } \sqrt{\frac{24 \times 5\cdot341}{\cdot0217 \times 34{,}100}} \times 24 = 9{,}984$$

So the quantity passing is nearly 10,000 cubic feet per minute.

Second, in airways passing equal quantities, s will vary as their areas cubed; now let us assume that an airway 20 feet area is to pass the same quantity as the airway given in the question, then s for

				s	s'
First section	= 48³	: 20³	:: 28,000	:	2,025·47
Second section	= 31½³	: 20³	:: 27,500	:	7,038·67
Third section	= 35³	: 20³	:: 36,000	:	6,717·20
Fourth section	= 24³	: 20³	:: 34,100	:	19,733·8
Rubbing surface of assumed airway,					35,515·14

Then

$$\sqrt{\frac{p\,a}{k\,s}} \times a = q = \sqrt{\frac{9\cdot62 \times 20}{\cdot0217 \times 35{,}515\cdot14}} \times 20 =$$

9,992, quantity passing. The slight difference is due to the fractions.

The answer given by "S. U. P.," in your August issue, is too great a quantity as it would require a pressure of more than 16 lbs. to pass 12,962 cubic feet of air per minute in the airway given in the question.

Yours, etc.,
T. S. C.

Gardner, Ill., August 24th.

Certificated Mine Foremen.

Editor Colliery Engineer:

SIR: In the August number of your invaluable mining journal, I find some well considered editorial remarks touching "Certificated Mine Foremen." There is no such thing as perfection, and objections can be raised to the operation and results of Certificated Mine Bosses; but that the advantages greatly outweigh the disadvantages of this system must be admitted by every one desiring to see increased safety in subterranean mining.

At the summer meeting of the Ohio Institute of Mining Engineers, in 1890, and again during the last winter's meeting of the Institute, I called attention to the necessity of such a law for the coal mines of Ohio. To my astonishment, the Chief Inspector of Mines, Mr. Hazeltine, and several of his assistants, set up a vigorous opposition to such a scheme, Mr. Hazeltine asserting as the results of *his* experience that the more illiterate a mine boss was, the better boss he made.

I was glad to see some discussion follow my article in THE COLLIERY ENGINEER on this subject, and hope to see it thoroughly ventilated by some of your able correspondents.

In my opinion, mine bosses and mine inspectors should be required to undergo examination and receive certificates of competency previous to assuming their duties.

I feel proud of the success of my old friend, Mr. Austin King. He is an example of what an intelligent miner can do for himself if given a chance. By the way Mr. Hazeltine quoted Mr. King as opposed to mine inspectors and mine bosses being examined, if Mr. King thinks so now, he has changed his opinion since he left Ohio.

I trust my friend, Mr. Hazeltine, will take no offence in my quoting him in this letter. The question is one of public interest to mining, in which he and I have always agreed, except as to this matter.

Wishing THE COLLIERY ENGINEER increased success.

Fraternally yours,
ANDREW ROY.

Glen Roy, O., August 24th.

Mechanics.

Editor Colliery Engineer:

SIR:—Will some of your readers kindly answer the following question:

On an incline rising 1 in 10, the loads weighing 12,000 pounds, and the empties 3,000 pounds, the drums, ropes, and sheaves 5,000 pounds; the friction of the cars equal 1% of their weight, and the friction for drums, ropes, and sheaves $\frac{1}{10}$ of their weight. When they are being let down by a brake, it takes 4 minutes to run 300′, now what is the amount of friction applied by the brake?

Yours, etc.,
J. T. G.

Braidwood, Ill., August 25th.

Blasting.

Editor Colliery Engineer:

SIR:—I wish some of your correspondents would answer the following question:

There is a blast-hole charged with powder and tamped ready for firing. The needle is withdrawn and from the hole or orifice molded by the needle there issues fire-damp. When this fire-damp or gas is ignited at the mouth of the needle will it explode the powder at the end of the hole? State reasons, whether the answer is in affirmative or negative.

Yours, etc.,
JOHN KANE.

Coal Bluff, Indiana, August 15th.

Pumping.

Editor Colliery Engineer:

SIR:—Permit me to send you a few lines in reply to "Tyro's" article, in your last issue, regarding "Pumping:"

The volume of water discharged by a pump is ascertained by multiplying the cubical contents of the pump by the number of strokes per minute, the cubical contents being the product of the sectional area of the pump and the length of stroke. We have therefore the following formula:

$$\underbrace{D^2 \times \cdot7854}_{\text{Area}} \times S \times N = \text{cubic inches or feet where}$$

all quantities are in inches or in feet. If we wish to obtain gallons discharged the formula becomes

$$\frac{D^2 \times \cdot7854 \times L \times N}{231} = D^2 \times L \times N\ \cdot0034 =$$

gallons.

The example given works out therefore as follows:

8² × 60 inches × 30 × ·0034 = 391·68 gallons per minute, instead of 32·64 as stated.

One of Keuffel & Esser Co.'s (New York) $2.50 pump indicators gives this result at a glance without any computation whatever.

Yours, etc.,
WM. COX.

Bay View Hotel, Tompkinsville,
Staten Island, N. Y., July 21st.

Correction.

Editor Colliery Engineer:

SIR:—In my answer to Mr. Arthur Crossland's question in the August issue, where I said the quantity of air should not be less than 100,000 cubic feet per minute, I should have said 150,000 cubic feet.

Yours, etc.,
JOSEPH CAIN.

Whitwell, Marion Co., Tenn., August 22d.

Examination Question.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to question by J. W. S.:

[The solution sent in is similar to that of "A. B.," which was inserted in the August issue.—ED.]

Yours, etc.,
F. B.

Maccan, N. S., August 2d.

Pumping.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to J. T. Rogers' question in the August issue:

The receiver and 3″ T should be connected by a 4″ pipe instead of a 3″ pipe to give proper results, as to carrying capacity to both slopes at same time, and the 6″ pipe for intermediate, 1,800′ is quite right as it offers less resistance to flow of air. Nothing would be gained by using two 3″ pipes from 6″ pipe to the pump, unless a pipe giving corresponding area is used direct from receiver.

Yours, etc.,
J. EDWARD SLATER.

S. Norwalk, Conn., August 20th.

Examination Question.

Editor Colliery Engineer:

SIR:—I submit the following in answer to question by "J. W. S.," of Westville, Picton Co., N. S., in your July issue:

5·2 ÷ ·0763 (weight of a cubic foot of air at 62° F. and 30″ barometer) = 68·15′, the motive column that will produce 5·2 lbs. pressure; and 68·15 ÷ 400 = ·1703. Then

459° + 40° = 499 × ·1703 = 84·98° + 40° = 124·98° F., the temperature in the upcast.

By the following formula we can prove the work.

$$M = D\,\frac{T - t}{459 + t}$$

M = motive column.
D = depth of shaft.
T = temperature in upcast.
t = temperature in downcast, then

$$\frac{124\cdot98^\circ - 40^\circ}{459^\circ + 40^\circ} = \cdot1703 \times 400 = 68\cdot12 \times \cdot0763 =$$

5·197556 lbs., or 5·2 lbs. nearly.

Yours, etc.,
H. L. D. W.

Lethbridge, N. W. T. Canada, August 1st.

Mechanics and Surveying.

Editor Colliery Engineer:

SIR:—I send the following solutions in reply to Samuel Lewis, of Scranton, Pa., whose questions appeared in the July issue:

(1). What is the reason for reducing the column pipe of an engine? In a given case the diameter of the engine is 10″ and of column pipe 8″. There is a short reducer set in the column near the pump, what is this for, and what is gained by it?

The diameter of the water cylinder equals 10″, and of the column pipe 8″, which under ordinary circumstances may be considered a fairly practical size. The relative capacities or areas are 10″² and 8″², or the mean areas are

pump = 78·54.
pipe = 50·2656.

The area of the piston rod must be deducted from one stroke, or one-half from each stroke. We will assume it to be a 3″ rod, then the area is 7·068″.

78·5 − 3·5 = 75, then under ordinary circumstances a pump may be expected to give about ·85 per cent. of efficiency, which would reduce the relative capacity of the water cylinder to about 63·75, then the area of pipe being 50·25, the flow of the water in the pipe would have a speed of 63·75, while the piston moves 50·25, then the piston must stop at the end of each stroke, so it may be seen that the pump, if not working at full power, can do the work. However, a 9″ pipe would have an area of 63·6, and to obtain the best possible results large pipes are required, for the friction is increased as the square of the speed, and directly as the length of the pipe.

(2). In answer to his second question, I would say that the inner branch of the siphon remains full and the outer branch will be emptied at about half the rate of flow when working, for as the water runs out air will force its way in at the end of discharge, and will occupy about half the area.

Yours, etc.,
F. B.

Maccan, N. S., August 1st.

Ventilation.

Editor Colliery Engineer:

SIR:—I submit the following in answer to S. U. P., of Red Bank, Pa.:

(1). The velocity is found by dividing the volume by the area of the shaft, thus

43,982·4 ÷ 87·9648 = 500′ per minute, the velocity.

(2). The formula used in finding the pressure is

$$P = \frac{K\,S\,V^2}{a}, \text{ substituting their values}$$

we have

$$\frac{\cdot0000000217 \times 24111\cdot552 \times 500^2}{87\cdot9648} = 10\cdot6764 \text{ lbs.}$$

pressure per foot, and 10·6764 ÷ 5·2 = 2·0531 inches W. G.

Yours, etc.,
LEWIS C. HUGHES.

Avoca, Pa., August 20th.

Algebra.

Editor Colliery Engineer:

SIR:—In answer to question by "A. B. C.," of Pittston, Pa., in your August issue, I would say that I find the value of x to be 2, and of y to be 5.

Yours, etc.,
SUBSCRIBER.

Connellsville, Pa., August 19th.

Siphon.

Editor Colliery Engineer :

SIR:—I send the following in reply to "Miner," of Elizabeth, Pa.:

Can a siphon have too much fall for its lift, and why?

I have good reasons to believe that it can, as I had an opportunity to test the matter some time since. A siphon was laid in a mine, the length of the pipe from inlet to summit being 300′; vertical height 12′, and the discharge 35′ below the summit. For an experiment I added enough pipe to the discharge to make it 35′ below the inlet, or 47′ below the summit and found that the siphon would cut off, or stop flowing in three or four hours, while I knew it to run a week or ten days continually before the fall was increased. When the fall was reduced the siphon worked as well as ever.

Now, I may be wrong in my surmise, but the most satisfactory solution I could arrive at for the difficulty was this: In a siphon we have only the atmospheric pressure of 14·7 lbs. per square inch to overcome the friction of the pipe, and to lift the water, or rather force it to the summit. In order to create a vacuum we must have the discharge lower than the inlet. From inlet to summit we have two forces to overcome, *i. e.*, friction and weight, or force of gravity, while in the discharge there is only friction, the force of gravity assisting the flow, the atmospheric pressure being overbalanced before the siphon will flow. Now, as the velocity increases, friction increases also requiring more power, also there are more pounds to be lifted. As the fall is increased we get more weight, or pressure, and this increases the velocity until the friction due to increased velocity will eventually absorb the atmospheric pressure, and the water will run away from the summit faster than it can be forced to summit from inlet.

The above may not be the correct explanation of a fact, but it is a fact that a siphon may have too much fall for its lift, as I have proved by experiment.

Yours, etc.,
S. U. P.

Red Bank, Pa., August 22d.

Ventilation and Mining.

Editor Colliery Engineer:

SIR:—I submit the following in answer to the three questions asked by "A. L. G.," of Audenried, Pa., in your August issue:

(1). In the formula given

A = the major axis, or 16′
a = the minor axis, or 8′

Substituting these values in the given formula, it becomes

$$\frac{\frac{\sqrt{256+64}}{2} + \frac{16+8}{2}}{2} \times 3{\cdot}1416.$$

Collecting we have

256 + 64 = 320 ÷ 2 = 160, and $\sqrt{160}$ = 12·6491 +.
16 + 8 = 24 ÷ 2 = 12, and 12·6491 + 12 = 24·6491, and this divided by 2 = 12·32455 × 3·1416 = 38·71980628′ = perimeter of the ellipse.

(2). In opening out a roadway for a turnout, it would probably be necessary to double the length of the collars. The condition of roof, etc., being the same, the new collar would have to support twice the weight. In the "Colliery Engineer Pocket-Book," page 22, I find this example: If a collar 6 feet long, 8″ diameter, supports a certain weight, what must be the diameter of a collar 12′ long to support the same weight? The answer given is

$\sqrt[3]{6} : \sqrt[3]{12} :: 8'' : x$, or 10″ +.

That question calls for the support of the same weight, but we have to provide for double the weight, consequently

6 : 12 :: 10³ : 2000, and $\sqrt[3]{2000}$ = 12·6″ diameter of collar to support twice the weight.

(3.) Pressure varies as the square of the velocity, therefore a velocity of 1 in the 9′ × 9′ airway means a velocity of 1·125 in the 12′ × 6′ airway. Then

1² : 1·125² :: 10 : x, or 12·65625 = new pressure.

Yours, etc.,
J. V.

Punxsutawney, Pa., August 24th.

[Answers to the above questions similar as regards the principles used were received from J. T. G., of Braidwood, Ill., August 25th, and David P. Brown, of Adelaide, Pa., August 27th.—ED.]

Ventilation and Mining.

Editor Colliery Engineer :

SIR:—Please insert the following in answer to "A. L. G.," of Audenried, Pa.:

(1). In the formula let A = 14, and a = 8, then it becomes

$$\frac{\sqrt{\frac{14^2+8^2}{2}} + \frac{14+8}{2}}{2} \times 3{\cdot}1416 = 35{\cdot}185 +, \text{ perimeter.}$$

(2). We will assume the collars to be 7′ between the notches, and 10″ in diameter, then for the double track or turnout they would be 14′ between the notches. The diameter required for the collars over the double track under similar conditions would be found thus

$$\frac{2 \times 10^3}{1} = 2{,}000, \text{ and}$$

$\sqrt[3]{2{,}000}$ = 12·5″ the diameter, if the weight were the same; but where the width of the place is doubled, if the top follows the same law, the weight will also be doubled. This would cause the roof to weaken and the average weight upon the timber to increase as the width, the same as the resistance of the timber decreases. Therefore we would conclude that a 14′ collar would have to support double the weight of a 7′ collar, because the space was doubled. By this assumption the 14′ collar would have to be 4 times as strong; twice as strong for the double length, and twice more for the double weight. If the 7′ collar is 10″ in diameter then the 14′ collar should be

1 : 4 :: 10³ : 4,000 ; $\sqrt[3]{4{,}000}$ = 15·8″,

or nearly 16″ in diameter.

(3). According to the conditions of the question $q = q$, that is $a\,v = a\,v$, or

$$a\sqrt{\frac{P\,a}{K\,s}} = a\sqrt{\frac{P\,a}{K\,s}} \text{ and as } s = s, \text{ we have}$$

$a\sqrt{P\,a} = a\sqrt{P\,a}$, or squaring both sides of the equation $P\,a^3 = P\,a^3$, whence

$$P = \frac{P\,a^3}{a^3},$$

substituting the given values we have

$$P = \frac{10 \times 81^3}{72^3} = 14{\cdot}22 \text{ lbs.},$$

therefore the pressure required is 14·22 lbs. per sq. ft.

Yours, etc.,
P.

Whitney, Pa., Aug. 29th.

Ventilation.

Editor Colliery Engineer :

SIR:—Please publish the two following questions in your next issue:

(1). An airway 8′ × 8′ × 1000′ is passing 40,000 cu. ft., of air, what diameter should a circular airway 1200′ long be to pass one-half the quantity, the pressure remaining the same?

(2). A mine is ventilated by natural ventilation passing 10,000 cubic feet of air per minute with a pressure of 5·5 pounds, the temperature in the downcast being 42°. The air current is reversed by erecting a furnace at bottom of the downcast producing 14,000 cubic feet of air per minute, what is the effect on the pressure and temperature?

Yours, etc.,
A. B.

Hanna City, Ill., August 22d.

Ventilation.

Editor Colliery Engineer :

SIR:—Please insert the following in answer to "S. U. P.," of Red Bank, Pa.:

(1). The velocity is found by dividing the quantity of air passing by the area, thus

43982·4 ÷ 95·0334 = 462·80091′ the velocity.

(2). The pressure is found by the formula

$P = \frac{K\,S\,V^2}{a}$, substituting their values and multiplying we have

96·37399 ÷ 95·0334 = 1·014106 lbs., pressure, and 1·014106 ÷ 5·2 = 0·19502 = water gauge.

Yours, etc.,
I. E. J.

Moosic, Pa., August 27th.

Efficiency of Fans.

Editor Colliery Engineer :

SIR:—A fan 16′ in diameter, which is making 130 revolutions per minute, gives a water-gauge of 3·2″, what is the fan's efficiency?

Yours, etc.,
M.

Braidwood, Ill., August 27th.

Ventilation.

Editor Colliery Engineer :

SIR:—I submit the following in reply to "S. U. P.," of Red Bank, Pa.

(1). Let
a = semi-major axis.
b = semi-minor axis.
π = 3·1416.
Then

$\pi \times a \times b$ = 87·9648 area, and
43982·4 ÷ 87·9648 = 500′ velocity.

(2). We can find the perimeter by the formula

$$\frac{\frac{\sqrt{14^2+8^2}}{2} + \frac{14+8}{2}}{2} \times 3{\cdot}1416, \text{ which is } 35{\cdot}29$$

nearly, then

35·29 × 600 = 21,674, or s.

And by the formula

$\frac{K\,S\,V^2}{a}$ = w. g. = ·257055″ +, or 1·33669 lbs.

Yours, etc.,
J. V.

Punxsutawney, Pa., August 24th.

Examination Questions.

Editor Colliery Engineer :

SIR:—Will you kindly publish the following questions for answer in your valuable journal:

(1). Suppose we increase the wires of the gauze of a safety-lamp three times their usual thickness, what effect, if any, would it have on the safety of a Davy lamp?

What kind of oil would you prefer to use in safety-lamps, and state the reasons why?

(2). How would you proceed to develop a field of coal 1,000 acres in extent lying 500′ below the surface, the coal-bed being 4′ thick with an inclination of 1 in 300 west to east. The output to equal 1,200 tons per day. Give a description of all necessary appliances required, also the number of men necessary to produce this output continually. Assuming 250 gallons of water to accumulate per minute, what size of pump would be required to keep it emptied out?

(3). Is there any safe practical method of detecting explosive gas in mines other than by the use of the safety-lamp? Explain fully.

(4). A furnace at the bottom of a shaft 400′ deep produces 15,000 cu. ft. of air per minute with 5·2 lbs. pressure per sq. ft. The temperature in the downcast shaft is 40° F., what is the temperature in the upcast shaft, which is 450′ deep.

Yours, etc.,
M.

Mansfield, Pa., August 28th.

Mining.

Editor Colliery Engineer:

SIR:—Will any of your readers kindly give plan and directions how to erect a door in a 4½′ vein to be opened by mules traveling both ways.?

Yours, etc.,
SUBSCRIBER.

Lehigh, Ind. Ty., August 28th.

Ventilation.

Editor Colliery Engineer :

SIR:—Will you please insert the following questions in your next issue for some of your able correspondents to answer:

A mine (drift opening) is ventilated by furnace. The outside temperature is 41° F., and the upcast shaft, which is 100′ in depth, has a temperature of 191° F., the dimensions of the underground airway are 7′ × 9′ × 4,000′.

(1). Using Atkinson's co-efficient of friction what will be the volume of air obtained under the above conditions?

(2). What will be the length of the motive column; (show method and formula by which length is ascertained)?

(3). What horse power will be expended by the furnace in producing this volume of air?

(4). Suppose the length of the airway is increased to 9,000′, what would be the quantity obtained, the area and pressure remaining the same?

(5). What will be the horse power expended, when the length is increased? Explain cause of difference in horse power, if any?

Yours, etc.,
S. U. P.

Red Bank, Pa., August 22d.

Ventilation.

Editor Colliery Engineer :

SIR:—I send the following in answer to question (1) submitted by "A. L. G.," of Audenried, Pa., in your last issue:

The formula referred to is simply this: To half the sum of the two diameters add the square root of half the sum of their squares, multiplying the last sum by 1·5708, which is half of 3·1416; the product will be the perimeter.

For example, suppose an elliptical shaft, the diameters of which are 8′ and 14′ respectively, then

8 + 14 ÷ 2 = 11, or half the sum of the two diameters. And

8² + 14² ÷ 2 = 130, half the square of the two diameters, then

$\sqrt{130}$ = 11·4 + the square root of half the sum. Whence

11 + 11·4 × 1·5708 = 35·18592′ the perimeter required.

Another formula is to multiply the sum of the two diameters by 1·5708, and the product will be the perimeter nearly, thus

8 + 14 × 1·5708 = 34·5576′, perimeter.

Yours, etc.,
Avoca, Pa., Aug., 20th. LEWIS P. HUGHES.

Measuration and Mining.

Editor Colliery Engineer :

SIR:—I submit the following in answer to questions 1, 3, and 4, asked by "Miner," of Philipsburg, Pa., in your August issue:

(1). The inside measurements of a pit car are length, 6′ 6″; depth, 2′ 6″; the bottom section 1′ in height, and 3′ 2″ in width; the top measurement of upper section is 4′ in width, how many bushels of coal will it contain, computing 2,688 cubic inches to the bushel?

First, we will find the cubical contents of the bottom section of the car, reducing the measurements in feet to inches, we have

Length = 78″; width = 38″, and depth 12″ then,
78″ × 38″ × 12″ = 35,568 cu. ins,

and for top section

Width = 48″; bottom width 38″, and depth = 18″, or 30″ — 12″ = 18″. The average width of top section is found thus

48″ + 38″ ÷ 2 = 43″, then
43″ × 78″ × 18″ = 60,372 cu. inches.

Adding this to cubical contents of bottom section we have

35,568 + 60,372 = 95,940 cu. ins., and
95,940 ÷ 2,688 = 35·7 bushels nearly.

(3). In a mine generating a large amount of fire-damp, where the coal vein dips 10′ in every 100′, what ventilating apparatus would be best, and where would you erect the same?

I would select a Guibal fan; split the current so as to ventilate each district from the downcast, having the foul air pass direct to the upcast. I would, if possible, place the fan so as to have the outlet on a rise from the downcast, by doing so the gas would be more easily removed if the ventilation is ascensional than when the current is forced down the dip. The gas being lighter than air, will rise, and the air inside being lighter than on the outside especially in Winter, it would be more easily directed to the rise than to the dip. As to whether the fan should be a blower or an exhaust, I would be guided by circumstances and in any case make it reversible so that in case of fire in either shaft the fan can be reversed, and the smoke drawn out until the men can be gotten out safely. Another advantage to be gained would be in case the fan exhausts it could be reversed at night to clear the downcast of ice in the winter time.

(4). If a mine generated 200 cubic feet of fire-damp per minute, and 1,000 cubic feet of black-damp, there being 120 persons employed, how much air would be required to keep the workings in a healthy condition?

Two hundred cubic feet of fire-damp per minute may be diluted and rendered harmless by having say, 4,000 cubic ft. of air in circulation, this would be in a proportion of 1 in 20, as the mine gives off 1,000 cu. ft. of black-damp per minute, and a mixture of 7% of black-damp will render fire-damp non-explosive. The 200 cu. ft. given off in this case is not explosive as 1,000 cu. ft. of black-damp would "damp" 14,285 cu. ft. of gas, but since a mixture of 8% of black-damp is dangerous to breathe, and 10% will extinguish lights, it will require a volume of 10,000 cu. ft. of air to bring the mixture to the point where a light will be extinguished, and 12,500 cu. ft. to make the mixture 8% damp, then in order to make the air safe it would require at least 50,000 cu. ft. of air and then there would be 2% of damp.

According to law 120 men would require 12,000 cu. ft. of air, and, say, 8 mules allowing 500 cu. ft. for each mule, which would make

$8 \times 500 = 4{,}000$ cu. ft., or 16,000 cu. ft. in all if only a normal amount of gas was given off, but in this case it will be necessary to have at least 50,000 cu. ft.

Yours, etc.,
S. U. P.

Red Bank, Pa., Aug. 22d.

Ventilation.

Editor Colliery Engineer:

SIR:—I submit the following in answer to question by S. M. Roberts, in your August issue:

The length of the box is 841·868′ +, and is found as follows:

Since the area and rubbing surface are given, we must find the perimeter and divide the rubbing surface by it, the quotient will be the length, thus—

$\sqrt{28{\cdot}5714} = 5{\cdot}34525' =$ one side of the box; $5{\cdot}34525 \times 4 = 21{\cdot}381 =$ perimeter, then $18000 \div 21{\cdot}381 = 841{\cdot}868'$.

I have worked this out as a separate airway.

Yours, etc.,
L. P. H.

Avoca, Pa., August 27th.

A Well Managed Mine.

A friend who recently visited Blue Creek Mines Slope No. 5, of the DeBardeleben Coal and Iron Company, at Adger, Ala., sends us the following:

The work of sinking Slope No. 5 was started four years ago under the superintendence of Mr. L. W. Johns, the present superintendent. In June, of this year, the mine was the largest producer in Alabama, having shipped 19,567 tons in 21½ days. The slope is 1,000 ft. long, with an average dip of 14°, to the basin, which at this point is 100 ft. wide. When the slope had reached the basin, Mr. Johns employed Mr. James Hillhouse Sr. as inside superintendent, and in doing so he secured a most competent official.

Mr. Hillhouse started six headings, two six hundred feet from the top of the mine, one east, and one west, and 4 in the basin, 2 east and 2 west, each of which are now over 4,000 ft. long. A slope was driven up the pitch on the other side of the basin 1,500 ft. Four headings were started from this slope, at distances of 300 ft. and 600 ft. from the bottom. The coal from these headings is run down to the foot of the main slope by gravity, the loaded cars hoisting the empties. Owing to the basin widening and dipping to the west, Mr. Hillhouse has driven a slope down the center of it, and the coal from it is hoisted by a pair of engines and landed at the bottom of the main slope. Every thing is so well planned and conducted that things run "like clock work."

The ventilation is effected by two 15 ft. fans and is excellent, the mine being probably one of the best ventilated in the State, and Mr. Hillhouse deserves credit for and is justly proud of this fact.

Mr. James Hillhouse, Jr. son of the Inside Superintendent, who has just completed a course of mining engineering at the State University, is employed as Mine Boss and Assistant Engineer, and as he has worked in all capacities from a slate picker in Pennsylvania up to his present position, he has before him a bright future and will probably become one of the leading colliery officials of the State.

A United States Association of Government Geologists to be Formed.

A meeting was held at the Colombian University, Washington, D. C., on the 28th ult., which promises to result in the formation of an association for the advancement of geological work, and especially of official geological work. This is an official organization of the directors of the State and National Geological Surveys.

There were present at this meeting Maj. J. W. Powell, director of the United States Geological Survey; Prof. James Hall, State Geologist of New York; Prof. J. M. Safford, State Geologist of Tennessee; Prof. J. W. Spencer, State Geologist of Georgia; Prof. E. A. Smith, State Geologist of Alabama; Prof. J. A. Holmes, State Geologist of North Carolina; Mr. Arthur Winslow, State Geologist of Missouri; Mr. E. T. Dumble, State Geologist of Texas; Prof. J. Lindahl, State Geologist of Illinois. Maj. Powell was elected chairman of the meeting. Mr. Winslow was elected secretary. After a few preliminary remarks in explanation of the reasons for calling the meeting, Mr. Winslow read a paper suggesting a plan of organization and explaining the objects of and the results to be derived from such an official association. As prominent among the important objects of the Association the following may be cited:

1. The determination of the proper objects of public geologic work.
2. The improvement of methods.
3. The unification of methods.
4. The establishment of the proper relative spheres and functions of national and state surveys.
5. Co-operation in works of common interest and the prevention of duplication of work.
6. The elevation of the standard of public geologic work and the sustenance of an appreciation of its value.
7. The inauguration of surveys by States not having such at present to co-operate with the other state surveys and with the national survey.

As an immediate result of this meeting a committee of six was elected to consider the matter of organization, with the power to frame a constitution and by-laws, to be reported to the association at a time and place to be selected by the committee. This committee consists of Maj. J. W. Powell, Director of the United States Geological Survey, Chairman; Prof. E. A. Smith, State Geologist of Alabama; Prof. J. A. Holmes, State Geologist of North Carolina; Dr. J. C. Branner, State Geologist of Arkansas; Mr. Arthur Winslow, State Geologist of Missouri, and Prof. W. H. Winchell, State Geologist of Minnesota.

It is a matter of sincere congratulation that the Association, whose organization has been an oft-mooted question, is now in a fair condition to become an established fact; that it will serve as an invaluable agent in securing harmony and efficiency in the important public work will be readily appreciated.

Mining Classes.

An evening class, which has for its object the training of candidates for the next competitive examination for Mine Foremen's Certificates, under the new Anthracite Mine Law of Pennsylvania, is commencing in Wilkes-Barre, Pa., under the supervision of Mr. Alexander Dick, M. E., English Government Certificated Colliery Manager. Mr. Dick has conducted similar classes with success in Great Britain, and he expresses his determination to use all efforts in obtaining a good percentage of successful students at the forthcoming examination. The great benefits to be derived from such a class have never before been offered to the miners of this district, and as it is to be hoped that the opportunity may be embraced right now we strongly advise all whose ambitions rise above a "breast of work" in the mine to place themselves in immediate communication with him.

As will be seen by our advertising columns, Mr. Dick is also starting correspondence classes, a method of teaching which has been adopted in England and Scotland with great success. As we understand the *modus operandi*, any pupil can by means of these classes be placed in direct contact with the teacher, no matter how far away he may be residing, and now that the States of Alabama and Illinois have followed the lead of Pennsylvania in making competitive examinations compulsory, such a class is sure to prove of immense advantage to mining students, as we have no doubt the other mining states will, in course of time, follow suit.

Low Rate Harvest Excursions.

The Missouri Pacific Railway and Iron Mountain Route will run a series of low rate Harvest Excursions to Southwest Missouri, Kansas, Arkansas, Texas, and all points West and Southwest, August 25th, September 15th and 29th. Tickets good for thirty days to return with stopover privileges for the inspection of land. Further information furnished by any of the company's agents or H. C. Townsend, General Passenger and Ticket Agent, St. Louis, Mo.

Messrs. Crawford and McCrimmon, of Brazil, Indiana, report that their mine fans are meeting with great success wherever introduced. They are so constructed that they can be readily changed from the exhaust to forcing fans or *vice versa*. They are now in use in every important American coal field, and are giving great satisfaction. Besides the construction of improved fans and fan engines, Messrs. Crawford and McCrimmon manufacture general mine machinery. Their Deluge mine pumps, hoisting and haulage engines, and stationary engines for all purposes are built on correct principles from best materials and the strongest proof of their excellence lies in the fact that whenever the purchaser of a Crawford and McCrimmon fan, engine, or pump, found it necessary to enlarge his plant, he invariably patronized the firm. Their prices are reasonable, and they will cheerfully furnish estimates on all kinds of mining machinery.

During a recent visit to the Clearfield region, we particularly noticed the large number of Beagle Mine Hames in use at the collieries, and as the general agent for the hames carries an advertisement with us, we asked several prominent colliery officials how they liked them. The answer was invariably "first rate. They are the best hames we have ever had." We therefore advise our readers to write for prices and information to George Wise, General Agent, Jeddo, Pa.

Water Supply for Collieries and Coke Plants.

The development of the various coal fields always has more or less effect on the sources from which the water supply is drawn, and unless the fountain-head is outside of the coal measures, the extensive underground workings tap and drain the springs. After the water once enters the mine and flows along in contact with the minerals, it takes up foreign substances both by dissolving them, and by being fed by small streams or droppers strongly impregnated with them. This renders the mine water unfit for use in boilers, or in fact for any other use where it comes in contact with iron. It not only eats out the pipe, but it soon destroys the machinery with which it comes in contact.

Therefore the water supply for steam raising purposes must, if possible, be obtained from points far enough removed from the center of mining operations to ensure a constant and ample supply. If possible, the water necessary for other purposes, such as washing coal, and cooling coke, should also be drawn from sources uncontaminated by mineral acids. This is necessary to ensure long life to the pipe lines, and to valves both of which are as a rule expensive.

The expense of bringing a sufficient water supply to the point of utilization is in many instances much more expensive than it would be if the colliery owners and superintendents would, instead of using metal pipes, use first-class guaranteed wooden water-pipes.

Although wooden water-pipes are of earliest origin, their advantages and usefulness for this purpose have only recently been appreciated by colliery officials. They are now largely used in the Anthracite regions, where, owing to large steam plants, a great deal of water is daily converted into steam. They have been found to last longer than iron pipe, are easier laid, as they are more flexible, and cost much less. The trench does not have to be dug with so smooth a bottom and irregularity in alignment does not effect the joints.

In a recent conversation with Mr. Frank T. Wyckoff, of the Wyckoff Pipe Co., of Williamsport Pa., he informed us that his company turned their pipes directly from the log, and made a specialty of extra strong pipe which they guaranteed. Their pipe is made extra thick and the demand for it for all purposes, where the water head does not exceed two or three hundred feet is enormous. Their total sales from January 1, 1891, to date have been over half a million feet, and of this amount, over 50,000 ft., or about ten miles, have been for colliery use.

When once used the merit of the pipe manufactured by the Wyckoff Pipe Co. becomes so firmly established that subsequent orders always follow, and we advise our readers to look into and test it in a practical way. Inquiries addressed to the company at Williamsport, Pa., will always receive careful and courteous attention.

Merit Appreciated.

The new type heavy hoisting engine which the Lidgerwood Manufacturing Company, lately placed upon the market, has received a flattering reception. Thirteen of them have already been sold in less than a year. The following endorsement from the president of the Vermont Marble Co., Proctor, Vt., Fletcher D. Proctor, son of the present Secretary of War, is notable:

July 31st, 1891.

LIDGERWOOD MANUFACTURING CO.,
New York, N. Y.

Gentlemen:—The two drum hoisting engine which you sent us last spring, is a success, and we do not hesitate to recommend it for what you claim for it. It runs two derricks with one engine, hoisting twenty ton blocks, without any trouble, 152 feet in a minute and a half. This with a steam pressure of about 60 pounds, 300 feet away from the engine, and I am satisfied that with a stronger pressure it would hoist this weight in from a minute to a minute and a quarter. The workmanship of the engine and power is perfect, and we can heartily recommend it.

Very truly yours,
(Signed) VERMONT MARBLE CO.
Fletcher D. Proctor, Pres.

Firemen's Tournament at Atlantic City, N. J.—Half Rates via Pennsylvania Railroad.

The Firemen's Tournament to be held at Atlantic City on September 29th, 30th, October 1st and 2d, promises to be one of the most interesting events of its kind ever held in this country. Invitations have been sent to all the prominent fire companies of the East to be present and enter the lists, and the number of entries already registered assures a brilliant success. The programme of events is a most elaborate one and includes everything that pertains to the firemen's art. Hose races, team races, steamer trials, prize drills, and other firemen contests, together with concerts, torch-light procession, and a grand parade. Beside this, the arrangements for the entertainment of the visitors are very elaborate.

For the better accommodation of visitors and contestants the Pennsylvania Railroad Company will sell excursion tickets to Atlantic City from all principal stations on its system at a single fare for the round trip. The tickets will be sold September 25th to October 2d, valid for return until October 6th, 1891. The facilities presented by the Pennsylvania Railroad for reaching Atlantic City quickly and comfortably are too well known to need comment.

THE Jeffrey Mfg. Co., of Columbus, Ohio, have in the hands of the printers, a revised Illustrated Catalogue and Price-List, showing all the chain links and specialties manufactured by them. A wrought chain is one of the latest additions to their already large list of chains. This Company has the largest line of chain links, from which to select, of any manufacturer in the world, and their list should be consulted by dealers and users of such machinery in general.

The Colliery Engineer.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed
THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Scranton, Pa.

Cable Address—"Retsof, Scranton."

THE FIRE-BOSSES MUST HAVE THE SAME CERTIFICATES AS MINE FOREMEN.

ON the 24th ult., Hon. Fred. W. Gunster, Assistant Law Judge of Lackawanna County, handed down an opinion in the case, which Inspector of Mines Patrick Blewitt, and Mr. William Connell, Chairman of the late Commission to revise the Anthracite Mine Law, had submitted to secure a legal interpretation of the provisions of the new Anthracite Mine Act in regard to the qualifications of persons who perform the duties of fire-boss. Judge Gunster decides that they must have certificates of qualification the same as the mine foremen. The opinion in full is as follows:

The defendants are the owners of a coal mine in this district over which the plaintiff is Mine Inspector. They have a mine foreman and also a qualified fire-boss. At times when the mine foreman cannot personally carry out the provisions of the act of assembly entitled "An Act to provide for the health and safety of persons employed in and about the Anthracite coal mines of Pennsylvania and for the protection and preservation of the property connected therewith." Approved June 2d, 1891. They require the fire-boss to perform the duties prescribed by Rule 5, of article XII of said Act. The question presented for consideration is whether these duties may be performed by a fire-boss, who has qualified as such by filing a certificate of experience as requested by Section 9 of Article VIII, but who is not registered as a holder of a certificate of qualification as mine foreman or assistant mine foreman prescribed by Section 4 of Article VIII of said Act. Rule 5 referred to is as follows:

"In mines generating explosive gases, the mine foreman or his assistant shall make a careful examination every morning of all working places and traveling roads, and all other places which might endanger the safety of the workmen, before the workmen shall enter the mine, and such examination shall be made with a safety-lamp within three (3) hours at most, before time for commencing work, and a workman shall not enter the mine or his working place until the said mine or part thereof, and working place are reported to be safe. Every report shall be recorded without delay in a book which shall be kept at the colliery for the purpose and shall be signed by the person making the examination."

These duties are among the most important if not the most important to be performed in the Anthracite coal mines. They call for a high order of intelligence and skill and it is only necessary to mention them to realize the importance of ascertaining by whom they may be performed.

The practical difficulty in answering the question lies in determining who are intended in the term "mine foreman or his assistant" used in the rule. It is contended on the part of the defendant that a fire-boss who has filed a proper certificate of experience is not prohibited from acting as mine foreman or assistant mine foreman, and that even if he is prohibited from so doing, the mine foreman, whenever he cannot personally carry out the provisions of the Act of the Assembly, may be authorized by the owner of the mine to employ competent persons to act as his assistants, and that if he employs the fire-boss as assistant he is such an assistant as is contemplated by Rule 5. There are isolated portions of the Act which seem to give color to this contention, but we do not think it can be sustained. The faults chiefly relied on by the defendants are Sections 1 and 9, Article 8, and Rule 2, Article 12. They are as follows:

Section 1. Article 8—"It shall not be lawful, neither shall it be permitted for any person or persons to act as mine foreman or assistant mine foreman of any coal mines or colliery unless they are registered as a holder of a certificate of qualification or service under this act."

Section 9. Article 8—"And no person shall be permitted to act as fire-boss in any coal mine or colliery, except he has had five years practical experience in mines as a miner, three of which he shall have as a miner wherein noxious and explosive gases are evolved, and the said fire-boss shall certify to the same before entering upon his duties before an Alderman, Justice of the Peace or other person authorized to administer oaths, and a copy of said deposition shall be filed with the District Inspector of Mines wherein said person is employed."

Rule 2. Article 12—"Whenever a mine foreman can not personally carry out the provisions of this Act so far as they pertain to him, the owner, operator, or superintendent shall authorize him to employ a sufficient number of competent persons to act as his assistants who shall be subject to his order."

The words, "or service under this act," contained in Section 1 certainly tend to confuse, but we do not see how they can be construed as applicable to a fire-boss. If they can, then a fire-boss can act as mine foreman without further qualifications. Strictly speaking there is no such thing as a certificate of service recognized by this act though the certificate of practical experience which a fire-boss is required to file, is something similar to it. But fire bosses are not registered and their certificates are not recorded, while mine foremen and assistant mine foremen are registered and their certificates recorded in the office of the Secretary of Internal Affairs. The words were evidently inadvertently copied by the scrivenor from the Act of 1885, in which they are used in connection with mine foremen, who were granted certificates of service in case they had acted at any mine as mine foreman under said act for at least one year prior to July 1, 1886, Act June 30, 1885, Article 8, Section 4.

This is the more apparent from the fact that the position and qualifications of a fire boss do not appear to be mentioned in the Act of 1885, while under its provisions there were certificates of qualification and certificates of service for mine foremen. But what seems to me as conclusive upon the question before me is the fact that an assistant mine foreman is put upon the same basis as a mine foreman by the act of 1891. He must pass the same examination, give satisfactory evidence of the same amount of practical experience as a miner and of good conduct, capability and sobriety and be registered as a holder of a certificate of qualification. Unless he complies with these requirements the command is absolute that it shall not be lawful, neither shall he be permitted to act as assistant mine foreman. This was not so under the act of 1885. Neither the position of assistant mine foreman, the qualifications for it nor its duties are mentioned in it. It is true that Rule 2 of the act of 1885, authorizing the mine foreman to appoint assistants in certain cases is identical in language with Rule 2 of the act of 1891, but the act of 1891 has in it a new element and must be construed with that element in it, and in the light of antecedent legislation and experience. The command that no person shall be permitted to act as assistant mine foreman unless he is registered, and a holder of a certificate of qualification, is without qualification. It was put into the act for a purpose, and that purpose obviously was to secure greater safety to health and life and property. It would be of no avail if the mine foreman whenever he cannot personally attend to his duties, could appoint anyone whom he thought competent, to assist him whether such assistant was qualified or registered, or not.

We are of the opinion that the fire-boss or person who performs the duties prescribed by Rule 5, Article 12, of the Act of June 2, 1891, is required to be registered, and the holder of a certificate of qualification prescribed by Section 4, Article 8, of said act, and in accordance with the terms of the case stated, direct judgment to be entered in favor of the plaintiff for the sum of six cents and costs.

This opinion is a clear explanation of the provisions of the Act and if appealed from will not be reversed. What was intended by the framers of the law was a certificate of qualification for mine foremen and assistant mine foremen secured by passing an examination and a certificate of experience for fire-bosses, but the Committee failed to change Rule 5 of Article XII which provides that the examinations for gas must be made by the mine foremen or their assistants. The new law provides for fire-bosses who must file a certificate of experience before they can serve, but it says that the duties of the fire-bosses shall be performed by the foremen or assistant foremen who must have certificates of qualification secured by passing an examination. Judge Gunster decides that the fire-bosses cannot make the examinations for gas because in doing so they are performing the duties of the assistant foremen which must be performed by persons holding certificates of qualification. It was not the intention of the Committee that the law should have this effect, but through the failure to change Rule 5 of Article XII so as to permit the fire-bosses to make the examinations for gas the law has this effect and since it cannot be altered it must be obeyed.

To avoid, if possible, the necessity of requiring the fire-bosses to stand the same examination as the mine foremen, a consultation was had, we understand, by a committee with the representative of the Attorney-General, and as the result of that conference at a joint meeting of members of the different Examining Boards of the Anthracite districts held at Hazelton, June 29th, the following resolutions were adopted:

"*Whereas*, It is the opinion of the Attorney-General of the Commonwealth of Pennsylvania 'That the persons now holding Certificates of Service or Qualification as Mine Foremen under the Act of June 30, 1885, must qualify under the Act of June 2d, 1891.

"*Resolved*, That all persons now holding Certificates of Qualification or of Service under the Act of June 30, 1885, shall be entitled to receive Certificates of Qualification under the Act of June 2, 1891, provided the Board of Examiners are satisfied that applicant are competent.

"*Resolved*, That all persons now holding the position of Assistant Mine Foreman or Fire-Boss, or who desire to fill the said position, shall, upon presenting an affidavit certifying that he has had five years practical experience as a miner, three of which as a miner in a gaseous mine, be entitled to have a Certificate of Qualification as Assistant Mine Foreman.

"*Resolved*, That the Examination of Applicants for Certificates shall be held Monday and Tuesday July 6th and 7th, 1891."

We understand the Examining Boards with the exception of that of the former First District (Inspector Blewitt's) have acted in accordance with these resolutions and that certificates of qualification as assistant mine foremen have been recommended for persons who have filed an affidavit certifying that they have had the necessary experience. In Inspector Williams' District 179 persons were recommended for certificates as assistant mine foremen, the blanks for that purpose having been furnished by the Secretary of Internal Affairs. In Inspector Blewitt's District applicants for assistant mine foremen's certificates were examined on the same questions as were asked the candidates for mine foremen's certificates, but they were not required to make as many points to pass the examination. Eight of the applicants will be recommended for assistant mine foremen's certificates. In the light of Judge Gunster's decision, however, neither of these courses is legal. The Judge holds that the act does not contemplate two classes of certificates and that the fire-bosses and assistant foremen must have the same certificates as the mine foremen.

There are over five hundred fire-bosses in the Anthracite collieries, very few of whom have certificates of qualification and all who have not are illegally filling their positions. There are probably five hundred persons who have certificates of qualification obtained by passing the examinations since the Act of 1885 went into effect, who are not now filling positions either as bosses or fire-bosses. It is a question, however, if all the fire-bosses who are illegally performing their duties were removed whether it would be possible to fill their places with competent persons legally qualified. A fire-boss to efficiently perform his duties must possess good sight and hearing, be a close observer, have good judgment and have had experience in making examinations, and he must also have a thorough knowledge of the workings, methods of ventilation, etc., of the colliery in which he is employed. This information cannot be picked up in a day and these qualities are not possessed by all, and in consequence many operators and superintendents will be loath to discharge their fire-bosses and to fill their places with inexperienced men, notwithstanding the latter may have certificates and are qualified legally to fill the positions. How this difficulty is to be gotten over it is not easy to see. It will not be safe to discharge the fire-bosses and fill their places with men who are strangers to the workings. The best plan will be to give the fire-bosses an opportunity to obtain certificates.

The assistant bosses and fire-bosses should have all the knowledge of the art of mining and the sciences related to it that is required of persons who pass our present examinations for mine foremen. A number of the most destructive accidents that have occurred can be traced directly to the incompetency or carelessness of fire-bosses. It is a fact that there are more persons killed in proportion to the number of tons of coal produced and the number of employes in the Anthracite mines of Pennsylvania than in any other coal district in the world. Some of the conditions attending mining here make the occupation more dangerous than elsewhere, such as the large amount of powder used in getting the coal and the greater thickness of the seams, but there are also conditions which are more favorable here than in other mining districts. There has never been a great explosion in which the whole mine was involved and a great many lives lost for the reason probably that our dusts are not as explosive as Bituminous dusts are. To reduce the number of accidents in Anthracite collieries better education as to the phenomena attending the occupation among both mine officers and miners and stricter discipline is needed and any legal requirements which will increase the knowledge of the fire bosses will be beneficial in the end, although it may cause some inconvenience now.

Any person can pass an examination if he will try. The next examination may not be held until next June and by that time if the fire-bosses will apply themselves they can qualify to obtain certificates. When the fact is taken into consideration that the law has been passed with provisions (not intended by the Committee or the Legislature) we think no one will object to giving the fire-bosses an opportunity to qualify for their positions. If they cannot qualify after having had an opportunity to prepare for the examination then they will have to be removed, and amongst those who have certificates of qualification now a sufficient number can be found competent and willing to fill the places that will thus become vacant.

The standard of the examinations should not be lowered, however, to enable the fire bosses to pass. The main thing to find out in a candidate who presents himself for examination is, does he understand the principles involved. It is not so important that he be a good penman or an expert figurer if he has the intelligence to understand the principles which underlie the phenomena which he encounters, but that he has this knowledge should be insisted upon and no person should be given a certificate who does not possess it. We think any intelligent miner or fire-boss who will apply himself during the next nine months can learn everything that it is necessary for him to know to pass an examination to obtain a certificate of qualification and the standard of the examination need not be lowered to enable him to do this.

COAL AND IRON AT THE CHICAGO EXPOSITION.

ONE of the largest and most interesting departments of the World's Columbian Exposition, will be that of Mines and Mining. Here will be grouped in an artistic manner all the mineral products of the earth's strata. Everything useful or beautiful, from coal and iron to the precious metals and finest gems will be shown. The whole world will contribute to make the display a grand one, but America, with her wonderful mineral resources, must lead all other nations.

How extensive the mineral exhibit from other countries will be cannot be estimated as yet, but the exhibit of this country, not only as a whole, but of each state and section, will be most complete. Chief Skiff, of the department of Mines and Mining, is working hard to secure an exhibit that will surpass in size, grandeur, and utility, anything heretofore attempted.

Most of the matter so far published relating to the exhibit in this department has been concerning the precious metals, gems, and rare collections of minerals, and this has led many to believe that the baser metals and minerals were to be neglected. Such an inference is entirely wrong. The management realize their great industrial importance, and it has been determined to organize a sub-department to take special charge of the coal and iron exhibit, and later, a similar subdepartment to take charge of the copper and lead exhibits.

The coal industry of the United States is of gigantic proportions, involving the investment of many millions of capital, and the subsistence of probably a million and a half of people. The census bulletins recently issued, show the production of coal in the United States, in 1889, to have been over 140,000,000 tons, the value of which at the mines was over $150,000,000. Twenty-nine of the States and Territories are coal producing. Large as is our present annual production, it is small in comparison with the possibilities. Our coal resources are practically inexhaustible, and many large fields have not as yet been developed. Vast areas of coal measures, thousands of miles in extent, are distributed over our national area, and in the West and South the coal mining industry is rapidly increasing in importance.

The exhibit of coal at the Exposition, will of course be qualitative, rather than quantitive. Not only will the different varieties of coal, which the different localities produce, be shown, but chemical analyses of each, and the results of physical tests determining their economic value, and adaptability to various uses, will be shown. The coal resources of the different States and sections will be shown by geological maps and drawings, showing configuration, stratification, etc., which will make apparent at a glance, the extent and accessibility of the various beds.

So, too, as regards iron. The most strenuous efforts will be made to have an exhibit worthy of that great branch of industry. This country is now the first nation in the world in iron production, having recently forged ahead of Great Britain, its only real competitor. Our production of pig iron now exceeds 10,000,000 tons annually, or nearly four times what it was ten years ago, and the production of steel now aggregates about 5,000,000 tons a year, a growth of nearly 300 per cent. in the decade. The development of the iron resources of the Southern States has been especially great and rapid. The display at the Exposition will be prepared and collected under the fullest appreciation of the magnitude and importance of the iron industry. There will be shown all the many varieties of ores, with full data as to the location and extent of their beds, the analysis of each ore, and, so far as possible, the different processes of treatment in the manufacture of iron and steel.

Another exhibit which will be very extensive and varied will be that of building stone. Granite, limestone, marble, sandstone and bluestone, in scores of varieties, and scores of colors, will be shown by the finest specimens procurable. Nearly every State has quarries of native material of excellent quality. From one to half a dozen of the twenty or more recognized varieties of granite, for example, are quarried in twenty-eight States, Massachusetts, Maine, California, and Connecticut being the largest producers. The value of the granite output in 1889, was $14,464,095, an increase of more than $9,000,000 over that of 1880. Limestone is quarried in almost every State, Pennsylvania and Illinois taking the lead. The value of the output in 1889 was $19,095,179. This is exclusive of the output of marble, which, as is well known, is a species of limestone, the quarrying of which in a number of the States is an important and extensive industry. Sandstone, including bluestone, was quarried in 1889, to the value of $11,758,081, nearly every State being a producer. The exhibit of building stone, Chief Skiff intends, will be given the importance it justly demands. Thousands of specimens, many of them highly polished, and very beautiful, will be shown, and accompanying each will be the results of tests made to determine strength, durability, and other merits as construction material. The exhibit, which will be made in the Mines and Mining department, will, it is believed, mean very much in the matter of rapid development of newly discovered mines and quarries, and the attraction of capital to many which, through lack of it, have been but little worked.

COMMENT AND NOTICE.

THE United States is entering on what promises to be the most prosperous year in the history of the Nation. The crop situations here and in Europe are such as to assure this. Our crops are the largest ever known, and far exceed the most sanguine estimates, while those of Europe are remarkably small. It is practically settled that Europe will need to import between two and three hundred million bushels of wheat from America. Our production this year has been so great that this large amount can be spared without enhancing the price of breadstuffs at home. The farmer will reap his profits from the greatly increased production of his land and Europe's necessities. The mining and manufacturing interests will be benefited by an increased demand for their productions from the agricultural classes, and from the enhancement of the volume of general business incident to a largely increased export trade. The surplus of wheat alone in the United States and Canada will this year aggregate fully 200,000,000 bushels. It assures a revival of prosperity in which all classes of people will share. But in order to realize all that is possible from the splendid opportunity, it is necessary that all schemes which may have an effect to obstruct the natural course of trade be avoided. Under natural conditions great prosperity is assured. Speculation cannot entirely spoil the prosperous future, but it can materially lessen its value, and all efforts to corner the grain market should be deprecated. Prosperity to the agricultural interests means prosperity to all interests.

THE number of accidents in Northern England is proportionately less than in other portions of Great Britain or than in this country. The reason is believed to be because of the deputy over-man system as carried out in that section of England. The deputies set all the timber, the miners not being permitted to do this work. As the setting of the timber is the special duty of this class of sub-officers it is performed, and as a consequence the number of deaths and injuries from falls of sides and roof in these collieries is less than in others. Then it is contended that the presence of the deputies in the workings greatly assists in the maintaining of discipline and discipline is the most important means of preventing accidents.

MR. F. M. WARDELL, Inspector of Mines for the Yorkshire and Lincolnshire (England), districts, relates these facts in relation to an explosion of coal-dust which took place on the surface, where gas did not contribute in the smallest degree to producing the results:

"The crank shaft of a slack crusher vertical engine broke, and it was necessary to hang a pair of rope blocks near the roof of the engine house in order to raise the fly-wheel sufficiently to admit of the removal of the shaft. A man was sent to the top of the engine-house to fix the blocks, and in order to place a plank from which they were to be fixed perpendicularly above the fly-wheel, he commenced to turn it over. This plank had not been touched for several months, and had become heavily loaded with very fine coal-dust from the crusher underneath. A fitter was, at the time standing on the engine, and other men were present on the floor of the engine house. They all had ordinary torch-flaming lamps. The dust, on the plank being moved, fell on to these lamps, and an explosion immediately followed, the men being seriously burned. The explosion was of a violent character, and blew the slates from the roof of the engine house.

MR. W. B. SCOTT, Inspector of Mines for the South Staffordshire District, of England, makes the following practical suggestions in his annual report:

"There would appear to be an opportunity for county councils of those counties in which mining is carried on, and for town councils of county boroughs within whose bounds the same industry flourishes, to apply a portion of the grant which they have received for the purposes of technical education to the support of a peripatetic lecturer, who could visit the local centers in the county or borough, or in a group of counties and boroughs, and there deliver lectures upon mining. This would be a great boon and convenience to those students, and to the practical workers who are striving to rise from the ranks, who find it difficult from expense and want of time to gain the necessary theoretical part of their training."

We would suggest to the leaders of the Knights of Labor that if they desire to secure legislation which will be of great advantage to the miners of the State they should direct their efforts to securing the establishment of schools for the instruction of miners in the dangers attending their occupation and how to avoid them. The State should maintain night schools for the benefit of those miners who wish to improve themselves, and it should also maintain a central college, the same as the State Agricultural College, which the students of night schools could attend to thoroughly inform themselves in the sciences related to mining. If legislation authorizing such a system of night schools and a State College cannot be obtained perhaps the passage of a law can be secured to provide for traveling lecturers as suggested by Inspector Scott. The men must be educated as to the dangers they meet in their toil and as to the best means to avoid them, and strict discipline must be enforced before any considerable reduction in the number of accidents can occur.

MR. ARTHUR WINSLOW, State Geologist, of Missouri, reports that during the month of July the survey under his charge have been studying the occurrences and distribution of coal in Carroll, Chariton Howard, Monroe, Buchanan, Nodaway, Gentry, and Daviess Counties. Work on the iron ores was begun during the latter part of the month and inspection was made in Callaway and Wayne Counties. Zinc and lead were examined and were reported upon in Newton, McDonald, Barry, and Lawrence Counties. An estimate is being made for the survey of the total amount and value of the mineral products of the State up to the present date.

OUR "PRIMARY EDUCATIONAL DEPARTMENT."

The following is an extract from a letter received from Mr. John Kane, of Coal Bluff, Vigo County, Indiana. Mr. Kane saw the advertisement of THE COLLIERY ENGINEER in *The National Labor Tribune*, and having sent for and examined a sample copy he became a subscriber. Mr. Kane writes: "Your Primary Educational Department is peculiarly adapted to the needs of the uneducated miner. There is by far too much space wasted on practical miners in articles couched in language and signs which, to them is so much hieroglyphic matter. The result is that men who are thirsting for such knowledge as is contained in the articles turn away from them discouraged and disappointed because they lack the training to understand the technical terms and signs employed. The articles referred to are oftentime full of valuable information and are perfectly in place for persons who have had educational advantages.

"I hope you will continue your Primary Educational Department and that each number will sustain the reputation of the preceding one. The result will be, if the merits of your journal are generally made known, a higher grade of efficiency among the miners of the country, thus making the occupation less hazardous than when the knowledge of the sciences related to mining was confined to a few, such as mine inspectors and others whose visits to any particular mine are at intervals so far removed as oftentimes to be of little or no value."

CERTIFICATED MINE FOREMEN.

The last issue of *The Coal Trade Journal* contains a communication from a correspondent who signs "S. T. Z." In speaking of the Pennsylvania law requiring certificated mine foremen he says: "It is a well-known fact that the examinations as required by law are a veritable farce, for instead of increasing the efficiency of the employes, it is openly stated that a poorer class of men are in these positions than was the case before the radical reform was inaugurated."

Such a statement could only emanate from a man of the densest ignorance concerning the conditions existing in Pennsylvania coal mines. Since 1886, when the law requiring certificated mine foremen went into effect, there has been 20·7 per cent. more coal mined per fatality than during the preceding sixteen years, though mine inspection was provided for by law during that period. The ratio of fatalities per 1,000 employes, previous to the advent of certificated mine foremen, was 21·5 per cent. greater than it has been since. These figures can be verified by the official reports of the various mine inspectors. In contrasting these results it must also be borne in mind that the dangers incident to coal mining have increased in recent years owing to the workings reaching greater depths, and the fact that an ordinary colliery to-day produces fully twice as much coal as it would twenty years ago. This necessitates the greater use of machinery, and greater liability to accidents from that source.

As we write, the General Mining Superintendent of one of the large Anthracite companies is in our office, and we asked him the following question: "Major, how does the present certificated mine foreman compare, as regards efficiency, with the old-time mine foreman?" His answer was: "There is no comparison between them. The mine foreman of to-day is infinitely more competent."

The statistics of the mine inspectors and the opinions of operators and superintendents both conclusively prove that "S. T. Z.," either knows nothing of the subject on which he writes, or he is a disappointed candidate who failed to pass an examination.

The Anthracite Trade.

The Anthracite coal trade has improved slightly since our last issue, and a gradually increasing demand is perceptible in all prominent markets. This improvement will be more marked during the ensuing month and the close of September promises to show a really active market and well maintained prices. Restriction was rigorously enforced during August and the production was kept down to the agreed amount of 3,000,000 tons. The companies are firm in their determination to improve the condition of the market by restriction, and buyers are beginning to realize that they must speedily lay in their winter stocks or pay much higher prices for coal in the three last months of the year. The companies have seen that strict adherence to the policy of restriction during August has materially improved the trade conditions, and unless something entirely unlooked for at present intervenes, harmonious action will be the rule, and the trade for the balance of the year will be on a firm basis and prices will be well maintained.

The sales-agents held a meeting on the 27th ult., and adopted the proposal made at the previous meeting, to limit the production for September to 2,500,000 tons.

The Bituminous Trade.

The Bituminous trade is gradually brightening, due to the near approach of fall and winter weather. Pittsburgh operators consider prospects for the balance of the year good, and are jubilant over another rise in the price of natural gas which will naturally force more local consumers to return to coal. The outlook at western and southern markets is good. In some markets, notably Chicago, stocks are large and prices easy, but the general impression among dealers is that the fall trade will be very active and that fairly good prices will be obtained. The stocks on hand at Buffalo are light, and the demand is also. The outlook for the ensuing month, however, is favorable for increased business and slightly better prices. Large shipments are being made to New England on old orders, owing to prevailing low freight rates. Coal is freely offered in the Boston market at very low prices, particularly coal of inferior reputation. The New York market is fairly active. The demand for standard varieties is good, but inferior varieties are being offered at prices that vary from fairly good to ridiculously low.

The Coke Trade.

The coke trade is steady and the prospects for the future are good. The conditions existing in the iron trade always influence coke, and as the iron trade is steady, the coke trade is also. The Connellsville operators, who practically control the trade, have wisely adhered to a policy of restriction that keeps the markets in good shape. Prices for Connellsville coke are firm, as follows: Furnace coke, $1.90; foundry coke, $2.30; crushed coke, $2.65; all f. o. b. cars at ovens.

In its issue of the 28th ult., *The Connellsville Courier* says:

"The coke trade dropped off a few points last week. Production was restricted about 7,000 tons and shipments were scaled down accordingly. The number of ovens in blast, however, remains about the same. Better times and better trade are anticipated very shortly, and the operators expect to have use for all the ovens now fired. Hence they are keeping them hot rather than blowing them out. The iron trade journals predict a more active demand next month. Cars continue in good supply and labor is plenty.

Consolidation of Asbestos Firms.

For several years The Chalmers-Spence Co., manufacturers of steam pipe covering, have advertised in this journal, and have done an extensive business among American collieries. This business was invariably satisfactory to all concerned as their work and goods always gave the greatest satisfaction. In order to increase and improve the quality of asbestos products, and to decrease costs, this company has in conjunction with the H. W. Johns Mfg. Co., Asbestos Packing Co., Shields & Brown Co., and Chas. W. Trainer & Co., formed a consolidation under the corporate name of the H. W. Johns Manufacturing Co. The officers of The Chalmers-Spence Co. will take a leading part in the management of the new company, and the services of the principle agents and salesmen will be retained. This consolidation is bound to be of advantage to both the consolidating concerns and purchasers of their products, and we particularly desire to call the attention of our readers to the change in the advertisement of The Chalmers-Spence Co., which is now signed by the H. W. Johns Mfg. Co. The Philadelphia branch has been removed from 24 Strawberry Street, to 170 and 172 North Fourth Street.

An Improved Fuse-Cap Fastener.

Mr. N. W. Moody, of Fresno, Fresno County, Cal., has recently patented a device which is especially designed as an improved implement for fastening the caps on fuse employed in exploding giant powder. The pliers are formed of two similar parts, connected by the pivotal rivet, each part having a cheek with notches, at the sides of which are cutting edges for cutting the fuse. The curved jaws beyond the cheek pieces, when closed, form a circular aperture, around which the jaws are beveled, one jaw having a tongue which fits in a groove in the other jaw. The pliers are employed for contracting the end of the cap on the fuse firmly and absolutely water-tight, thus avoiding the dangerous operation of digging out wet and unexploded loads. Miners who have used implements of this class will appreciate the improvements in the one designed by Mr. Moody. The instrument crimps the cap on the end of the fuse firmly. The fuse-cutter is simple and efficient. This implement is neatly gotten up of the finest cast-steel and nickel-plated. It is small and light, but strong and well adapted for its purpose.

It is well known that numbers of miners are killed annually in the United States and elsewhere while going through the dangerous operation of digging out wet and unexploded loads, to say nothing of those losing an eye or a limb in the same way. Accidents of this nature could be avoided, and the handling of Giant Powder made comparatively safe, by the use of an instrument such as this invented by Mr. Moody. Mining companies would also relieve themselves from the liability of damage suits were the use of such an instrument adopted by them. Another item of interest and benefit to mining companies is the time saved in preparing the cap and fuse for use. Instead of taking time to use soap and a string or tar, after the usual effort to fasten the cap to the fuse, this implement enables the miner to cut the fuse and fasten the cap on firmly, and absolutely water-tight; and this is done in a few seconds, which means no loss of time at all. Any one familiar with blasting operations can appreciate the advantages of this implement.

MINE FOREMEN'S EXAMINATION.

A List of the Successful Candidates.

The following is a complete list, by districts, of the applicants who passed the mine foremen's examination held in the Anthracite regions of Pennsylvania, on July 6th and 7th, 1891:

First District, Patrick Blewitt, Inspector—Matthew Gray, Michael J. Murray, and P. S. Malia, Dunmore; Richard Williams, Peckville; W. H. Walters, Olyphant.

Second, District, H. McDonald, Inspector—Thomas Smiles, Jr., John Joyce, Thos. O'Brien, Gilbert S. Jones, John Bone, Alexander McCormick, Patrick Eagan, Gottlieb Smaltz, Pittston; Hugh McCutchen and Daniel A. Sullivan, Miners Mills; Michael Gilboy, Duryea.

Third District, G. M. Williams, Inspector—John Arnott, Nanticoke; Enoch I. Jones, Wilkes-Barre; Henry D. Hughes, and A. Casewell, Larksville; Daniel B. Lewis, James Roberts, Thomas H. Picton, John H. Evans, and David W. Morris, Plymouth; Wm. F. Rees, Alden.

Fourth District, John M. Lewis, Inspector—Stephen Cairns and Geo. W. Meneeley, Sandy Run, Luzerne County; James Lawson, Freeland, Luzerne County; Tobias Seiwell, Oneida, Schuylkill County; Isaac M. Davies, Lansford, Carbon County.

Fifth District, Wm. Stein, Inspector—Thomas Whittaker, Yatesville; Benjamin Williams, Silver Brook; Henry F. Javins, Shenandoah; Charles Harlor, Raven Run; George Richardson, Maple Dale; Thomas D. James, Wm. Penn; John Conway, Suffolk; Lawrence Murphy, Lost Creek; John Schwint, Shenandoah; Edward J. McDonald, Colorado; Patrick Fenton, Buck Mountain; F. H. McCormick, Shenandoah; Samual Platt, Wiggans; Richard Rosby, Gilberton; John Garvey, Gilberton; Stephen Gervill, Mahanoy City; Thomas T. Williams, Audenried; Thomas Beddow, Mahanoy City; David Jones, St. Nicholas.

Sixth District, William McMurtrie, Inspector—Valentine Kline, Mt. Carmel; James Daily, Locust Gap; Henry Achman, Locust Gap; J. C. Brown, Shamokin; Charles Gallagher, Centralia; John Phillips, Williamstown; Nicholas Brecker, Locust Dale; John E. Davis, Ashland; John Mainey, Shamokin; F. W. Luckenbill, Shamokin; Evan Jenkins, Centralia; Robert Ansty, Locust Gap; Henry Carl, Locust Gap; James Finley, Shamokin; Henry Welker, Shamokin; Thomas Ramage, Green Ridge; William Krab, Locust Dale.

Seventh District, Samuel Gay, Inspector—Lewis Minnbach, Tremont; George Young, New Boston; Charles Forney, St. Clair; James Flemming, Donaldson; W. F. Jones, Minersville; John Conville, Branchdale; Michael Murphy, Heckscherville; Patrick Conville, Tower City; Andrew Gantley, Branchdale; William Beverage, Swatara; Joseph H. Zimmerman, Pottsville; Thomas M. Brennan, Heckscherville; John Kelly, Minersville; James Reese, Morea; David Griffith, St. Clair; Eli Snyder, St. Clair; James Tracey, Forestville.

Mining Lamps.

Mining lamps are small things and are not expensive, yet they are as great an improvement over candles as any other modern appliance is over the appliances used around collieries forty or fifty years ago.

Though simple in construction and cheap in price, they are not always of a uniform standard of excellence. Therefore, it is well, when ordering mining lamps, as in other specialties, to know that you are dealing with a responsible manufacturer, and one who is not ashamed to stamp his name on his products.

The stamp of "T. F. Leonard, Scranton, Pa.," on a mine lamp, ensures the purchaser that he is getting a lamp that is perfect in construction and made of the best material. All Mr. Leonard's lamps are seamless. They have stood the test of years, and are regarded as standard lamps wherever used. They are made with either single or double spouts, and with either single or double hooks. His facilities for manufacturing them are such that large numbers are turned out daily and none but best materials are used in their construction. His prices, owing to improved machinery and convenient shops, are as low as any other makers, and we advise our readers to write him for circulars and prices.

The Stratton Separator.

Manufacturers and steam users generally will be interested in the following communication:

PURDUE UNIVERSITY, La Fayette, Indiana.

THE STRATTON SEPARATOR CO.,
32 Cortlandt Street, New York.

GENTLEMEN: We have been using for about a year one of your 4-inch separators in connection with the compound engine in our Engineering Laboratory.

Steam for this engine is supplied by boilers located 380 feet away, and notwithstanding the long length of pipe through which it is thus required to pass, it was never found, *by repeated calorimeter tests*, to contain as much as 3% of moisture when it passes out of the separator, regardless of the amount of water previously held by the steam.

Very truly yours,
WM. F. M. GOSS,
Professor Experimental Engineering.

MR. JAMES F. BEATTIE, formerly of the Newburgh Orrel Coal and Coke Co., of Newburgh, Preston Co., W. Va., has accepted the Superintendency of the Gaston and Barnsville Mines and Coke Works, at Fairmont, W. Va.

ANTHRACITE COAL STATISTICS.

Statement of Anthracite coal shipments, for month of July, 1891, compared with same period last year Compiled from returns furnished by the Mine Operators, by John H. Jones, Chief of Bureau of Anthracite Coal Statistics.

	JULY 1891.	JULY 1890.	DIFFERENCE.		FOR YEAR 1891.	FOR YEAR 1890.	DIFFERENCE.	
From Wyoming Region, - - -	2,024,941·18	1,738,124·07	Inc.	286,817·11	11,609,194·09	9,613,856·07	Inc.	1,995,338·02
From Lehigh Region, - - -	569,487·12	532,843·18	Inc.	36,643·14	3,473,200·05	3,463,452·08	Inc.	9,747·17
From Schuylkill Region, - - -	1,196,910·00	1,019,110·13	Inc.	177,799·07	6,674,029·07	5,598,716·01	Inc.	1,075,313·06
Total - - - - - - -	3,791,339·10	3,310,078·18	Inc.	481,260·12	21,756,433·01	18,676,031·16	Inc.	3,080,401·05

The stock of coal on hand at tide-water shipping points, July 31st, 1891, was 703,634 tons; on June 30th, 1891, 678,144 tons; increase, 25,490 tons.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since our Last Issue.

Osceola Consolidated Mining Co.,	San Francisco, Cal.
Crescent Coal Company,	What Cheer, Iowa.
Vernon Mining Company,	Nevada, Mo.
Motor Mining Company,	Helena, Mont.
The United States Mine Equipment Co.,	Chicago, Ill.
Algoma Nickel Company,	Chicago, Ill.
Essex Iron Company,	15 Cedar St., New York N. Y.
The Heckla Consolidated Gold Mining Company,	Gold Park, Eagle Co., Colo.
The Peck Montana Company,	Chicago, Ill.
Dutton Phosphate Company,	Gainesville, Fla.
Williamson Mining and Mfg. Co.,	Williamson, W. Va.
The Southeastern Georgia Timber Land Company,	Philadelphia, Pa.
The Atcheson Coke Company,	Dunbar, Fayette Co., Pa.
The Great Western Consolidated Mining Company,	Great Falls, Mont.
The Kentucky and Texas Mining and Investment Company,	Denver, Colo.
Lacoochee Phosphate Company,	Lacoochee, Pasco Co., Fla.
Eureka Block Coal Company,	Chicago, Ill.
The Summit Mining and Milling Co.,	Neihart, Mont.
Granite Hill Mining Company,	Barker, Mont.
New England Mining Company,	Portland, Me.
The St. Helene Phosphate Company,	Portland, Me.
The Empire Mining and Reduction Co.,	Silverton, Colo.
The South American Mining and Milling Company,	Denver, Colo.
The La Veta Coal Company,	Denver, Colo.
Cayuga Lake Salt Company,	Ludlowville, N. Y.
Gulf Stream Phosphate Company,	Tallahassee, Fla.
Chenango Mining Company,	Joplin, Mo.
Tyler Mining Company of Oregon,	Wardner, Idaho.
Crevasse Mountain Mining Company,	Helena, Mont.
Enterprise Company,	New York, N. Y.
Castle Cattle and Coke Company,	Castle, Mont.
The Tuerto Mountain Copper and Gold Company,	Santa Fe, N. M.
Minneapolis & Webb City Mining Co.,	Minneapolis, Minn.
The Inter-State Mining Company,	Weir City, Kans.
Oatka Dairy Salt Company,	Warsaw, N. Y.
Running Wolf Mining and Milling Co.,	Great Falls, Mont.
Standard Mining Company,	Helena, Mont.
Michigan Iron Mining Company,	Ashland, Wis.
Santiago Mining & Milling Company,	Oakland, Cal.
The Shoal Creek Mining Company,	Galena, Kans.
The Mountain State Mfg. and Mining Company,	Terra Alta, W. Va.
The Cinnibar King Mining Company,	Healdsburg, Cal.
Wenona Iron Company,	Duluth, Minn.
Wabigon Iron Company,	Duluth, Minn.
Minawa Iron Company,	Duluth, Minn.
Nibiru Iron Company,	Duluth, Minn.
Missosh Iron Company,	Duluth, Minn.
Monitor Coal Company,	Centreville, Iowa.
The Jeannette Mining Company,	Bonner's Ferry, Idaho.
Security Mining Company,	Great Falls, Mont.
Weser Mining Company,	Helena, Mont.
Archdale Phosphate Mining Company,	Charleston, S. C.
Fire Center Gold Mining Company,	Milwaukee, Wis.
The American Silica Sand Company,	Cleveland, Ohio.
The Commercial Mining and Milling Company,	Denver, Col.
Great Falls Mining Company,	Monarch, Mont.
The Cliff Mining Company,	Missoula, Mont.
World's Fair Mining & Developing Co.,	Helena, Mont.
The Trusdell and Grimes Rock Salt Company,	Lyons, Kans.
The Bluff Spring Mining Company,	East St. Louis, Ill.
The Columbia Mining Company,	Denver, Colo.
Green Mountain Mining Company,	Chicago, Ill.
The Happy Coal Co., of Centerville, Ia.,	Centerville, Iowa.
Russellville Coal and Mining Company of Russellville, Ark.,	Russellville, Ark.
Boston and Idaho Silver Mining Co.,	Portland, Me.
Eureka Phosphate Company,	Ocala, Fla.
The "Agnes C." Mining Company,	Manitou, Colo.
East Side Land Company,	Goshen, Va.
Muhlenberg Coal and Land Company,	Louisville, Ky.
La Pierre Phosphate Company,	Charleston, W. Va.
Republican Mining Co. (of Washington),	Wardner, Idaho.

H. WARD LEONARD & CO.

Mr. H. Ward Leonard, the General Manager of the Light and Power Department and also of the Intelligence Department of the Edison General Electric Company, resigned upon August 5, in order to start an independent electrical engineering business under the above title. The new concern will be an incorporated company under the laws of the State of New Jersey. Mr. Leonard will take with him several well-tried assistants who have been associated with him in the past, some of them as far back as 1885. Among those who will thus be connected with the Company are Mr. A. St. C. Vanse, Mr. E. H. Harrison, Mr. C. H. Bloomer, and Mr. August Monning.

The Company will operate specially in a field which is full of promise for the future, and is at present inadequately occupied, namely, the transmission of power by electricity and the application of electric motors to the operation of special machinery, such as is not at present operated by electric motors, or whose operation is subject to improvement by careful attention to the requirements of the case.

Mr. Leonard's experience since 1883, when he became a member of Mr. Edison's first electrical engineering staff, has brought him into contact with every branch of electric light and power work. He has held positions from the lowest to the highest in the exploiting parts of the business, as well as in the constructing and in the operation of every kind of electric light and power plants, and it is not, therefore, altogether surprising that he should feel willing to resign his office with the Edison Company to take up a line of work which promises so well for one having such an exceptional experience as he has been fortunate enough to have.

H. Ward Leonard & Co. will have one important feature of their business which will be entirely unique, namely, an electrical intelligence department. To any isolated plant, the Company offers at a very moderate subscription price ($25 a year) the privilege of corresponding upon any electrical subject of practical interest and thus an isolated plant will be able to secure expert information as to its own plant and the best methods of operating it, and about any new electrical apparatus or methods and the principles underlying various devices, and the prices thereof. For central station companies, whose queries would go further into steam engineering and methods of distribution and would also cover business questions as to relations with consumers, systems of accounts, etc., the annual subscription charge for this electrical intelligence will be $50.00.

The scheme strikes us as an excellent one and we have no doubt that any plant will get several times the value of the subscription price by placing before this Company the matters upon which it desires information, data, and statistics. As Mr. Leonard created and developed the Intelligence Department of the Edison General Electric Company, he has had the broadest possible experience in this line since information of every character issued to those in the Edison Company has been issued by the Intelligence Department of that Company. In case expert judgement of the Company be desired as to the comparative merit of various competing apparatus or methods, such expert judgment will be given by special arrangement, although the Company prefers to merely supply full information under the subscription arrangement and allows the purchaser to form his own conclusions.

H. Ward Leonard & Company will do no manufacturing and will do no supply business, neither will they under any circumstances, act as the selling agents of any concern, directly or indirectly.

They will, however, act for the purchaser, either as Consulting Engineers, Supervising Engineers, Inspectors, or Purchasing Agent. When acting in this way they will make the following charges, based upon the contract price:

For making preliminary plans, designs, distributions, and estimates,	1%
For making final plans and specifications,	1%
For drawing and executing contract on the behalf of the purchaser,	1%
For supervising an installation made by another contractor,	3%
For inspecting and reporting on the work of another contractor,	1%
For acting on the behalf of the purchaser in making a settlement with another contractor	1%
For acting as the agent of the purchaser from the beginning to the final settlement of a contract, including the making of estimate plans, determinations, specifications, contract, supervising the installation, final inspection and report, and final settlement,	5%

It will be seen from the complete schedule given above, that the purchaser will be able to obtain the services of this Company for any portion of the work, and under terms which are so reasonable that there can be no question in the minds of those familiar with the subject, that any purchaser contemplating the installation of an electric plant would not only save a great deal of his own time, and be spared a great deal of annoyance, but would actually effect a very material saving in retaining the services of a concern such as this to represent the interest of the purchaser.

The various parent companies will also, no doubt, welcome the advent in the electrical field, of an electrical engineering concern of this order whose experience and ability is undoubted, and who are free from prejudice and have no affiliations of any kind with any of the various electrical concerns. Any parent electrical company can refer a prospective purchaser to such a concern as this, with confidence that any opinions given by it to the purchaser will be based on the honest judgment of those thoroughly competent to judge any practical electrical question.

H. Ward Leonard & Company will make a specialty of the transmission of power and the application of electric motors to such uses as necessitate the application of a wide experience in both mechanical and electrical engineering. Such applications of electric motors as are met with in elevators, pumps, hoists, mine tramways, printing presses, etc., are those which this Company feels itself especially qualified to undertake under guarantee of perfectly satisfactory results.

The Sterling Water Safety-Boilers.

The Sterling Company, manufacturers of the Sterling Water Tube Safety-Boilers only four months ago completed their shops at Barberton, Ohio. That the Sterling boilers possess great merit is evidenced by the rapidity with which they are being introduced. The Company has already furnished boilers to the amount of 25,000 horse-power. A plant of three boilers aggregating 450 horse-power has been furnished to the Compania Metalurgica Mexicana, San Luis, Potosi, Mexico, and one of three boilers aggregating 550 horse-power to the Acadia Coal Co., Stellarton, N. S.

BOOK REVIEW.

We have received from the publishers Messrs. Funk and Wagnalls, of New York, the prospectus and some advance pages of "The Standard Dictionary of the English Language." It promises to be the most convenient dictionary yet published. It will be slightly larger than the unabridged Webster or Worcester dictionaries, and will contain nearly 4,000 illustrations. Its various departments have been edited by the leading specialists of America and in many important points it differs widely from the plans of other dictionaries. For example: (1). The "locating" of the verifying quotations; that is, the giving in each instance not only the name of the author, but also the name of the book and the number of the page where the quotation can be found; to thus "locate" 50,000 quotations is of itself a herculean task. (2). The use, in the pronunciation of words, of The Scientific Alphabet, adopted by The American Philological Association. (3). The placing of the etymology after the definition. (4). The placing of the most important current definition first, and the obsolescent and obsolete meaning last, that is, the substitution of the order of usage for the Historic Order usually followed in dictionaries. (5). In the case of disputed pronunciation the giving of the pronunciations preferred by other dictionaries, as well as the pronunciation which we prefer. (6). The giving of 50,000 vocabulary words more than are to be found in any other single volume dictionary in England or America, (no new word is admitted to a vocabulary place, unless it has been passed upon by the able men in charge of this department, namely, Julius H. Seelye, of Amherst College; Edward S. Sheldon, of Harvard University; Edward Everett Hale, Charles A. Dana, and Howard Crosby.) (7). The indication by the use of upper and lower case initial letters, as to whether words in the vocabulary are to be written as proper names or common names, etc., etc. The list price of the dictionary, when issued will be $10.00. It will be bound in heavy sheep, and a special discount will be allowed to advance subscribers.

New Anthracite Inspectors.

Messrs. Patrick Blewitt, present Inspector of the First Anthracite District, and Edward Roderick, of Stockton, Pa., were recommended for appointment as Inspectors of the Second and First Districts respectively, by the Board of Examiners, who held the examination at Wilkes-Barre, Pa., on the 3d and 4th ult.

ANTHRACITE MINE INSPECTORS' EXAMINATIONS.

Opinion of the Attorney-General Regarding the Publishing of the Questions and Answers.

OFFICE OF ATTORNEY-GENERAL,
Harrisburg, Aug. 28, 1891.

JOHN B. LAW, ESQ.,
Chairman Board of Examiners,
Pittston, Pa.

Dear Sir:—In answer to your letter of August 24th, inquiring as to the meaning of that clause of Section 5, Article II., of the Anthracite Mine Law of 1891, which requires the examiners to report to the Secretary of the Commonwealth and to publish in the local newspapers "the names of the applicants, the questions asked and answers thereto, etc.," I have to say:

The clause referred to is general and comprehensive in its character, and while it restricts the recommendation of the examiners to such candidates as shall have answered ninety per centum of the questions, and to such applicants "as they find qualified for the office," no such restriction is contained in the directions regarding the matter to be transmitted to the Secretary of the Commonwealth. The language of the Act is "the names of the applicants, the questions asked and answers thereto shall be sent to the Secretary of the Commonwealth, and published in at least two local newspapers, daily or weekly." The purpose of this provision seems to afford the public and the executive authorities an opportunity of knowing in what manner the examiners shall have performed their duty, and as to whether or not a fair and proper judgement was made upon the merits of the various applicants. I am therefore of the opinion that the answers of all the applicants should be published and transmitted to the Secretary of the Commonwealth.

Very truly yours,
(Signed) W. U. HENSEL,
Attorney-General.

A Successful Electric Haulage Plant.

Mr. James T. Gardiner, consulting engineer of the Pleasant Valley Coal Co., of Salt Lake City, Utah, in a recent letter regarding the haulage plant at the Castle Gate Mine, says:

"We have for the past year, at the Castle Gate Mine, in Utah, used a hoist or haulage drum, operated by electricity. The drum was made by the Lidgerwood Manufacturing Company, of New York, and the electric motor, and the electrical equipment was furnished by Thomson-Van Depoele Electric Mining Co., together with all the electrical apparatus for the power station.

"Trains of sixteen large pit cars run out of the mine by gravity, dragging the tail-rope after them. The empty trains are hauled back into the mine by the haulage drum located nearly 2,000 feet from the chute in the interior of the mine. The operation of this apparatus has proved so satisfactory and so economical that, by my advice, the company has ordered two more electric hoists of more powerful type.

"In every way the electrical apparatus has been satisfactory to the company, so satisfactory, that for the Winter Quarters Mine, operated by the same company, we have ordered an electric locomotive and the equipment of nearly two miles of underground railway with the Thomson-Van Depoele system.

"I take pleasure in testifying both to the excellent quality of the materials and machinery that have been furnished the Pleasant Valley Coal Company and to the economical working of electric haulage in coal mines where the conditions are adapted to the use of this power, and where the power is properly applied.

"I have been so well satisfied with the results of the application of electric power to the mines of the Pleasant Valley Coal Company that I am expecting to apply it to the mines of other companies where favorable conditions exist."

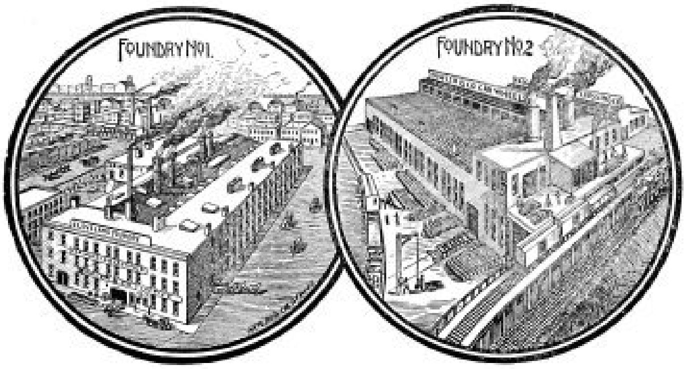
We have received from the Wm. Powell Co., of Cincinnati Ohio, a very handsome catalogue which illustrates and describes the many varieties of valves, (for steam or water), lubricators, steam whistles, gauge-cocks, etc., etc. The book is handsomely bound in cloth, and should be on the desk of every colliery and coke plant superintendent. The articles illustrated and described have won a national reputation for excellence, and as the book contains much valuable information, we would advise our readers to write to The Wm. Powell Co., 50 to 54 Plum St. Cincinnati, for a copy. It will be cheerfully sent you.

Messrs. J. & J. B. Milholland, of Pittsburgh, who make a specialty of endless and tail-rope haulage machinery, and who, as builders and designers of such machinery, have won a national reputation for excellence of machinery, combined with reasonable prices, inform us that their business is booming, and at present they have orders on their books for five new haulage plants.

THE MANUFACTURE OF CHILLED CAR WHEELS.

Messrs. Bowler & Co., of Cleveland, Ohio, rank among the leading manufacturing firms of Cleveland, Ohio, and the reputation of the car, engine, truck, and mining wheels manufactured by them, has been won by the use of only the best grade of materials and excellent workmanship. The illustration given below shows Foundries Nos. 1 and 2, and furnishes the reader an idea of the firm's capacity.

The foundry erected expressly for the casting of car wheels is one of the most complete establishments of the kind in the world, constructed from original designs, equipped upon the most liberal scale in every department, and provided with all practical modern improvements and facilities. The building is 140 x 200 feet in dimensions, one end facing Bessemer Avenue and the other the New York, Pennsylvania, and Ohio Railway.



The sidings are a special feature which deserve mention. The track running to one end of the building is raised to a charging platform forty-eight feet in width and twenty feet above the level of the molding floor. Here the raw material of every kind is received, and delivered directly to the pile from which it is to be used in charging the cupolas, two in number. It has storage capacity for 500 tons of the various grades of charcoal iron used, and several carloads of coke. Upon this platform is a thousand-pound hammer, with a drop of fifteen feet, for breaking old wheels. Its capacity is at least thirty wheels an hour—a vast improvement over the old-time sledge-hammer. Another spur runs on a lower level to the other end of the building to receive the finished product. The floor plan is entirely novel. Beginning at the south end (underneath the platform mentioned above), the middle portion is occupied by two cupolas, one 5 feet in diameter, with a capacity of 125 wheels per day, and the other 6½ feet in diameter, with a daily capacity of 300 wheels. A large Roots blower furnishes blast, and by an ingenious application of mercury in a U-shaped tube, the blast can be exactly determined.

In the engine room, adjoining the cupolas, is a 100 h. p. Lord, Bowler & Co., engine, which drives the blower and shafting that propels the cranes. In the room adjoining is the department for turning up axles, boring wheels, and putting them on axles. To the left of the cupolas is the sand bin, and next adjoining this are the core ovens. There are three ovens, 10 feet square, each holding 100 cores.

In the middle portion of the shop, of course, are the molding floors. A central shaft, running the entire length of the building, conveys the power by belts and gears to sixteen cranes, each surrounded by a molding floor, the total capacity being about 320 wheels per day. On either side of the room are overhead tramways, by which the wheels are run to the cooling or annealing pits at the further end. Over these pits is a traveling crane running across the shop and propelled by means of a cable and drum. After remaining in the pits three or four days, for the purpose of securing slow and even contraction, the wheels are removed and cleaned up ready for shipment. The chill is, of course, secured on the original castings by contact of the molten metal with a cold iron ring.

N. P. Bowler established this house in 1863. A year later Wm. Bowler and Thomas Maher were admitted, and in 1870 Mr. C. A. Brayton became a partner, the firm adopting the style of Bowler, Maher & Brayton. The two last named retired in 1880, whereupon Mr. W. W. Balkwill was admitted, and the style changed to Bowler & Co.

PACKING.

The packing question is one which is eternally agitating the mind of every engineer. There are good packings and poor ones, and packings adapted for special places, but you seldom, if ever find one line of packings which can be so manufactured as to do good service in all places. The Garlock Packing Company, whose main office and factory is at Palmyra, N. Y., manufacture the Elastic Ring, Sectional, Spiral, and Special Water Packings, and by using good judgment the purchaser can always obtain from the list, a packing which will exactly suit the special place where he wishes to apply it.

This packing has a world-wide reputation, but probably the greatest reward which comes to the inventor is the substantial business which he has been able to work up. The Elastic Ring packing is made in rings (as also the Sectional and Special Water Packing) and is subjected to a perfect lubricating process. Where the rods are true and smooth and the box and glands properly beveled it is well to adopt the Elastic Ring. The word "Elastic" explains the nature of the packing very well. It readily expands when steam is applied, and needs no attention except that the bolts should be screwed up with the fingers only very slightly. Should it leak water when starting, do not tighten for it will stop when it gets heated through. After properly applying it should be left alone.

The Sectional Ring Packing is especially adapted for rods out of line, cut rods, flat bottom stuffing boxes, rods working in ammonia or in acidulated water, and places that are very difficult to keep tight. This packing is positively automatic and is subjected to the same lubricating process as the elastic ring.

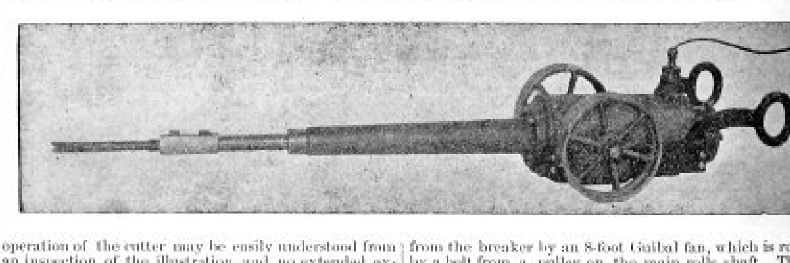
The Garlock Spiral Packing can be applied in places where the Elastic Ring or Sectional are used. Its chief advantage is in its being put up for a stock packing so as to be kept by dealers or large concerns. Consumers having a number of glands of the same size will find the Spiral Packing a very handy article. It is made of the same material as the other packings and thoroughly lubricated.

Probably the greatest improvement in packings made in many years has been that of the Garlock Special Water Packing, which will not only hold water successfully but is especially adapted for the most difficult places, generally speaking. The other kinds of Garlock Packings worked as well as any other packings in water and the Sectional Packing will hold very many difficult places, but the Special Water Packing the company guarantees to suit every time. They are introducing this packing with great success in places which no other packing would hold. The packing is made in two sections and works automatically. The company are anxious to put a set in with every company having any trouble anywhere whatever. The Garlock Packing Co. has three (3) factories respectively situated at Palmyra, N. Y., Rome, Ga., and Omaha, Neb. They have offices in all of the principal cities, and will be glad to correspond with anyone about the packing question. See advertisement.

A SOLENOID COAL CUTTER.

In some grades of coal it is found desirable to make the undercut with a machine concentrating its power upon a single reciprocating shaft, carrying a chisel at its extremity. This type of cutter or drill is very compact and is controlled by one man, the direction of the blow being varied as occasion demands. Several machines of this type, operated by steam or compressed air, are on the market, and while in many ways satisfactory, the application of electricity as the motive power possesses many decided advantages.

The illustration shows the Van Depoele Solenoid Coal Cutter, manufactured by the Thomson-Van Depoele Electric Mining Co., of Boston. The type shown is the present standard form, though modifications can be made to suit special requirements. The operation of the cutter may be easily understood from an inspection of the illustration, and no extended explanation is required. The direction of the blow is determined by the operator, who sits on the floor facing the breast, his feet resting against the wheels, and his hands grasping the handles at the rear of the cylinder, thus obtaining a double leverage, by which the machine, being almost exactly balanced, is easily turned on its points of support.



A simple switching device turns the current on or off, as desired, while lights, pumping apparatus, electric ventilators, etc., may be run on the same system of wires which supply power to the coal cutter, if desired.

The weight of the apparatus is a little over 700 pounds, the number of strokes usually from 300 to 350 per minute, although the rapidity of the blow can be varied at pleasure. The stroke is from five to six and one-half inches. The tension guide can be furnished in different lengths, according to the depth of undercut desired.

Steel Roofing.

A representative of this journal recently called at the office of the Canton Steel Roofing Company, of Canton, Ohio, and in reply to his question as to the business they were doing, he was told: "Our business has increased 58 per cent. during the first half of the current year. We have been compelled to enlarge our buildings and put in a great deal of new special machinery of our own invention. We now manufacture more steel roofing than any other firm in the world, and our competitors all admit that we manufacture a larger variety of goods than any other house in this line, and that we have the best systematized plant and use only best materials. We are holding all our old customers, and are rapidly extending our business in new fields."

Such a satisfactory state of affairs can only be attained by furnishing first-class roofing and siding at reasonable prices, and we congratulate the Canton Company on its success.

A Successful Young Coal Company.

The Langcliffe Coal Company started operations at the Langcliffe Colliery, near Avoca, Pa., in December 1889, and under the efficient management of Mr. Wm. T. Smyth, this colliery, which was previously designated as a "dead horse," has been made a large producer of coal of excellent quality.

When old operations on the land worked were suspended a few years ago, Mr. Thos. H. Phillips, then superintendent of the Lehigh and Wilkes-Barre Coal Co., recognized the value of the coal which former operators thought worthless, and secured an advantageous lease on it. He then sublet it to a party who in turn sold out to the Langcliffe Coal Co., the present operators.

The success of the Langcliffe Company lies chiefly in having as a superintendent, Mr. Smyth, whose ability as a practical miner is recognized as equal to that of any other man in America. His excellent underground management and his labor-saving and economical methods of cleaning and handling the coal have made the colliery. His associates in the company are men of broad views and experience, and therefore second his efforts to make the colliery a phenomenally successful one.

The veins worked are locally known as the Red Ash, 7 feet thick, which corresponds in geological position with the Buck Mountain vein in the lower Anthracite regions, and the Checker vein, 6 feet thick, which lies in nearly the same position as the bottom split of the Mammoth vein in the Middle Coal Field. The former vein is opened by a shaft 150 feet deep which was sunk by the old operators. The latter vein is worked from a drift opening. The Red Ash vein was overlaid by another vein, worked years ago, and in some places the strata between them runs only from 18 inches to 3 feet thick. Where this is the case the coal is worked on the Longwall retreating plan. Where the strata between the two veins is thick enough, and this is the case most generally, the method of working adopted is the pillar system.

The Langcliffe Co. leases in all about 700 acres of land, but owns the few acres on which the improvements are located, in fee simple. The tracks under the breaker were laid by the company, and they own them to the switches, where they connect with the New Jersey Central, Lehigh Valley, and Delaware and Hudson Railroads. This enables them to ship over any of the roads mentioned or over the Erie and Wyoming, Ontario and Western, or Pennsylvania R. R., without lateral tolls.

The present breaker which has a capacity of 900 tons per day is "one-sided," and so arranged that another side of like capacity can be added. It is a very conveniently-arranged structure, and while no space is wasted, it is very roomy. Machinery is used to do all that machinery can effectually do in the way of handling and cleaning the coal, and this machinery is so arranged that there is absolute safety for the employes engaged in the breaker. The dust is drawn from the breaker by an 8-foot Guibal fan, which is run by a belt from a pulley on the main rolls shaft. The atmosphere in the various rooms of the breaker is therefore much healthier and clearer than in the old time breakers. The cleaning of the coal is done so effectually that nothing but absolute waste goes to bank. The six boilers used to generate steam are heated with the refuse from the slate-pickers, which makes a good fuel, but is unsalable. Mr. Smyth, in reply to our question as to what percentage of the coal in the vein was brought to the surface said that he was confident that counting final robbing, he would get out 90% of it. Labor is economized at every point, and no coal is wasted.

Since the colliery was started there has been but one accident, and that was to a Hun, who was so ignorant as to disregard all cautions, and who was therefore a victim to his own carelessness.

PRIMARY EDUCATIONAL DEPARTMENT

FOR CANDIDATES FOR

MINE FOREMEN'S CERTIFICATES

AND FOR

STUDENTS OF MINING.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the sciences related to mining and to learn how to answer the questions in ventilation, surveying, and mechanics which are asked at the examinations for mine foremen's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine foremen and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and many calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

It will be seen the whole of th letters of the alphabet depend primarily for their correct construction upon the four laws of penmanship given in our first lesson, and we repeat them again: First, all strokes should be parallel; second, all strokes should be proportionate in distance; third, all lines should be proportionate in size; and fourth, all curves should be elliptical; and it must be clear to the mind of everyone that the least digression from these simple laws develops a deformity inexpressibly painful to the eye and the feelings.

In Fig. 14 (as before we will refer to the letters by numbering them from left to right) the first letter C satisfies the requirements of the four simple rules and is pleasing to the eye; the second letter illustrates the elements out of which the letter is constructed; the third letter is a deformity arising out of the imperfect

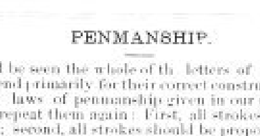


Fig. 14.

development of the upper loop, which is too short in the major axis; the fourth letter is not imperfect in the upper loop but very imperfect in the bottom scroll; first, the ellipses that ought to have developed it are too short in the major axis, and the fine hair stroke terminating the scroll is not parallel to the stem of the letter.

In Fig. 15 the first letter the bottom scroll is too large, and the upper loop too small. In the second letter the upper loop is too large both in the major and minor axes, andthe termination of the bottom scroll is an out-

Fig. 15.

rage on parallelism. In the third letter the upper loop is too long, and is an evident deformity; in the fourth letter the upper loop is developed out of an ellipse out of all proportion to the magnitude of the letter.

In Fig. 16 we have the letter D as it ought to be rendered in letter 1; in letter 2 we have the development of the letter, and it will be seen that to write this

Fig. 16.

letter with beauty and grace, the large ellipse ought to have its major axis inclined something after the order of the large ellipse of the letter B.

In Fig. 17 the first letter not only has the large ellipse the wrong inclination, but the hair stroke of the inner scroll is a violation of the first rule of penmanship, namely, that all strokes shall be parallel. In the second letter the large ellipse is inclined at the wrong angle, so much so that it makes an angle of 90° with what ought to be the true inclination of the major axis. The same occurs with the third letter, but the terminating scroll is a violation of the third rule, namely, all strokes shall be proportionate in size.

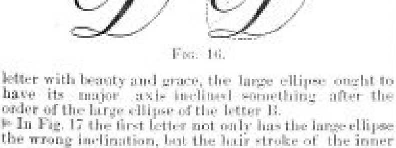

Fig. 17.

The study of these letters teaches more lessons than one, not only the necessary symmetry in writing, but it excites the observing faculties in noticing what is beautiful, proportionate, and harmonious in the development of all figures that are represented by lines.

CHEMISTRY RELATING TO MINE VENTILATION.

[CONTINUED.]

Proper Names of Gases.—The student must learn to give the compound gases their modern names, instead of using such obsolete terms as "carbonic acid gas" for there is not and cannot be, such a gas; this gas only manifests acid properties when dissolved in water.

CHEMICAL NAMES.	TECHNICAL NAMES.
Methyl Hydride.	Light Carbureted Hydrogen.
Hydride of Ethyl.	Silver Gas.
Carbon Monoxide.	Carbonic Oxide.
Carbon Dioxide.	Carbonic Acid.
Hydrogen Sulphide.	Sulphureted Hydrogen.
Nitric Oxide.	Nitric Oxide.
Water Gas.	Watery Vapor.

The Chemical and Physiological Action of the Simple and Compound Gases.—Hydrogen is the lightest known body and if atmospheric air be taken at 14·42 specific gravity, hydrogen is 1; consequently hydrogen is 14·42 times lighter than air. It is a colorless, tasteless, and invisible gas without smell; it cannot burn of itself; no amount of heat will alter it further than cause it to expand into a larger volume. It will not support life, and only destroys it by suffocation. If two volumes of this gas are mixed with one volume of oxygen gas, and a light be applied to the mixture, it explodes with terrible violence.

Oxygen is a colorless, invisible gas, without taste or smell, and is a little heavier than air in the proportion of 14·42 to 16, or, air being 1, oxygen is $\frac{16}{14.42} = 1\frac{1.58}{14.42}$. It exists in a free state in the atmosphere, and is the most active chemical element known, forming nearly one-half of the entire globe. It actively supports life and combustion, and at a suitable temperature all the known elements excepting fluorine will burn in it, forming oxides.

Nitrogen is a colorless, invisible gas, without odor or taste, and is slightly lighter than air in the proportion of air 1, nitrogen $\frac{14}{14.42}$. It forms nearly four-fifths of the atmosphere, and neither supports life or combustion after the manner of oxygen although it forms a part of the animal tissues. It extinguishes life not as a poison, but by suffocation.

Carbon dioxide = CO_2. The weight of air being 1, carbon dioxide is $\frac{22}{14.42} = 1\frac{7.58}{14.42}$, or nearly $1\frac{1}{2}$ times the weight of air. It is a colorless, inodorous, and invisible gas, and has a slightly acid taste. When breathed into the lungs its first physiological effects are manifested in the extremities, so that a man will fall paralyzed in his legs before mental consciousness is lost. Being a heavy gas it can be poured from one vessel to another like water; this can be proved by pouring it on the flame of a candle. It is known in mining as "choke damp," and is frequently found in old wells, is exhaled by men and animals, and is produced wherever carbon is burnt in air, as in coal gas, the oil of lamps and coal or coke fires. It will not support, but extinguishes flame. Carbon dioxide is soluble in water, one cubic foot of water at 32° F., absorbs 1·797 cubic feet of this gas at all pressures, so that such gas at a high pressure will be very soluble in water. The volume of the gas absorbed is inversely as the temperature, so much so that at boiling point all the gas is expelled from the water. At 68° F. each cubic foot of water is capable of absorbing ·901 of a cubic foot of gas. At the average temperature of 60° F. water will absorb a volume equal to its own of this gas.

The law of absorption is by weight directly as the pressure, and inversely as the temperature.

This gas is destructive to life, producing suffocation, and will not support combustion.

Methyl hydride, CH_4. The weight of air being 1, this gas is $\frac{8}{14.42}$, or little more than half the weight of air. When pure it is invisible, colorless, tasteless, and inodorous; but as found in mines it is seldom pure.

When mixed with twice its volume of oxygen or ten times its volume of air, it explodes when ignited with great violence. It burns with a bluish yellow flame, emitting very little light. It is known as "fire-damp" and as "marsh gas." It will not support life, and produces suffocation when breathed into the lungs.

Carbon monoxide, CO. The weight of air being 1, it is $\frac{14}{14.42}$ or slightly lighter than air. This is a poisonous gas, highly destructive to animal life. It is colorless and tasteless.

Hydrogen sulphide, H_2S, the weight of air being 1, that of this gas is $\frac{17}{14.42}$. This is a poisonous gas and should not be breathed into the lungs. It makes its presence strongly felt, having an odor like that of rotten eggs. It is soluble in water to which it gives a filthy taste. It is given off by stagnant water in mines, and by such waters as drain into the mine and hold this gas in solution. It burns with a bluish flame like sulphur, producing sulphur dioxide and water; it has a very low point of ignition, taking fire at the temperature at which lead melts. From this cause it is one of the most dangerous gases met with in mines.

Hydride of Ethyl, C_2H_6. This gas is heavier than air in the proportion of 1 to 1·04, and is nearly double the weight of ordinary fire-damp. It is true this gas is not found abundantly in coal mines in the United States, but it is nevertheless found in marked quantities in the steam coal of South Wales and the cannel coals of Wigan and Scotland. It is very explosive, the most explosive mixture being 1 of this gas to 10·6 of ordinary atmospheric air. It burns with a luminous flame, and rapidly elongates with a white tail the flame of a lamp, and from this cause it is called "silver gas."

The elementary gases, hydrogen, oxygen, and nitrogen, have no color, taste, or smell. Oxygen will burn in an atmosphere of hydrogen, just as hydrogen burns in an atmosphere of oxygen; but nitrogen will neither burn itself or support combustion in the ordinary sense.

The compound gases, methyl hydride or fire-damp, CH_4; hydride of ethyl or silver gas, C_2H_6; carbon dioxide or carbonic acid, CO_2, carbon monoxide or carbonic oxide, CO; are all without color or smell when pure. Hydrogen sulphide or sulphureted hydrogen, H_2S, has no color, but smells like rotten eggs, and carbonic acid has an acid taste.

The relative weights or specific gravities of the gases, simple and compound, from the standpoint of the chemist, calculated from the weight of a unit volume of hydrogen, are as follows:

Hydrogen	1	Methyl Hydride	8
Nitrogen	14	Hydride of Ethyl	15
Oxygen	16	Carbon Dioxide	22
Carbon	12	Carbon Monoxide	14
Sulphur	32	Hydrogen Sulphide	17

The specific gravity unit of the chemist however, is not adopted by the miner, because this unit does not suggest with sufficient clearness the tendency of the gases to float or sink in air; consequently the unit weight of gases adopted by the miner is that of air; therefore, air being 1, the specific gravities of the compound gases are:

Methyl hydride, or marsh gas	·55
Hydride of ethyl, or silver gas	1·04
Carbon dioxide, or carbonic acid	1·52
Carbon monoxide, or carbonic oxide	·97
Hydrogen sulphide, or sulphureted hydrogen	1·17

MECHANICS IN MINING.

PUMPS.

Ordinary Lift Pumps.—The mechanical requirements of a lift pump are first, that the bucket at the top of its stroke shall never reach an elevation higher than 28 feet above the water in the well or sump. No pump will work satisfactorily at this elevation if the upward velocity of the bucket exceeds 20 feet per minute, and even then the clack and bucket valves must be very light. For good average work the elevation should not be greater than 20 feet.

Perhaps to elucidate the subject of lifting pumps it would be better to explain their mode of acting. (See Fig. 1.) Externally an ordinary hand pump consists of the tail-piece T, and the barrel B. Internally we have the clack-piece C, which is placed in a suitable seat at the bottom of the working barrel, as shown at C. The clack piece consists of a cylindrical shell, which is packed either with hemp or leather to make it watertight. On the top of the clack-piece is a valve which opens on the ascent of the bucket. Now by a little con-

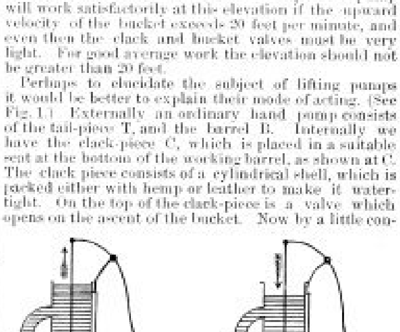

Fig. 1.

sideration it will be seen that as the bucket ascends it tends to produce a vacuum between itself and the clack. The atmosphere then immediately forces water up through the clack-valve into the barrel, so that when the bucket reaches the top of its stroke the barrel is full of water. On the downward stroke there being no force under the clack-valve it drops, but the bucket cannot descend without the bucket-valve opening to allow the water to pass through it. Fig. 1 shows the positions of the bucket and clack-valves for the upward and downward strokes which are indicated by arrows besides the pump spears.

Hand pumps of this variety are not now much used for mining purposes, plunger pumps having to a large extent taken their place. Lifting sets, however, are still extensively used in the sinking of shafts and for ordinary main pumps for ordinary mine drainage.

The lifting pump as used for shaft work, is a ponderous and expensive machine, and is only used in modern mining as a disagreeable necessity. It holds its own for the bottom set in a sinking pit for the following reasons: There is not and cannot be any standage; second, should anything happen to render the clack or the bucket inoperative, the spears may be drawn and the bucket changed; or should the clack fail in its action it can be fished up and a new one inserted in its place. To any person having a very elementary knowledge of pumps it will be clear that if the valves of a forcing set become inoperative, before repairs or corrections could be made, the water would rise in the shaft and flood the valve cases in such a way that they could not be reached.

What is true of a sinking pit is equally true of a mine where a danger exists of the valve cases of a forcing set being submerged under the conditions of a sudden outburst of water from old workings. It is, however, only necessary to make the bottom set a lifting one where the depth of the shaft exceeds 240 feet. In some old-fashioned arrangements two lifting sets are employed, one above the other, and the engine is balanced by a diagonal spear and bell-crank lever in such a way that when one set is plunging the other is lifting; but where a lifting and a forcing set are employed, both sets are worked by one main spear working from one end of the main beam of the engine, (see Fig. 2) L L is the lifting set F is the forcing set.

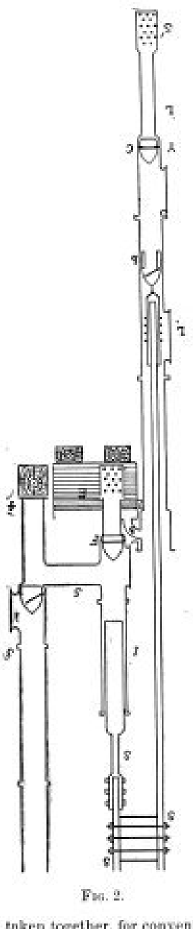

Fig. 2.

It will now be necessary to describe the principal details of a lifting and forcing set. At the bottom of the lifting set we have the strum marked S^3, and we have the clack and clack door seen at *c*, and the bucket and bucket door marked *b*, the spears S S S, and the cistern for the supply of the forcing set marked E. It will be here noticed that the lifting set delivers into a cistern from which the forcing set pumps the water to bank. The forcing set is provided with a strum, as seen in the cistern. Perhaps the portion of an ordinary forcing set of special interest to the student is what is called the H piece (the parts 1, 2, 3, 4, and 5 taken together, for convenience are here designated as the "H piece"). By close attention to the figure it will be seen the plunger works through a stuffing box on the top of leg, 1 of the H. Immediately below the cross-piece in the same leg of the H is seen the clack valve. Immediately above the cross-piece in the other leg of the H is seen the "keep" clack, which supports the water column by being shut when the clack valve is open. It will further be observed that the spear attached to the plunger is fastened on to the main spear by offset pieces in such a way that the main spear supports the ram, and the wet spears of the lifting set.

The thickness of pump sets is calculated by the following formula (English rule): The radius *r* of the set in inches multiplied by the pressure of the water per square inch *p*, and divided by the pounds in half a ton, 1120, or

$$\frac{r\ p}{1120} = T.$$

Here T is the thickness of the sets in inches.

The student must intelligently notice that it would be wasteful to make all the pipes in a long column of uniform thickness, but the thickness should never be allowed to fall below three quarters of an inch. The pressure of the water per square inch may be found by multiplying the vertical depth in feet by ·434. For example: A pit is 300 feet deep, and the set 16 inches in diameter; required the thickness of the set in inches. Here the pressure per square inch due to the water head will be 130 lbs, and the radius of the pump eight inches. Then

$$\frac{130 \times 8}{1120} = {\cdot}928 \text{ inch,}$$

or nearly one inch thick.

Generally the thickness of cast-iron water pipes is calculated by Mr. J. T. Fanning's formula as follows:

$$\text{Thickness in inches} = \frac{(\text{pressure in lbs. per sq. in.} + 100) \times \text{bore in ins.}}{4 \times \text{ultimate tensile strength.}} + {\cdot}333 \left(1 - \frac{\text{bore in inches}}{100}\right)$$

The ultimate tensile strength is usually taken at 18,000 lbs. per sq. in. According to the formula the thickness of set in above question would be thus:

$$\frac{(130 + 100)\ 16}{4 \times 18{,}000} + {\cdot}333\ (1 - \frac{16}{100}) \text{ or,}$$

$$\frac{230 \times 16}{7{,}200} + {\cdot}333 \times \frac{84}{100} = {\cdot}709 \text{ inches.}$$

The quantity of water in gallons that a pump of given dimensions will deliver to bank may be found in the following manner: First, to find the sectional area of the pump, we square the diameter in feet and multiply by ·7854, and this product multiplied by the length of the stroke will give the cubic feet of water lifted in one stroke of the pump; further multiply this last product by the number of the strokes the pump makes per minute and this will give the cubic feet of water the pump delivers per minute. But the work of pumps is generally given in gallons and not cubic feet, and there being 7·4805 U. S. gallons in a cubic foot; therefore multiply again by 7·4805, and you have the gallons of water delivered per minute by the pump. For example, a pump has a six feet stroke and a diameter of 16 inches; how many cubic feet of water will be delivered by one stroke?

Here $\frac{16}{12}$ is the size of the pump in feet, then

$$\frac{16 \times 16 \times {\cdot}7854 \times 6}{12 \times 12} = 8{\cdot}3776 \text{ cu. ft.}$$

To find the gallons of water as explained above, we multiply this by 7·4805, the gallons in one cubic foot, or

$$8{\cdot}3776 \times 7{\cdot}4805 = 62{\cdot}6686.$$

Suppose again, the pump makes six strokes per minute, then

$$62{\cdot}6686 \times 6 = 376{\cdot}0116 \text{ gallons per minute.}$$

The three questions already given would be stated as follows:

First,

$$\frac{16 \times 16 \times {\cdot}7854 \times 6}{12 \times 12} = 8{\cdot}3776 \text{ cubic feet.}$$

Second,

$$\frac{16 \times 16 \times {\cdot}7854 \times 6 \times 7{\cdot}4805}{12 \times 12} = 62{\cdot}6686 \text{ gallons.}$$

Third,

$$\frac{16 \times 16 \times {\cdot}7854 \times 6 \times 6 \times 7{\cdot}4805}{12 \times 12} = 376{\cdot}0116$$

gallons per minute.

It will be observed in these questions considerable calculation is required, but this may be avoided by the construction of a constant number which we will now proceed to explain. Take for example the second by way of illustration:

$$\frac{16 \times 16 \times \overline{{\cdot}7854} \times 6 \times \overline{7{\cdot}4805}}{\underline{12} \times \underline{12}}$$

Notice that the numbers above the line ·7854 and 7·4805, which are overlined, will always occur in questions of this kind, and the numbers 12 and 12 below the line that are underlined will also occur. Now, if the product of the first pair of figures be divided by the product of the second pair, we will get this constant, or

$$\frac{{\cdot}7854 \times 7{\cdot}4805}{12 \times 12} = {\cdot}0408.$$

It will be clearly seen that by the use of this constant the calculation is both shortened and facilitated, for instead of the previous long calculation we now have

$$16 \times 16 \times 6 \times 6 \times {\cdot}0408 = 376{\cdot}01 \text{ gallons.}$$

Or multiply the constant by the square of the diameter in inches and by the length of the stroke in feet, and the number of strokes per minute and we find the gallons the pump delivers per minute.

The ordinary pipes in a lifting set are made one inch larger in diameter than the bore of the working barrel, so that in the event of having to draw the bucket or clack they may pass freely through the set. The spears are made of the best pitch pine, and the section of the spears is calculated at the rate of five square inches per ton of load; or the following convenient formula may be employed: The square of the diameter in inches multiplied by the length of the column in feet, and by the constant number ·0008, will give the sectional area of the spears in square inches, and the square root of that will give the sides of the spears in inches.

The student will perceive that the section of a main spear will be equal to the sum of the sections of the lifting sets employed, if there be more than one.

NOTE.—In connection with the above it would be well to study the pump problems worked out on page 261, of the June issue, under the heading "Mechanics in Mining."

ARITHMETIC.

We are constantly meeting with people that are fairly expert in multiplying and dividing with whole numbers, but make the most outrageous mistakes when decimal points are involved. This statement should be a sufficient apology for the care we are taking in explaining the various modes of pointing off.

Suppose that from 27 it was necessary to subtract ·05. Now ·05 is a very small fraction of 1, indeed it is five hundredths of 1, and if you were presented with five one-hundredths of an apple you would immediately discover its miniature value, because if an apple was cut into a hundred parts, you would at once be conscious that they were no bigger than peas; and if you were presented with a fragment of an apple, the volume of which was no larger than five small peas, you certainly would not express your thanks very warmly for the gift.

Now the whole of the processes in arithmetic, and in advanced mathematics, are easily understood if people would endeavor to reconcile the queries involved by contrasting them with the common things of everyday experience. We are well aware that many of the words are new to beginners, and the object of these articles is to render the meaning of these terms clear to the uninitiated.

Let us return again to our problem, namely, the process of subtracting ·05 from 27, and let us suppose absolute ignorance of the use of the decimal point, and proceed as though the relative positions of the figures might be disregarded—by way of illustration let us notice that 2 at the left-hand side of 7 represents 27 or two tens and seven. Now invert the two figures, that is, set the 7 before the 2, and the altered positions of these figures will represent 72 or seven tens and two. It may almost appear to be playful, this mode of proceeding, nevertheless we must assume that the student's knowledge is either at zero or little above it, to develop the teaching of the lesson properly. Again

$$\begin{array}{r} 72 \\ {\cdot}05 \\ \hline 67 \end{array}$$

It will be seen that we have subtracted the 5 as though they consisted of five perfect units or five perfect things, and by thus proceeding we have made a fatal mistake. We have acted as though ·05 represented five entire apples, whereas it really consisted of an exceedingly small fragment of one apple. Again suppose we disregard the decimal point and even the units place, and so place the 72 over the ·05, as shown:

$$\begin{array}{r} 72 \\ {\cdot}05 \\ \hline 22 \end{array}$$

Now we have proceeded as though ·05 represented 50 apples, because we have taken it from the tens, and as 7 tens are 70 and 5 tens are 50, we must discover the serious error that has been made. Now, again, suppose the figures are wrongly placed for subtraction, as shown:

$$\begin{array}{r} 72 \\ {\cdot}05 \\ \hline 71{\cdot}5 \end{array}$$

We have committed another error by thus proceeding, we have used ·05 as though it was half an apple and the result is 71·5 apples are represented as being left. But let us make the subtraction correctly, then

$$\begin{array}{r} 72 \\ {\cdot}05 \\ \hline 71{\cdot}95 \end{array}$$

The result is 71·95 which is correct. Now then let us notice that either in adding or subtracting the decimal point is always set at the right hand side of the column of units or singles, or at the right hand of any figure representing units or singles. We are quite aware that the word unit is derived from the Latin language and never should have figured in the English language when the Saxon language had furnished us with a word the exact equivalent, namely, *one* and the word unit means precisely the same as *one*.

SCIENCE RELATING TO MINING.

Centrifugal Fans.

To those unacquainted with the principles of theoretical mechanics, the action of the Guibal, Waddle, and Schiele fans will be somewhat perplexing. It is a very easy statement to make, when it is said that they are centrifugal fans, and that the air is thrown off by centrifugal force. It is not our business in this article to give the mathematical value of the force, but to make the mode of its action plain and easy to understand. Newton first taught us that when matter was first moved by a single force, the particle of matter moved would continue its progress in the path of a straight line, until acted upon by another force, tending to move it in a different path. Now, centrifugal force is generated when an attempt is made to continually change the path in which a particle of matter is moving. If a straight lath be made to turn on one end as a center, while the opposite end is free to revolve in the path of a circle, and a marble to be placed about an inch or two from center, and the other end of the lath be made to revolve, the marble will at once begin a journey outward from the center of motion, and at once fly off from the other extremity of the lath. What moved the marble outward from the center of motion? Simply the marble by its inert force was moving in the direction of a more uniform, or a more nearly straight line path, one linear inch measured on the curvature of a small circle, is a greater divergence from a straight line than one linear inch measured on the curvature of a large circle. It is said that bodies have a tendency to fly off from the center of a circle, when they are confined to move in a curvilinear path. But the expression "to fly off" is so very vague, that we prefer the explanation previously given. Now, examples of the operation of this force are abundant in nature, the planets in the solar system would all fall into the sun, by his superior attraction, but for the counteraction this force exerts in the opposite direction to that of gravitation. The earth and the moon would run together with increasing velocity but for the preservative counteracting centrifugal force. The equilibrium of a planet in its path, may be imitated by fastening a piece of iron or lead to one end of a piece of string two feet long, if this weight be held by the piece of string at arm's length from your body, and you turn rapidly round on your heels, the ball will at once fly outwards, and remain at such an increased distance as will allow centrifugal force to exactly neutralize the force of the earth's attraction, tending to pull the weight of the string into the vertical direction of a plumb line. A very pretty illustration of centrifugal force is seen when a cup of tea is rapidly whirled round with a spoon, better still when a clear glass filled with water is placed on a dish. If the water is rapidly whirled round with a spoon, a depression will at once be formed on the surface of the water, after the manner of what is called a parabolic curve. By looking through the sides of the glass the depression can clearly be seen, and the water that overflowed from the full glass will be exactly equal in volume, to the depression produced by the centrifugal force. The governors of a steam engine are another illustration of the action of this force. A very beautiful illustration is met with, in the naturally serpentinous courses of rivers. At the outside of every curve it will be noticed that the centrifugal force of the particles of water in the moving current eats the land, or cuts it away, making the outside of the bend of the river precipitous, whereas a sloping shore will be seen on the inside of the curve where centrifugal force does not act. This is the exact analogue of the water pressing on the side of the glass, and the bottom of the depression in the glass corresponds to the pebbly sloping shore, on the in-side curve of a river. Now, how easily we can associate these illustrations, with the action of a centrifugal fan. The air is continuously taking in at an orifice round about the center of the fan, and the centrifugal force developed is made to be equal to the frictional resistance of the air current, that circulates through the mine.

The Air in Mines.

The average temperature of all mines is above that of the surface air; why it is so has never yet been clearly shown. One thing, however, is quite clear, that at the depth of about 50 feet, some say 100 feet, the rock or earth has a constant temperature corresponding to the mean annual temperature of the air, of any particular region. It is extremely probable that the temperature between 50 and 100 feet will be constantly nearly the same. In descending into the earth's crust, below 100 feet the temperature of the rocks increases at the rate of one degree for every 50 or 60 feet of descent. We say 50 or 60 because the temperature increases more rapidly in some cases than in others. In very deep mines the surface air is only at the hottest periods of the year, at the same temperature as the return air that has performed the circuit of an extensively-worked deep mine. In shallow pits the external air is always hotter than the air in the mine, because as the ventilating current traverses the galleries of the mine, it is cooled, the rocks being at a lower temperature than that of the external air. But this is not all, the cooling of the air produces a marked change in its composition. Hot air contains a large quantity of watery vapor, or more properly expressed, water as gas. The quantity of water-gas that air contains varies directly as the temperature of the air, this is why wet clothes held before a hot fire are rapidly dried. The air between the fire and the wet article is heated, and at once abstracts the water from the cloth, as water-gas; but the moment this hot air is cooled a cloud like that of condensed steam is seen, because the cool air can no longer retain its previous full charge of water-gas. Now, in summer time, especially on warm days, the roads in the mine are very wet, and unpleasantly dirty, the roof is covered with drops of water, and it is thought by some that the rocks shed more water in summer than in winter. This is quite a mistake: the water that makes the roads sludgy and covers the roof with drops is distilled from the air. Now the same mines in winter are characterized as being very dry. The reason of this is not far to seek; the cold air on entering the mine becomes heated, and on this taking place its power for absorbing water-gas is increased, the result is the water on the roof and on the roads is said to be dried up, that is to say, warm air has the power of converting the water into a gaseous form, and it is thus carried off. But what we have been speaking about in the mines takes place on a grand scale in nature, the air near the surface of the earth is always at a much higher temperature than the air of the upper regions of the atmosphere; it is for this reason that lofty mountains on the torrid zone are capped with everlasting snow. The warm air near the earth's surface absorbs water from the sea and the surface of the land, and when this air ascends to elevated regions it is chilled or cooled, and at once gives up its water in minute particles, so small that the mechanical movements of the air are quite sufficient to keep them floating, and countless millions of these little particles go to form clouds, which correspond with the cold drops of water on the roof of a seam in summer; so that what takes place in the seam is only a miniature copy of the operations of nature, in her more majestic transactions. It has often been observed that in the in-bye districts of a mine, where the air is warm and dry, warm because its temperature has been increased by the absorption of heat from the rocks, that the lamps do not burn so brightly, and that the men become dry and thirsty. The reason of this is deeply interesting. The greedy, parched air absorbs or dries the moisture out of the men's skins, and unless they have access to drinking-water, their blood becomes thick and hot, and they feel a feverish, painful lassitude which overtakes them. The same warm air, before reaching the lamps, has been greedily drinking up water in its journey, and is thus so heavily charged with water-gas, that its oxygen is diluted, and the result is dull, sickly, unexciting lights.

This subject is full of interest, for while the hot air dims the flames of the lamps, it renders the fire-damp with which it may be charged less dangerous and explosive. Nature is full of such marvelous counterchecks, and it must have been observed that explosions of fire-damp are more frequent where the air is fresh and cool than in surcharged hot air.

The Pressure of Gas in Coal.

Coal in the Bituminous seams, is always more or less subjected to bleeding. This is well known to the practical miner, he is constantly observing the sweating of the coal, accompanied with a hissing sound. The sweating undoubtedly is produced by the pressure of the gas stored up in miniature cavities and fissures of the seam.

The pressure of the gas is a subject of increasing interest, it has been found in some cases to be nearly equal to the pressure of the steam in the boilers of steamships. Pressures of 200 lbs. and upwards have been found to be common in deep seams newly opened out. What is interesting about the matter is the co-relationship of the pressure of the gas to the pressure due to a vertical column of water, measured from the seam to the drainage level of the rocks overlying the seam.

To make this clear, let us suppose a seam to be 250 fathoms from the surface; again, let us suppose that the drainage level is about 50 fathoms from the surface. Now by this data we may with considerable accuracy calculate the pressure of the gas stored up in the cavities of the seam.

Suppose the seam has not been wrought, but has been pierced by a bore-hole; if a long iron tube was inserted in this bore-hole and made gas-tight, that is to say, made to fit the hole so closely by some system of packing that no gas could escape—and a pressure gauge was screwed on the upper end of this pipe and allowed sufficient time for gas to accumulate in the bore-hole, the pressure ultimately observed might first be calculated as follows: vertical height of water being 200 fathoms, then

$$\frac{200 \times 6 \times 62{\cdot}5}{144} = 520 \text{ pounds press-}$$

ure on the square inch.

This calculation might, however, have been made by a simpler process, which we highly recommend; a square inch column of water having a vertical length or rise of 6 feet, weighs nearly 2·6 pounds, therefore $200 \times 2{\cdot}6 = 520$, or is equal to a pressure of 520 pounds on the square inch, as before.

Often, as faults and dislocations, water and gas are met with in unusual quantities; sometimes on cutting a fault, gas is given off generally at the bottom of the seam, and this gas often consists of sulphureted hydrogen. Water is often met with at faults, and it generally comes off at the fault at the top of the seam, and after the water has expended itself, it is followed by gas, which also consists of sulphureted hydrogen. Now, why gas should be found at the bottom of the seam and water at the top of the seam is a matter full of interest. Water is sometimes given off at the bottom of the seam, and when that is the case the reason why requires observation and investigation.

Now when water is given off at the bottom of the seam, some cavity in the neighborhood of the fault contains gas at a high pressure, but is situated above another cavity filled with water, so that while gas is pressing on the water, water flows from the bottom of the seam, through some vent or parting in the fault; but as water is heavier than gas, if the water and the gas are found in one cavity in the bottom stratum of rock communicating with the fault or fissure, then gas only is given off, and sometimes at a high pressure. But it will be noticed that after a while the gas is all spent off, and the air in the neighborhood of the fault resumes its normal condition. The gas is expelled by the operation of Boyle's law; it exists in this bottom cavity at a pressure considerably above that of the atmosphere, and if the pressure of the gas in the cavity was three times that of the atmosphere, on that pressure being removed it would expand into three times its original volume, or every cubic foot in the cavity would expand into three cubic feet, two of which would be expelled.

When the water is given off at a fault at the top of the seam, we may certainly expect this water to be followed by gas, because, being lighter than water, it is pent up at a high pressure above it, and the high pressure of the gas causes a rapid or violent outflow of water. Now as the gas cannot sink in the water, being lighter, if the bottom of the cavity communicates with the fault, then no gas will spend off until the water has all been expelled.

These facts correspond with everyday experience, and happy is the man that takes a pleasurable interest in these matters, because it is out of such observations that knowledge and experience are matured, and men are made useful and profitable to themselves and others.

Mine Water.

Mining is a vast and comprehensive subject, nevertheless the important details that should be learnt can be mastered by moderate industry if the student can but possess himself, and make study a pleasure instead of irksome toil.

Mine waters are interesting from many points of view, some of them are so relatively pure and good that they may be used for drinking purposes; but such a state of purity is seldom met with, indeed, at many large mines thousands of pounds are spent annually in providing pure water to feed the boilers, and all the while delivering into neighboring streamlets volumes of water equal to five hundred or a thousand gallons per minute from the pumps that are draining the mines.

Now mine waters hold in solution corrosive substances such as the sulphates of iron, lime, soda, and magnesia, and the chlorides such as chlorides of iron, lime, and so on. Now these bodies held in solution are not only destructive to pumps, to the shoe leather of the miners, and to their clothes, but if this water should be used to feed the boilers it rapidly destroys the plates, and soon ends in making the boilers worthless, or induces the greater peril of so weakening the plates as to produce explosions. This being the case, the matter is a serious one to the careful and competent mine engineer. So strongly are some mine waters charged with sulphates of iron, and even sulphuric acid, that the valves and their seats and the shells are rapidly destroyed, entailing serious expense, and often presenting difficulties that render working the mine a doubtful speculation. There is something marvelous about chemical action; actions and reactions are being constantly investigated, yet after all is done and said, there is a subtlety about chemical action that baffles the investigations of the most gifted minds; for example: sulphate of lime is known to the chemist as $CaSO_4$. Now this salt, when held in solution by water, and that water is in contact with iron, the SO_4 combines with the iron forming $FeSO_4$, the lime taking up the oxygen and carbonic acid from the water becoming again carbonate of lime. The quantity of sulphur in the shape of sulphide of iron contained in the rocks overlying and underlying the coal seams, and even in the coal seams themselves is a very large amount. Sulphur in coal is an undesirable constituent, reducing its commercial value, and doing damage in various processes of manufacture, such as in the smelting of iron, and reducing the commercial value of the iron or otherwise involving considerable expense in its removal, when it is necessary to produce the better qualities of iron or steel. The waters that percolate through the rocks become saturated with sulphur compounds, and in nature's marvelous laboratory the sulphur compounds indicate their changes, and we find the sulphur at last concealed in the interstices of a coal seam as sulphide of iron.

The Principle of the Jigger Screen.

The jolting or jigger screen, lately introduced into mining for screening, or more correctly, for sizing coals, is worth studying, and indicates the great advances that are being made by mankind in the pursuit of a knowledge of the operations of natural laws. The essential principles on which the screen acts, are three in number; first, the law of inertia common to matter; second, gravitation; third, friction.

The screen is made to move rapidly backwards and forwards, that is to and fro in the direction of its length, or, to use technical language, it has a reciprocating motion in the direction of its length, the throw being equal to 6″ or 9″, and this motion is produced by an eccentric and eccentric rod.

Now if the screen was set perfectly level, the coals would simply alternately move backwards and forwards, and would never advance to either end of the screen, consequently, the screen is made to have a small inclination, of about 1 in 18, this fall renders the force of gravitation about equal to the frictional resistance of the moving particles, so that on the backward motion of the screen, the pieces of coal are carried forward, by this simple and interesting arrangement, the jigger, or jolting screen, has made a complete success.

Its advantages are very great, not only can two screens be conveniently arranged under each other, and all the sizing done without having recourse to the old-fashioned methods of re-elevating the coals, and passing them through the second set of screens, but the coals are evenly distributed onto plate belts, where they may be screened and dressed for delivery into trucks.

Let the student take a small wooden board or thin sheet-iron tray, and place on this pieces of stone or coal and imitate the arrangement that has been described, and after having done so, he will then clearly understand all the principles involved.

Carbonic Oxide in the Fire.

When all the gas has been expelled and burned, which is given off by "green" or fresh coals, and the cinders are glowing with yellow heat on top of the fire, faint blue lambent flames are seen to be dancing; this flame is produced by carbonic oxide gas (CO), burning into carbonic acid gas (CO_2). The reason why carbonic oxide gas is produced in the lower portion of the fire is not far to seek; the immense surface of the rough cinders being at a high heat, are ready to consume more oxygen than the volume of air passing through the fire can supply, the result is the formation of (CO), instead of (CO_2), and it is only when the (CO) gas has reached the upper region of the burning mass, that additional air can be supplied to burn it into (CO_2).

Carbonic oxide is abundantly produced in blast furnaces, used for smelting iron, the hot blast can never be made sufficient to produce carbonic acid, and indeed, if carbonic acid gas was produced in the blast furnace, it would be at a lower temperature than that which produces carbonic oxide, and the result would be the wasting of the fuel. Here we are confronted with the beautiful operations of natural law, in the first place, the air injected into the furnace is at a high temperature, indeed, the temperature is such that the density of the hot blast is only about one-third that of the atmosphere, so that every cubic foot injected into the furnace is only equal in density to one-third of a cubic foot of normal air. The result is, if carbonic acid gas is for a moment produced, no doubt it will be when contacting with the first particles of burning coke; the upper particles of coke will take from that gas one particle of oxygen; producing two volumes of CO, thus while carbonic acid is produced at the lower portion of the furnace, the upper layer of incandescent cinders immediately converts the carbonic acid into carbonic oxide, and as carbonic oxide, it escapes from the upper portion of the blast furnace.

So conscious of this chemical fact are the smelters of iron ore, that in later days, a trap has been provided to collect this carbonic oxide, and burn it under boilers for generating steam.

Modern furnaces are provided with a kind of trap or bell top, so arranged that the carbonic oxide is carried away by pipes to the boiler fires to be burned, while the admission of coke, ore, and lime, only takes place intermittingly, and at the period of the admission of the charge, the characteristic carbonic oxide flame is seen on the top of the furnace.

Carbonic oxide gas is abundantly produced in cupola furnaces for melting cast-iron, and this characteristic flame may be witnessed when the cupola is in action at any foundry.

EXAMINATION QUESTIONS ANSWERED.

QUESTION 43.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

How would you examine the various safety-lamps in common use as to their safe condition for testing gas, also for working with, and what appearance has the flame of the lamp when brought in contact with various mixtures of an explosive nature?

ANSWER.—I would examine all parts of the gauze to see that it was clean and perfect. I would examine all joints to see that they were tight and perfect, and also examine the glass cylinder of those of the Clanny type to see that it was perfect.

With 2% of gas in the air, a small blue cap is discernible on the top of the flame. With 3% the cap will show from ·3 to ·4 of an inch above the flame. With 3½% the cap will be from ·6 to ·7 of an inch high. With 4% the cap will be nearly an inch high. With 5% the cap will almost fill the gauze, and with 6% an explosion of gas will frequently occur inside the gauze.

QUESTION 44.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

Will air diffuse with or dilute an accumulation of fire-damp quicker than an equal accumulation of black-damp? Give reasons in full.

ANSWER.—Air will diffuse with or dilute an accumulation of fire-damp much quicker than an equal accumulation of black-damp. Experiments have shown that a light gas will diffuse much quicker than a heavy gas, and that the ratio of diffusion is inversely as the square root of density.

Thus, the density of fire-damp is 8, the density of black-damp is 22, and the density of air may be approximately taken as 15. Then we have

$$\sqrt{15} = 3{\cdot}87 \text{ and } \sqrt{22} = 4{\cdot}69,$$

therefore their relative time of diffusion would be as 3·87 is to 4·69. In other words air will diffuse a given quantity of fire-damp in 3·87 minutes, while it will take black-damp 4·69 minutes to accomplish the same result.

QUESTION 45.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

Suppose you have charge of a mine generating fire-damp which requires active ventilation to keep the mine in a safe condition for working, upon arriving at the mine in the morning, unexpectedly, your fire boss reports that a certain door has been left open the evening before, causing a large accumulation of fire-damp in a certain part of the mine, how would you proceed to remove the same with the greatest safety to the men and the mine, the mine being ventilated by furnace power, and state what kind of lamps you would use while removing the same?

I would gradually remove the fire-damp in the following manner:

I would keep up as hot a fire as possible in the furnace, and increase the ventilating current. I would then, by opening and closing such doors as would suffice, divert a portion of the air current into the affected part, taking care to have a sufficiently large current flowing out of the main return to dilute the gas forced gradually out of the affected portion of the mine. I would keep this up until I had secured a normal state of affairs in the affected portion and would then restore the doors and main current to their proper conditions. While doing this I would allow no workmen in the affected portions but those necessary to restore ventilation and I would use no lamps but safety-lamps while prosecuting this work. Further, I would have no men engaged in the work but those who were accustomed to working in gas, and who fully understood the principles of the safety-lamp. After restoring the ventilation, I would endeavor to learn which of the employes had left the door open, and when found I would discharge him, for he would have shown by his action that he was too careless to have around the colliery in any capacity.

QUESTION 46.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

State fully how you would use the safety-lamp in testing gas, and under what circumstances is it unsafe?

ANSWER.—I would lower the flame as much as possible and slowly insert it in all places in which gas could accumulate, and would watch the flame carefully for a cap or for an ignition of gas in the gauze. If the latter occurred I would gradually withdraw the lamp, and if the gas still burned in the gauze I would smother the flame under my coat, always being careful to move the lamp slowly so as to prevent the flame being blown through the gauze.

In testing gas a lamp may be unsafe because the gauze is defective; because the gauze is greasy and dirty, and the grease and dirt ignite and fire the gas; because it is thrust into or withdrawn too rapidly from the explosive mixture and the flame be thus passed through the gauze; or because through inattention the lamp is left so long in the explosive mixture that the explosions inside and the heat thereof, have burst the gauze.

QUESTION 47.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

In a mixture of air and gas where safety-lamps are used, what should be done to prevent an explosion should the lamp become filled with flame?

ANSWER.—The lamp should be withdrawn slowly so that the flame be not passed through the gauze, and if the burning gas in the gauze does not die out owing to a better atmosphere, the lamp should be placed under the coat and the flame extinguished by depriving it of air, or in other words it should be smothered. It should never be extinguished by blowing.

QUESTION 48.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania on October 28, 29, 30, and 31, 1889.

How does fire-damp appear in a safety-lamp, and what proportion of fire-damp is mixed with the air when a cap begins to appear on the safety-lamp? At what proportion does it explode, and at what proportion will it extinguish lights?

ANSWER.—In the Galloway Royal Society's Journal of 1876, the following was given as to the appearance of fire-damp in a safety-lamp:

"The wick of the lamp, having been carefully trimmed, was drawn down until the flame presented the appearance of a small blue hemisphere about one-eighth of an inch high, one-quarter inch diameter at the base, and having a conical speck of yellow in the middle near the top.

"A mixture of one part of gas with sixteen parts of air gave a voluminous waving, spindle-shaped blue cap 3½ in. high.

"One part of gas with 18 parts of air gave a cap 2 in. high, which burned more steadily.

"One part of gas with 20 parts of air gave a cap 1½ in. high, with nearly parallel sides to about ⅔ of its height and then tapered to a point at the top.

"One part of gas with 25 parts of air gave a conical cap from ½ to ¾ in. high.

"One part of gas with 30 parts of air gave a conical cap ½ in. high.

"One part of gas with 40 parts of air gave a conical cap ¼ in. high.

"One part of gas with 50 parts of air gave a faint cap ⅛ in. high the top having the appearance of having been broken off.

"With one part of gas and 60 parts of air it was hardly possible to distinguish anything above the small oil flame."

Fire-damp explodes when it is mixed with air in the proportion of one part of fire-damp to thirteen parts of air. When there is only 9 or 10 times as much air as fire-damp, the explosive force is greatest. If the proportion of gas be greater than one part out of 9 or 10 of air, by volume, the force of the explosion gradually becomes less and less, until, when there is only five times as much air as gas, the mixture will not explode but will, on the contrary, extinguish a light.

QUESTION 49.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

If the temperature of 1,000 cubic feet of gas be raised from 60° to 90°, what will then be its volume?

ANSWER.—As air or gas expands $\frac{1}{460}$ of its volume for every degree of heat added, it will expand $\frac{30}{460}$ when the temperature is raised from 60° to 90°. Then as $\frac{30}{460}$ of 1,000 = 65·40, the volume at 90° will be 1,000 + 65·40 or 1,065 cu. ft.

QUESTION 50.—Asked at the Examination for Certificated Mine Bosses in the Bituminous Regions of Pennsylvania, on October 28, 29, 30, and 31, 1889.

If a room in a mine, 10 yards long, 4 yards wide and 3 yards high, be filled with fire-damp, how much pure air will be required to bring the mixture to an explosive point, and if the same was exploded, to what area would it extend?

ANSWER.—The room being 30 ft. long, 12 ft. wide, and 9 ft. high will have a cubical capacity of 3,240 cu. ft. To make 3,240 cu. ft. of gas explosive we must add to it 13 times as much air as there is gas. Then 13 × 3,240 or 42,120 cu. ft. of air must be added to make an explosive mixture.

The distance to which the explosion would extend cannot be accurately determined, but it has been found that the flame of a violently explosive mixture will expand to about 8 times the volume of the gas. As the explosive mixture in this case would consist of 3,240 cu. ft. of gas + 42,120 cu. ft. of air or 45,360 cu. ft., it would expand to 45,360 × 8 or 362,880 cu. ft. Then as the height of the workings is given as 3 yds., or 9 ft., the explosion would extend over an area of 362,880 ÷ 9, or 40,320 sq. ft.

QUESTION 4.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In a seam or vein pitching 65° and 30 ft. thick, where large quantities of fire-damp are given off, what plan or system would you adopt with regard to mining and ventilation?

ANSWER.—I would work the coal on the breast and pillar system, making the gangway or haulage road the intake, and I would ventilate with an exhaust fan. I would divide my air so as to have no more than four breasts on each split, and I would make the inside manway of the inside breast the intake for the split, and the outside manway of the outside chamber or breast, the outlet. I would take the air up the intake just described to the face, across the face and down the other side to the first heading or cross-cut from the face, through it to the next breast or chamber, up it, across the face, thence by way of the upper heading to the next breast, and so on until I reached the outside manway of the outside breast of the split or group, and from there I would take it direct to the main return air course. The work should all be done with safety-lamps.

QUESTION 5.—Asked at the Examination for Certificated Mine Foremen of the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In a seam or vein pitching 20° or less, and 8 ft. thick, where large quantities of fire-damp are given off, what plan or system of mining and ventilation would you adopt?

ANSWER.—I would work the coal on the pillar system, and ventilate the chambers or breasts in splits or sections of say 6 or 8 breasts each, and would have an air current of sufficient volume to dilute and carry off all gas. My system of ventilating would be similar to that given in the preceding answer.

QUESTION 6.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania on July 6 and 7, 1891.

What gases destructive to life are met with in coal mines—and what experience have you had with each, and in what mines did you encounter them?

ANSWER.—Light carbureted hydrogen, or fire-damp, carbonic acid gas, or black-damp, carbonic oxide, or white damp. I have worked in ——— colliery where large quantities of fire-damp are met with, and have been frequently driven out of my chamber by feeders that I cut. I have never been burned, because I could detect the gas in my safety-lamp and I was always on the lookout for it. I worked at one time in ——— colliery before the present owners had it and suffered from the effects of black-damp owing to insufficient ventilation. At one time the furnace, which produced the little supply of air we had, was carelessly allowed to go out, and I noticed that towards the close of the day I became sleepy, and very tired. My lamp did not burn with its usual brightness, and I knew that the cause was black-damp. I quit work and went to the surface. As soon as I reached pure air I was seized with a violent headache, and for several days felt the effects of the poisonous gas. I never worked at that mine again. I worked at ——— colliery at the time of the explosion in ——— and assisted in the rescue work. Owing to a portion of the mine being on fire a little carbonic oxide was met with in the air. A couple of the weaker men in the rescuing party were partially overcome by it, and I assisted in getting them to the surface in time to save their lives.

QUESTION 7.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Give the plan or system of ventilation adopted in some mine at which you have worked, and state the difficulties that may be encountered, when final robbing takes place, to maintain the ventilation?

ANSWER.—I always worked in collieries ventilated by either an exhaust fan or furnace, and the air current was divided into splits, so that each section of the mine had its own air. There was comparatively little difficulty in maintaining the ventilation when the final robbing was done owing to this split system. We did, however, have a little trouble at one time. The robbing brought on a squeeze that burst out several stoppings and also partially closed an air course. As the vein gave off considerable fire-damp, we were required to quit robbing, and to set to work to restore the ventilation as soon as possible. This we did by putting up temporary stoppings with brattice-cloth, while another force cleared up the falls in the air course. All work was done with safety-lamps, and two fire-bosses were on duty while this work was being done.

QUESTION 8.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

A tunnel is driven from the surface, cutting three seams or veins, and having two gangways on each seam or vein, also two gangways are in operation on each of these veins below water level. How would you ventilate this mine, using only one fan?

ANSWER.—I would drive an airway and second outlet in the vein from the face of the tunnel if I had pitch enough. If not I would sink a shaft. I would place an exhaust fan on this airway. I would drive airways in the veins from each of the lower level gangways to those on the tunnel level. Then with a series of stoppings and crossings I would ventilate each gangway with a separate split.

QUESTION 9.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In mines where fire is likely to occur, what precautionary measures would you adopt in your system or plan of ventilation, so as to guard against serious accident to life and property?

ANSWER.—I would have a line of water pipe along each gangway, attached to the column pipe in the slope or shaft, and I would have a number of places on the pipe lines where hose could be attached, or the water tapped. I would use the plan of separate splits in ventilating the mine, and would have doors so placed that by closing them I could reverse the air current in case the fire occurred in the intake air course. I would use no inflammable material in the construction of air stoppings.

Progress of Electro-Magnetic Science.

Arthur E. Kennelly, chief electrician of the Edison laboratory, at the close of a lecture delivered recently before the Brooklyn Ethical Association, on the evolution of electric and magnetic physics, thus summed up the important phases of the subject:

1. In electro-magnetic science the great achievement since Faraday's time has been the determination of the fact that all electricity flows, or tends to flow, in closed curves or circuits, so that we have the electrostatic circuit, the galvanic circuit, and the magnetic circuit, each resembling, as it were, an endless chain or a bundle of endless chains; and the laws which control these three different types of circuit show wonderful analogies.

2. The due appreciation of the influence of the ether and its importance in all electro-magnetic phenomena. While originally the electrical activity seemed to be confined to the battery or conducting wires of a galvanic circuit, it is now believed that the ether surrounding these conductors plays fully as active a part in the process of conduction; and the mind sees free space no longer void, but filled with an active and responsive substance—the ether. It looks almost as if matter were inert in comparison with the ether which surrounds it. Once more in the evolution of thought the tide of unbelief has turned, and we hold, under somewhat altered premises, the dictum that Torricelli refuted—namely, that "Nature abhors a vacuum." The properties of the ether almost threaten to surpass in interest and importance the properties of the matter it environs and pervades.

3. The evidence in favor of the proposition that light is a vibratory disturbance in the ether of an electro-magnetic nature is such as almost to amount to demonstration. When this shall be generally accepted, the whole domain of optics and radiant energy will be enrolled as one department and property of electro-magnetic physics.

Difficult as it is to clearly apprehend the course of evolution in the near past, where events press upon us in a narrow bounding throng, and the workers at the great loom of history yet stand by the mesh their hands have helped to weave, how still more difficult it is to guess the future! The prospect that opens is, however, a brilliant one. We may well believe that in science the same evolutionary process which has united electricity and magnetism, and welded both with radiation, will continue to magnify, simplify, and unify. Contrary to the course of evolution in the organic world, "from the homogeneous to the heterogeneous, the simple to the complex," the development of science is from the heterogeneous to the homogeneous, from the complex to the simple, and just as the evolutionary course of religious belief was from polytheism to monotheism, so with every fresh acquisition science becomes greater and grander and more succinct.

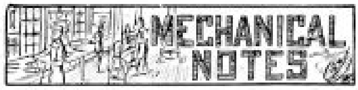
In the arts, electricity is destined, even apart from future discoveries, to take into its own hands the distribution of power. The telegraph has conquered time, and the electric motor is born to triumph over space; but whether we watch the vibrations of the telegraphic recorder that spells its messages across the sea, or watch the electric car, urged by invisible hands, pursuing its stealthy way, the rhythmic words of Ruskin rise into recollection's sight, "Not in a week, or a month, or a year, but by the lives of many souls, a beautiful thing must be done."—*The Northwest Magazine.*

The Study of Electrical Engineering.

We are constantly in receipt of inquiries from all over the country inquiring about the best ways, both practical and theoretical, of studying electrical engineering. An answer to these is by no means easy, on account of the great diversity in the needs and attainments of those who ask them. It should be borne in mind that electrical engineering is now rapidly becoming a crowded profession. The electrical schools are turning out every year hundreds of clever, well-educated young men who intend to devote themselves to the study of applied electricity. The result of this is two-fold—it makes competition rather severe, and the attainment of success by no means easy unless backed by a combination of ability and good fortune. In the second place it makes the task of the electrician who has graduated only from the workshop especially severe. Every profession goes through in its course of growth a series of sudden bursts of activity. Not many years ago civil engineering was the popular study among young men of scientific proclivities. The result was an enormous crowd of bright young engineers who glutted the market for brains for the time being, and by their very numbers made the chances of those who came after them much less than their own had been. It is all very well to quote the old saw that "There is plenty of room at the top," and say that for the young man of ability there is no such thing as a crowded profession. To a limited extent there is undoubtedly truth in these trite observations, but there is little comfort in them for the average man who enters the professions. Sheer ability alone seldom brings any man in professional life to the very front rank, and especially is this true of avocations in which the work is not individualized, as it is in the law and in medicine, but depends on great organizations. Both in civil and electrical engineering the first-class places that can be obtained are not very numerous, and the chances of individual work are lessened in the latter case by the existence of very large companies controlling the bulk of the business. The men who hold the good places, however they get them, are generally active and intelligent enough to keep them, and in electrical work the vast majority of the prominent men are under 40 years of age and consequently look forward to a quarter of a century of active professional life. They are sitting on the top of the ladder and smoking the pipe of peace, while the youngsters may have the privilege of cooling their heels on the bottom rounds. This is not in the least deliberately intended to discourage the study of electrical engineering, but its purpose is to hint to those who contemplate entering that profession that it is well not to raise their expectations of great and immediate success too high. To those who are willing to take up the study of practical electricity in a sensible, hard-headed way, looking on it as a lifework that will constantly interest them and as a means of livelihood at least as good as they are likely to find in business life under our present conditions, we would say, go in and work with every bit of energy you have. You may not get rich or famous, but you will have an honorable calling and a more respectable living than most of your fellow-mortals. The better education you start with the better off you are, but practical experience you have got to acquire somehow, whether you are a graduate of a scientific institute with a long name or not. You will most likely have to take off your coat and do a good deal of dirty, hard work, but it will not hurt you any more than it will any one of your 65,000,000 fellow-citizens. The only advice that we can give that will be of general assistance is to get as good a training as you can afford for the purpose of getting as good a start as may be, then get a foothold—a good one if you can, any sort of one if you cannot; and having obtained it hang on and do straightforward, faithful work.—*Electrical World.*

The London-Paris Telephone.

About fifty conversations per day are transmitted by the London and Paris telephone. These conversations are limited to three minutes each, unless one renews the payment, which is two dollars, and obtains another three minutes of this rather costly sociability. A bell rings automatically when the time is up, and the circuit is cut off; and no one is allowed the use of the instrument for more than six consecutive minutes. The receipts of the company at this rate are not less than $100 a day which would amount to $36,500 a year. The cable used has four conductors, giving two complete circuits. Each conductor consists of a strand of copper wire weighing 160 pounds to the mile, and covered with alternate layers of a composition and gutta percha. The four conductors are twisted spirally round each other and inclosed in a covering of twisted hemp, and this again in an outer covering of sixteen spirally wound galvanized iron wires.—*Mechanical News.*



Why Some Boilers Explode.

To many owners of plants a boiler is a boiler no matter how constructed, what shape or design it is, their only reliance is the thickness of plates and size of rivets. No attention is given to principle of circulation or difference in expansion between different parts of boilers and effects of same. The above class of proprietors do not believe in having inspections, they would save the cost of them and risk their own and the lives of those around. They know not that explosions have occurred with plenty of water in boiler or that many are due to unequal expansion and contraction through poor design; caused by dangerous defects and not discovered in time. They do not know that the safety of a boiler depends upon the circulation as much as upon the strength of the material. It is sometimes very hard to make them understand that thorough inspections by practical men are the only means of ascertaining the condition.

The ordinary two-flue boiler—and many are in commission to-day—have been very prolific in explosion; the greatest defect in design of this class of boilers is that of unequal expansion between flues and shell.

If large flues are put in they leave little space between flue and shell; leaving small body of water to amount of heating surface; dangerous cracks occur on heads at point between flue and shell on bends of flange and especially if bends of same are turned radical, or with small radius, either designedly or through attempts to fit head to shell.

If an iron head and grain of plate runs from top to bottom, as many are through lack of knowledge or want of thought in that direction they invariably crack, often on being first fired up.

Often sectional area above these boilers are poorly braced and heads thus receiving in addition to boiler pressure the pressure of expansion of flues.

Often braces in these boilers are found broken, and if these defects are neglected serious ruptures, if not explosion must follow.

Often it is impossible to see these checks when they first occur, especially if water used has lime or magnesia in it, that part (side of flues) is such that deposit collects around flange of heads, and heads of rivets of flue and shell; while being a bad place to clean it hides any of these defects from view, and should it be cracked through the leakage will help to draw deposit to that point, and should it be leaking bad it cannot be observed from inside. Many of these boilers are very long and no doors at the rear end of settings consequently the accumulation of ashes is so great that it is impossible to see the rear end only by taking down brick-work.

The above class of steam users will hesitate about doing any such work as it costs more than insurance usually to tear down and repair same; they do not consider it any advantage to them to be protected, they usually hire men to look after their boilers whose experience has been very limited, but are working cheap, but they are heard of often through the press of the country in something like the following notice: Small & Gains boiler exploded today with loss of life and property, cause not known; often remains not found yet.

Yet with such lessons almost daily, it is wondered why boilers explode.—*Stephen Christie, in the Safety-Valve.*

An Indicator of Acidity in Boiler Waters.

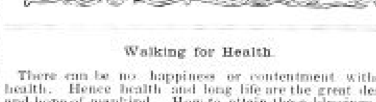
As is well known, water containing magnesium chloride is injurious to boilers, as the salt dissociates with the production of hydrochloric acid which attacks the plates. In large installations, where systematic purification of the feed water can be adopted, this evil is prevented, but in most cases the treatment in vogue consists in adding caustic soda to keep the contents of the boiler alkaline. An excess of the soda is wasteful and otherwise objectionable, and it becomes desirable to be able readily to ascertain when the water in the boiler ceases to contain alkali and needs a further supply. The handiest way to do this would be to have a certain quantity of some indicator always present in the boiler, but, unfortunately, all the usual indicators, such as litmus and turmeric, become decolorized under the influence of water at high temperature and pressure; the same objection applies to Congo red. Dr. Goldberg has, however, found that the sodium salt of paranitrophenol is entirely unaffected either by these conditions or by the salts usually present in feed waters. It is therefore possible, by introducing a sufficient quantity into the boiler, to judge of the alkalinity or acidity of its contents at any given moment by merely blowing the water out of the gauge glass and allowing it to refill. To give a distinct yellow color (the evidence of alkalinity) to the water, so that it may be seen in the small quantity of water in the gauge glass, about 20 to 30 grammes per cubic meter are requisite. The high price of the substance is the bar to its general use at present, the cost of the pure material being about 5s. a pound. As its successful application is not dependent upon its purity, a crude variety could doubtless be produced much more cheaply if a demand arose for it.—*Industries.*

Nickle-Plating Iron.

Iron is now plated with nickel by pressure between rolls at a welding heat, the nickel being recovered from the clippings and shearings of the plates by the action of dilute sulphuric acid at a temperature of 131°; the iron is dissolved and the nickel is obtained in the form of thin sheets as it was melted upon the iron. The operation is complete when the evolution of hydrogen ceases; even fresh acid at the same temperature has practically no effect. But though the separation of the two metals is apparently perfectly made, a curious fact is noted—namely, that when the residual nickel is chemically examined it is found to differ from its original composition, the amount of iron present being notably increased. For example, in a nickel containing originally only 19 per cent. of iron, two per cent. more was found when it was recovered from the plate cuttings, and even by a long-continued treatment with dilute acid, the iron could not be sensibly reduced. This peculiar behavior, it is believed, points to the possibility of positive chemical combination taking place between the metals, and that alloys of iron and nickel are produced in the process of welding. It being a fact very well known to chemists and metallurgists that iron, with but even a small proportion of nickel, resists the action of acids much more effectually than the pure metal.

Some Steam Statistics.

According to a recent estimate, four-fifths of the engines now working in the world have been constructed during the last twenty-five years. France owns 47,500 stationary engines, 7,000 locomotives, and 1,850 steamboat engines. Germany has 10,000 locomotives of all kinds, 59,000 stationary engines and boilers and 1,700 ship and steamboat engines. Austria has 12,000 stationary engines and 2,800 locomotives. The force equivalent to the working power steam engines represent is: In the United States 7,500,000 horse power; in England, 7,000,000 horse power; in France, 3,000,000 horse power; in Austria, 1,500,000 horse power, and in Germany, 4,500,000 horse power. In these figures the motive power of locomotive engines is not included, whose number in all the world at the beginning of 1890, was 105,000, representing a total of between 5,000,000 and 7,000,000 horse power, about 6,000,000 horse power, which, added to the other powers enumerated above, gives a total of 49,000,000 horse power for the world. A steam "horse-power" is equal to three actual horses' power, and a living horse's strength is equal to that of seven men. Therefore the steam engines of the world represent, approximately, the working power of 1,000,000,000 men, or more than double the working population of the world, the total population of which is usually estimated at 1,455,923,000 inhabitants. Steam has accordingly enabled man to treble his working power, making it possible for him to economize his physical strength while attending to his intellectual development.—*The Age of Steel.*



Walking for Health.

There can be no happiness or contentment without health. Hence health and long life are the great desire and hope of mankind. How to attain these blessings has been the aim and study of the sages of all ages. But notwithstanding all that has been done in the interest of health and longevity—to promote a more perfect development of the human system—the physical condition of man, as he exists to-day (in the cities at least), seems to be degenerating instead of advancing.

Not long ago there appeared in one of our leading monthly magazines some valuable statistics touching the subject of human longevity. The author of the publication sent out into all parts of New England some 5,000 circular letters asking for detailed information concerning the occupations, habits, &c., during life of persons over eighty years of age, male and female.

The inquiries were quite thorough and some interesting facts were furnished in the 3,500 answers that he received. The following among other facts were clearly established:

1. That longevity, without regularity of habits, is rare.
2. That physical activity is conducive to long life.
3. That bone and muscle are the basis and main support of health and long life.
4. That excessive flesh is rarely found in healthy old age.
5. That the percentage of those who attain a ripe old age is greatest among farmers, or those leading active lives in the country.

The statistics also showed a very low comparative health rate for the cities, in spite of the fact that cities and large towns enjoy the benefits of all that science can do in the way of improved hygienic appliances. In the cities, too, was found the greatest degree of physical degeneracy.

These unsatisfactory conditions are due largely to the inactive, lazy habits of city people, who take insufficient exercise. Street railways and cheap cab lines are responsible for a good deal of it. I once heard a well-known physician declare that every street car was a recruiting office for the hospital and the poor-house. Lazy people ride when there is no necessity for it, and when it would be a thousand times better for them to walk and save their money.

The important question, therefore, is, how can this tide of physical degeneracy which is destroying our manhood and womanhood be stayed? The answer is simple—outdoor recreation is the cure.

Nowhere is this evil more apparent than in the ranks of the rising generation. Boys and girls are growing up misshapen under their present careless and listless manner of carrying themselves. The physical culture of the youth of the land is a question of vast importance and it is one that is now occupying a good deal of attention. The establishment in the public schools of a department for training the pupils in the art of walking and other health-giving exercises is being vigorously advocated. This would seem to be a capital idea, for the true end of education should be development, the right adjustment of mind, body, and character. The need of some such system is unquestioned, especially in the interest of girls, who are more limited in opportunities for physical culture than boys.

Among the field sports, base-ball, croquet, and lawn tennis ought to be encouraged. These games furnish healthy diversion for both mind and body. Base-ball and croquet bring into play every joint and muscle of the body, and they are particularly efficient in promoting a healthy development of the organs of vision. Next to walking they are the best exercises for boys and girls.

The fact that tennis players, as a rule, use but one arm is an objection to the game, for it tends to promote uneven development. Lovers of this graceful fascinating sport should encourage the use of both arms.

That rational exercise is essential to a healthy condition of the human system will be admitted by all, but people are not so well agreed regarding the best method to be used. The relative merits of each of the various mechanical devices now employed are a fruitful source of discussion. Each method has its advocates as well as its critics. That each possesses advantages, as well as defects, cannot be denied. It must be said, however, that want of pure air and a natural tendency to over-exertion and straining are objectionable features of the gymnasium.

The bicycle, too—the upright, or large wheeled variety especially—must be objected to on account of its bad influence on natural physical development. It tends to curvature of the spine and other malformations of the system; and the boy or girl who takes to the wheel at an early age is apt to become stoop shouldered, weak-chested, and bow-legged, unless great preventive care is taken. The legs are abnormally developed at the expense of the arms and body, and grace and symmetry of figure are destroyed.

The superiority of walking, over any mechanical method, is so marked as to place it beyond the range of rivalry.

Walking is nature's own exercise. It is a health-promoting diversion which is free to all. The rich and the poor are alike welcome to its pleasures and benefactions. Little or no pecuniary expense is required in its enjoyments and it vouchsafes almost perfect immunity from the dangers which surround the gymnasium, the horse, the cycle, the boat, &c. And comparatively few can afford these luxuries. Sound feet and a reasonable amount of energy are the only capital required of the walker. Its very freedom from expense is, perhaps, the reason why walking is not more popular with city people. That which is cheap and easily acquired, is never eagerly sought after. But were the advantages and benefits to be derived from systematic walking better understood it is certain that its devotees would be numerous.

Very long walks are not to be recommended, especially in an enervating climate. Twelve to fifteen miles ought to be the limit. A walk to be beneficial must be enjoyed, hence fatigue should be avoided. Walking, when employed as a means of testing physical endurance—in other words, when it becomes a task—loses its charms and is positively injurious.

The best walking shoe is a snug-fitting calf gaiter (lace or button) with flexible oak-tanned leather soles. The soles should not be over heavy. Round toes are preferable to square ones.

To secure a good gait in walking the body should be erect, head up, feet low, a methodical, energetic step, the arms swinging lightly by the side.

A light cane might be carried with advantage.—*George Simmons in Washington Star.*

The Science of Old Age.

Old age has its special dangers and its special safety with regard to disease. For instance, whereas in a child the temperature goes up on the slightest provocation, in old age it can hardly be moved at all. The aged body is not, as a rule, prone to any acute disease. If a person passes eighty, it is rare for him to be seized with any special malady. In injuries, such as fractures, though from the lightness and brittleness of the bones they are easily met with, they are repaired solidly and quickly, even in centenarians. Slight shocks cause severe depression, but greater injuries are surmounted, and surprising recoveries made from severe maladies. Wounds and ulcers often heal quicker than in the young; the aged recover from attacks of congestion, paralysis, apoplexy, pneumonia, erysipelas and other affections in a surprising way. Diseases, as we have said, often pass them by. A man may live to one hundred in a house in which he had typhoid fever himself, and in which many of his children and grand-children have since died from it. It is probable these favorable results are due to the long time the organs have worked unitedly and helped each other, like old soldiers who pull well together and bear reverses under which younger troops would succumb. There is, on the other hand, a tendency in old age for slight diseases to become chronic. Now, as to the care of old age, the chief points are moderate and digestible food, sufficient warmth, and even, quiet life. The chief of the three is the food, or fuel for the lamp of life. While all fixed dieting is bad, where it can possibly be avoided, a few hints can be given that may prove of value. The older a person is after fifty, the less food he requires. Luigi Cornaro, who lived to one hundred, though of a feeble constitution, took 12 ounces of solid food and 14 ounces of fluid daily during the latter part of his life; and his most severe illness was caused by his increasing his allowance, through the continual entreaties of his friends. Very little proteid or animal food is required, and though in many respects false teeth are a great boon to the aged, they may lead to too great a consumption of animal food. It is not the amount of coal we put in a grate that warms the room, but the amount that can be burnt; and the great point is to avoid choking the digestive and excretory organs with excess of food. The food of the nursery is the best in old age. Bread and milk and honey is a capital diet. Milk agrees with nearly all. Hot milk with a little Mellin's food forms an admirable drink at night, and can be kept warm in a hot water jug covered with a cozy. Fruit is wholesome if ripe or well cooked. Fat is good, as cream or fresh butter. Warm food is very suitable. Soup enriched with cream or marrow is light and nourishing. All meals should be regular, and all excesses avoided. Of 800 persons over eighty, 60 per cent. were moderate eaters, 30 per cent. small, and only 10 per cent. large. If weight is being gained, the diet should be decreased. In addition to the after-dinner nap as years creep on, a doze after breakfast and before dinner is often helpful. As to clothing, it should be both warm and light. Fur is an admirable material. The underclothing should be of wool. A sealskin waistcoat is useful, and the feet and hands should be well and warmly clothed. An eider down quilt on the bed, which should be warmed in winter, is a good covering. No aged person should be suffered to get cold in bed. Two A. M., is the hour when most deaths take place, when the temperature of the body is lowest and its powers feeblest. All habits of old people should be respected, and not lightly altered. Whatever excites exhaustion should be forbidden. Early rising is therefore bad. Drinking hard water is not good, as it tends to hasten the calcareous changes in the body. Certain common errors in the care of the aged may be here pointed out; some we have already touched on.

1. That the aged require rich and nourishing diet.
2. That early rising is good for them.
3. That cold baths invigorate them; whereas they are fraught with imminent danger, and are often fatal.
4. That continual medicines and dinner pills are needed to digest the food; whereas, instead, less should be eaten.
5. That the rooms should be hot; whereas they should be cool, but not cold—65° to 70°.
6. That a fixed diet should be rigidly adhered to; whereas variety is often essential.

Old age is of two sorts: that which is natural, and that which is prematurely acquired in youth; and it need hardly be observed that it is only of the former variety we now speak. Self-denial often requires to be practiced by the aged in many ways, though not arbitrarily. All known weak spots in the constitution should be jealously watched. No care as a rule surrounds the aged as guards the young, because they are not in many ways the same objects of interest. But this is not as it should be, nor is it consistent with Christian profession. In animals, death when it comes is, as a rule, swift. There is, with the vast majority, no old age and debility suffered among them. No long wasting or disease or slow tumors embitter their lives; they are killed by their fellows when their powers fail, and are thus delivered from all these slow tortures by one sharp stroke. This apparent cruelty of nature is thus a merciful provision for those beings who know not the meaning of sympathy. In early ages and in savage life it was the same with man. The skulls found in the gravel beds are all full of teeth, as of those who died early. Now, in advanced civilization, love and care prolong life to a great age. This is not an unmixed good. Almost the very existence of slow decay and long disease has been brought about by the love and care that distinguish humanity. Hence it is peculiarly noble and Christan work to lessen the sufferings that in a sense our own care has made possible; and, as far as we are able, to make old age a period of serene sunshine and an unmixed blessing.—*Leisure Hour.*

USEFUL INFORMATION

Stick to the United States.

From time to time, numbers of people are seized with a craze to emigrate to some portion of South America, under the hallucination that certain prosperity awaits the settler in any part of that country. The fertility of its soil, the delightfulness of its climate, the fabulous richness of its mines of gold, silver and precious stones are set forth in glowing terms, and the fairy-tale is believed until the deluded emigrants arrive at their destination. Then they are speedily disillusioned, and after struggling a few years against the adverse circumstances of their environment, they either die, or return to the United States broken in fortune and in health.

A correspondent, who has been tempted to try his fortune in the southern half of the Western Hemisphere, but who seems to have thought it best to act with circumspection, wishes the *Ledger* to tell him why the fertile countries of South America advance so slowly in wealth and population. That is a very interesting question. In all that continent, which is considerably larger than North America, there are but twenty-six millions of inhabitants, while North America contains almost three times that number. Brazil, for example, which is about as large as the United States, and was settled sooner, contains only about ten millions of people, and nowhere exhibits anything like the prosperity which has marked every period of our own history.

The principal reasons of this difference are three in number. In the first place, nature herself in South America interposes mighty obstacles to the purposes of man. Vast plains exist, which, in the rainy season, are covered with luxuriant verdure, and in the dry season assume the appearance of a desert. The forests, owing to the fertility of the soil under a tropical sun, are so dense and tangled as almost to baffle the efforts of the pioneer to remove them. The principal rivers, which are the largest in the world, are more like flowing seas than navigable streams. The Plata, for example, is 130 miles wide at its mouth, and is full of strong, irregular currents. The Amazon, too, which is 4,000 miles in length, and navigable for one-half that distance, is, in many places, so wide that the navigator has to sail by the compass. The mountains, also, are precipitous and difficult of access, and contain thirty active volcanoes. All nature, in fact, is on a prodigious scale, and the very richness of the soil is frequently an injury rather than a help to man.

In the next place, the Spanish and Portuguese, who settled this continent, drawn thither by the lust of gold, were little fitted to wrestle with the obstacles which nature placed in their path. Lastly, the Spanish and Portuguese governments, narrow, bigoted, ignorant and tyrannical, for three centuries cramped the energies of the people and oppressed them by merciless exactions.

People who are thus oppressed for centuries lose heart and manliness of spirit; they sink into ignorance and superstition; they learn to be content with lives but little raised above the life of brutes, and so become incapacitated for prosperity. When, early in the century, owing to the heroism and and virtue of Simon Bolivar, the yoke of Spain was thrown off by the finest provinces in South America, the long-oppressed inhabitants were unable to profit by their liberation. They were totally unaccustomed to self-government; they had no conception of the binding obligations of public law or private agreements; they were not amenable to the influence of enlightened public opinion; they were incapable of restraining their provoked passions for the purpose of securing lasting future good, and so they have gone on from revolution to revolution, without stable governments, or steady industry, or thrifty commerce, and are now but little in advance of their condition half a century ago.

It is useless for citizens of the United States, who all their lives have been accustomed to obey and revere the laws which their fathers and themselves have made, to seek for a satisfactory home among people who have but crude ideas of the sacredness of public law and private obligations.—*New York Ledger.*

A Schedule of American Checks.

The banks of the United States receive for deposit in one day about $300,000,000. Often it far exceeds this amount, rarely goes below it. These receipts are accepted and placed to the credit of their customers, yet it is a remarkable fact that over 90 per cent. of these deposits are not currency in the common acceptation of the term. They are not gold, silver, greenbacks, nor bank notes. Ninety per cent. of them are checks. The business of the country is done chiefly by checks. A gives B a check for a thousand bushels of wheat; B gives C a check for a thousand bushels of potatoes; C gives D a check for fifty barrels of sugar; D gives E a check for a hundred sacks of coffee, each man paying his debt by check. Back of the check is supposed to be currency in bank subject to the checks of these parties, but the same $1,000 in currency answers for a dozen or fifty checks of a thousand dollars each. Not one of these men desires the currency. He would not accept the thousand dollars in silver for he could not carry it. He does not care to have on his person a thousand dollars in greenbacks or gold. The check suits him better, provided he is satisfied in his own mind that it will be honored when finally presented for payment, that is if the bank on which it is drawn certifies that it is good. Here then is a vast currency in the form of checks of which no account is made in the estimate of the circulating medium.

On a given day the forty-eight banks of New York City received and placed to the credit of their customers $165,193,347, of which 0·34 per cent. was gold coin, 0·01 per cent. was silver coin, 0·65 per cent. was paper currency, and 98·86 per cent. was checks.

Every check was good, and it was more convenient than the currency for the settlement of accounts between the parties doing business.—*New York Financier.*

Pigmies at the Fair.

There will be pigmies at the Fair. There will be a whole tribe of the little Central African dwarfs if the King of Belgians will permit the United States World's Fair Commissioner to carry them off, and the exposition authorities think that he will.

Lieut. Schufeldt, the agent of the Exposition in Africa telegraphs from Zanzibar that he could get all the pigmies desired if the King of Belgium would permit of their transportation. President Baker wants these pigmies and so does everybody else around headquarters, so when Schufeldt's telegram was received, Secretary of State Blaine was telegraphed and asked to use his influence with the Belgian monarch.

Walker Fearne, Chief of the Department of Foreign Affairs, anticipated no difficulty in that direction. He said the Belgian Government was friendly toward the United States.

Tippoo Tib, who has considerable influence in the Free State of Congo, must also be persuaded that the pigmies will be properly cared for.—*Chicago Journal of Commerce.*

What the Chinese Think of Us.

We are in the habit of expressing our views freely in regard to the peculiarities of the Chinese, their customs, clothes, politics, industries, and so forth; but it is comparatively a rare thing to meet with a statement of Chinese opinion touching American ways and institutions. The very oppositeness of their standpoint gives a piquant interest to the impressions they form of our national characteristics. Here is a recent utterance of the kind which is attributed to the *Pekin Gazette*. Speaking of the Americans, a writer in that journal is quoted as saying: "It is impossible to understand these barbarous people. One thing is certain: If they do a thing they do it with all their might. Thirty years ago they had a civil war. The whole country was turned into military camps and battlefields, and everybody, even to the women folk, were engaged in the war in one way or another, and one army numbered 2,000,000 men. And now there are young men, old enough to vote, who have never seen a company of soldiers in their life. In fact, these people seem to think that another war will never break out, especially in their part of the world. A person can travel clear across the American continent without seeing a soldier, and follow the main lines of travel, too. In fact, at the present time there is only about one soldier for every 2,000 persons, while Russia has one soldier to every 90."

Smoke From the Mint Carries Atoms of Gold Outside.

Three thousand dollars for an old tin roof would be a pretty steep price, but the man who gets the battered roof from the Tabernacle Church at Broad Street and South Penn square, which is now being torn away, for that sum will be in luck. Some years ago the paint was scraped off the old roof and yielded $5,000 in gold. It is almost certain to yield as much this time. The gold comes from the mint. When gold is being coined a considerable quantity of it volatilizes with the smoke through the chimney, and as soon as it strikes the air it falls. Much of it falls on the roof of the mint; so much of it that the officials save even the water that falls upon it during a shower. All the drains from the roof are connected with large vats in the cellar of the mint. Before the water finally gets to the sewer it is strained through many blankets and sieves which retain the gold. Notwithstanding all these precautions, the gold that is annually washed into the Delaware from the mint is worth thousands of dollars. Every particle of dirt swept up about the mint is carefully stowed away with the washings from the roof, and once every year it is sold to the highest bidder, as it cannot be used at the mint.—*Mining Industry.*

How Fish-Hooks are Made.

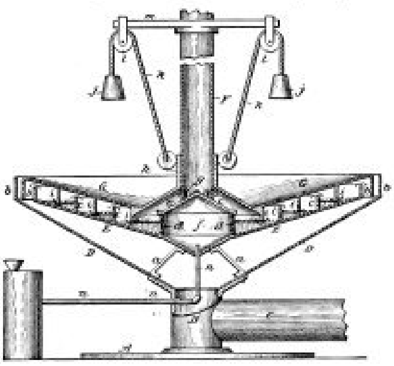
There is a little machine which turns out fish-hooks in six strokes. Stroke number one bites off a morsel of steel wire; number two makes the loop where you fasten your line; number three hacks the other end; number four flattens and bends back the barb; number five makes the point; number six bends the wire; and your fish-hook drops into a little bucket ready to be finished. Then it is either japanned—these are the common black fish-hooks—or it is tempered to the delicate blue that is sometimes seen in cutlery. For this finish it is heated red-hot and then cooled in oil.

Keeping a Grindstone in Order.

A grindstone has not, one would suppose, a very delicate constitution. It has never been chosen as a type of fragile sensitiveness, but it has nevertheless susceptibilities of its own, and the *Northwestern Mechanic* gives useful advice as to its care and treatment. The exposure of the stone to the sun, says that journal, has a tendency to harden it, and if one part be left in the water habitually it will grow soft, and wear away faster than the other. If the trough is put upon movable supports in a frame, it can be adjusted to the stone without much loss of time. Or allow the water to drip from a water-spout, and an old white lead keg will answer, fixed above the stone. Always clean off all greasy or rusty tools before sharpening, as grease chokes up the grit; and always keep the stone perfectly round by razeing it off when necessary.

AMALGAMATOR.

No. 452,177. John W. Culmer, New Brighton, Penna. *Patented May 12, 1891.* The mercury is carried in the conical pan E, which is divided into several compartments by circular partition rings c. The surface of the mercury in each compartment is covered by perforated metal plates, and the conical cover G is provided with circular partition rings i which touch the perforated plates. The water carrying the gold, enters through the pipe F and passes under the edge of the first and lowest ring i, exposing its gold to the mercury in the lowest compartment in so doing. It then flows over the first partition c, and under the edge of the second partition i, etc., until it finally escapes over



the edge b of the pan E into the pan D and flows away through the pipe C. As the diameter of the mercury compartments increases toward the outer edge of the pan, the flow of the water is slackened, having a larger area to flow over, and more time is thereby secured for amalgamation, in each successive ring. To warm the water and the mercury, superheated steam is let into the central chamber f by a pipe n. This chamber has a metallic cover e tightly cemented down on the ring d. This ring is made of hard burned potter's clay and is sufficiently porous to permit the passage of steam or hot gas for heating or agitating the materials. The cover G slides upon the inlet pipe F and is counter-weighted as shown.

GRINDING MILL.

No. 451,111. Henry A. Duc, Charleston, S. C. *Patented April 28, 1891.* Fig. 1 is a vertical cross-section of the mill on the line xx in Fig. 2. Fig. 2 is a vertical section along shaft J. The outer grinding ring B is supported by conical screens G and E which have trunnions mounted in the main casing A. The hub K on the shaft J has two pairs of lugs k, between which grinding arms L are pivoted. These arms are square in section, and are tubular. Rollers M are provided in the front end of each arm, which bear against the outer ring or die B, being pressed outward by their own centrifugal force, and also that of the arms, in addition to the force of the springs N. The arms act as brakes on the rolls compelling them to partly drag and partly roll over the material. The roll bears against the outer plate or rim of the arm, and is constantly scraped by it clean of all adhering material, the scrapings passing through the arm. The screen E at the receiving end, is composed of a series of independent ring plates, of successively

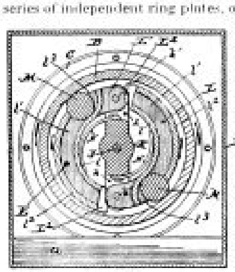


Fig. 1

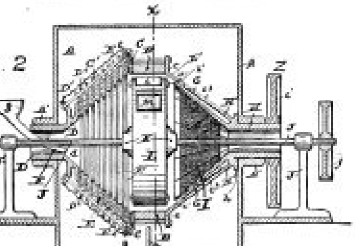
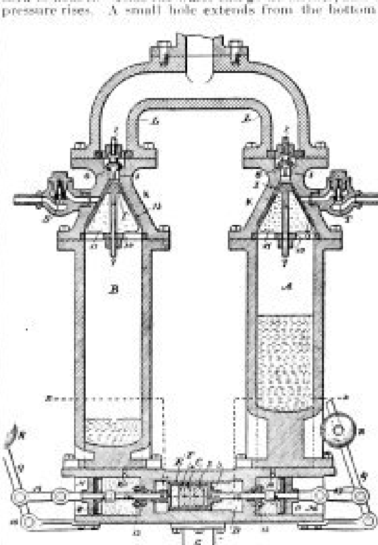
Fig. 2



greater diameters, and having lugs and eyes for suitable binding bolts as shown. These rings are separated by distance pieces of suitable thickness to make the desired mesh. A conical wire screen E' surrounds the ring screen E and serves to grade the material passing through it. Stuff which passes both screens falls out into the case A and passes out the hole a^1, and that which passes the rings only falls between the partitions shown, and out through the hole a^2. The delivery screens G and I are also conical, made of wire, in sections which are removable. Screen G is the finest, and receives only the ground material which passes the coarse screen I. All that fails to pass through it returns between the screens to the bottom of the die B and is again ground. The finished material which passes screen G passes out of the case by the hole a^3. The screens with the grinding ring B are rotated by a belt on the pulley Z, and the arms L are whirled in the opposite direction by a belt on the pulley j.

AIR COMPRESSOR.

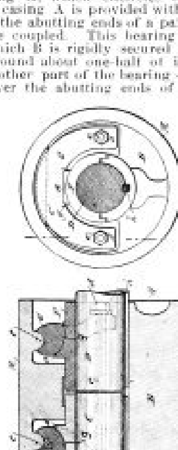
No. 451,460. Thomas C. Craven, Newark, N. J. *Patented May 5, 1891.* Water pressure is employed in this machine to compress the air or gas contained in the cylinders A and B. The water pressure pipe opens into the valve-chest D in which there is a common slide-valve E. This valve admits water to the cylinders alternately. As the water rises in the cylinder A it compresses the air to the density required to lift the check-valve G and then forces it out by the pipe L to the receiver. As the water reaches the neck of the cylinder it lifts the large conical valve I to its seat. This valve consists of a metallic shell filled with enough cork to float it. Thus the water can go no farther, and the pressure rises. A small hole extends from the bottom of



the cylinder to the chamber behind the piston O attached to the valve-stem. The piston is driven over until the play between the slide-valve and its yoke is taken up and the valve is moved so far as to shut off the pressure. By this time the weighted lever has swung its weight R beyond the fulcrum 16, and it falls by gravity still farther, far enough to move the valve and open the port to the other cylinder, in which these operations are repeated. When the valve opens cylinder B to pressure it opens A to the exhaust pipe G. The water in A runs out by gravity and air enters by the check-valve T. When the cylinder B is full, the pressure acts on the other valve-piston P and reverses the valve as before. The amount of extra pressure required to move the pistons and valve, is regulated by the weight and throw of the balls R.

SHAFT COUPLING.

No. 447,925. William B. Turner, Schenectady, N. Y. *Patented March 10th, 1891.* The coupling consists of a cylindrical casing A, which encircles the shafts to be coupled. The casing A is provided with a bearing upon its interior for the abutting ends of a pair of shafts C D which are to be coupled. This bearing is made in two parts, one of which B is rigidly secured to the casing A and extends around about one-half of its inner circumference. The other part of the bearing consists of a pair of caps E F over the abutting ends of the shafts C D,



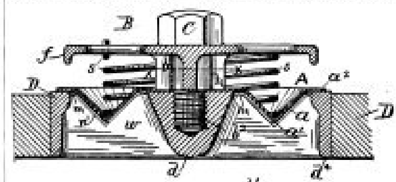
respectively. These two caps rest upon the halves of their respective shafts which are not inclosed by the lower bearing B, with their edges in contact with the upper edges of the latter bearing, as shown in the end view.

Each of the caps E F is provided upon its top surface with a seat a, preferably inclined, as shown, upon which rests the central cam-shaped under side g of a bifurcated lever G, the upper central portion of which is provided with a groove b, which receives a correspondingly-shaped rib r, formed upon the inner wall of the casing A.

The two levers G are connected upon each side of the shafts C D by rods z, which pass through the bifurcated ends of the lever, a nut d being provided at the end of each rod, by turning which the ends of the levers D are drawn inwardly toward each other. The seats a upon the caps E F are inclined upwardly toward the center of the casting, so that as the lower ends of the levers G are forced inwardly toward each other the cam-shaped portion of each lever rides up its inclined seat, thus forcing the caps E F down against the shafts C D and the bearing B, and thereby coupling the abutting ends of the shafts C D. For the purpose of giving the coupling a firmer hold upon the shafts the bearing B and the shafts C D are recessed, so as to receive a key h.

PUMP VALVE.

No. 453,347. George H. Remington and James T. Hexthorn, Providence, R. I. *Patented June 2, 1891.* This valve is spun or stamped of sheet metal, and is made with a deep **V** groove in which the spiral spring rests. The edges of the valve which form the seats are flat, as shown. The guard f limits the lift of the valve and guides it by means of wings or vertical ribs on its hub. The section of the hub is shown



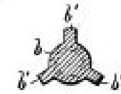


Fig. 2

in Fig 2. The ribs which connect the hub d of the valve seat, to the rim d^1, are notched to suit the under side of the valve. The **V**-shaped under side of the valve deflects the water both inward and outwardly, making its passage easier than with a flat valve. The valve cannot become cocked, because the notches in the seat ribs help to guide it to its proper seat at every stroke.

EXPANDING DRILL.

No. 451,789 Julius R. Watts, Springfield, Ill. *Patented May 5th, 1891.* This drill is designed to bore a hole to any desired depth, and then form a pocket at the end of the hole, big enough to receive a large amount of powder. The powder being enclosed in a pocket, there is much less liability of blowing out the tamping, and the blasting is done very effectively.

The feed screw 17, together with the divided feed nut and driving gear, are all mounted in a forked bracket, on a supporting bar stuck into the face, in the usual manner.

The bits A are hinged to the end of a rod 39, which passes through a tube 33, and couples to the end of the feed screw by a squared socket 22. When the rod 39 is forced forward relatively to the tube 33, the shanks of the cutters encounter a pin 41, which compels them to spread out to the dotted lines shown in Fig. 2, and thus enlarge the hole. The rear end of the casing tube is supported in a clamp box 28, which is arranged to slide along

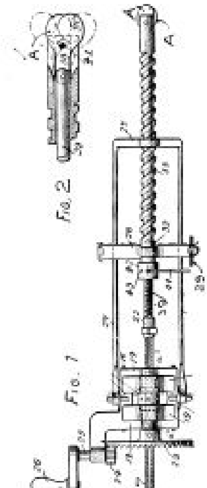

Fig. 2

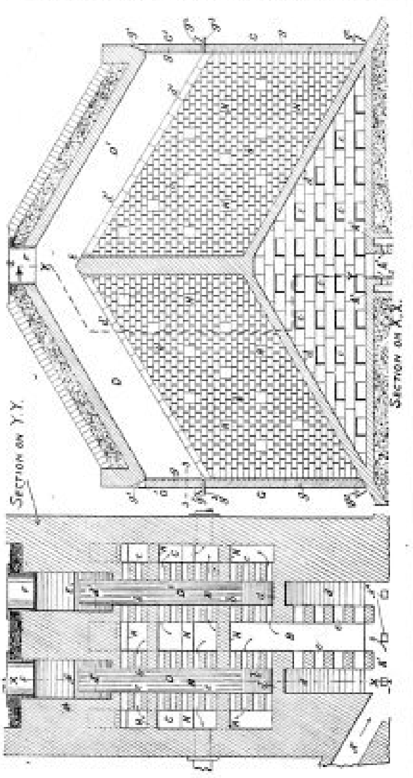
Fig. 1

on the guide frame 27. This guide frame consists of two light rods secured by pins to the box of the main feed nut, and united at the front end by a cross bar which rests loosely on top of the casing tube 33. The rear end of the bit rod 39 is threaded and provided with a nut 42. When this nut is jammed tight against the end of the casing tube, both 39 and 33 revolve together, with the bits drawn back as shown in Fig. 1, and they remain thus until the hole has been drilled the desired depth. To form the pocket at the end of the hole, the nut 42 is backed off enough to free the tube 33, and is prevented from revolving by sticking a pin 44 into one of the holes shown. The clamp box 28 is made fast to the guide rods by the clamp screw 29, thus securing the tube against backing out of the hole. Now when the main feed screw is turned, the bit rod 39, and casing tube 33, turn with it. As the nut 42 cannot revolve, the bit rod is forced forward thus expanding the bits, and producing the desired enlargement of the hole. The coarse spiral groove on the outside of the casing tube 33, serves to carry out the chips and borings.

COKE MAKING APPARATUS.

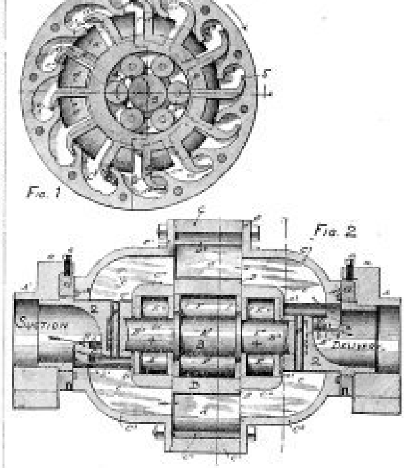
No. 451,488. Frederick J. Jones, St. Albans, England. *Patented May 5, 1891.* This apparatus is composed of five chambers, separated by perforated walls. The bottom of the chambers E E and B slant each way from the middle wall at a pitch of about 30°. Instead of holes through the walls, for the passage of gas, all the vertical joints in the brickwork from the bottom up to the shoulder d^3 are left open about half an inch. The width of the chamber E is from 12 to 18 inches according to the nature of the coal to be coked. Fuel gas from any ordinary "producer" is brought in by the flue A^1, and mixing with air admitted by the ducts A^2, it burns in the middle chamber B. Both chambers E are filled with coal through the funnels F and tightly covered. The burning gas in chamber B passes through the walls and permeates the coal in E rapidly coking it. The gas given off passes into the chambers C C. The side walls of each coking chamber are formed with a ledge or shoulder at d^3 at a slightly greater pitch than the inclined floor d, and upon these ledges the upper part of the charge, which fills the coking-chamber nearly up to the roof, rests and so seals the passage left by the contraction in bulk of the coal in the operation of coking and prevents gases of combustion passing round instead of through the charge. The discharge apertures of the coking chambers are closed during the coking operation by doors G G^1, hinged at one side, the lower door G closing the aperture up to the level of the ledges d^3, the upper door serving to give access for leveling the charge when the lower door



is closed, besides facilitating the sealing of the lower door. For sealing purposes, a rabbet is formed in the brick door-jambs, and a packing of dry sand, lime, or other suitable pulverulent material is easily run in after the door G is closed. This pulverulent packing absorbs tar from the gas and quickly makes a gas-tight joint, thereby avoiding the troublesome operation of luting in the ordinary way. The upper door G^1 is received in a similar rabbet and is made gas-tight in the same way, a space g^1 being left between the top flange of the door and the brick-work, into which sand, etc., is run, as well as into the side spaces. The joint between the doors is made gas-tight by the same means, (sand, etc., poured into a hopper g^2, carried by the upper door and resting on a plate g^3 on the top of the lower door, and so filling the joint). The lower door G is sealed in a similar manner. To insure the sufficient heating of the charge from below, the "producer" gas has access to the space beneath the floor d (which is of fire-brick) by orifices e in the lower part of the walls of the combustion chamber B, hot air being also admitted to the same space to effect perfect combustion. The mixed gases collected in chambers C, having absorbed fresh carbon by traversing the charge, may be burned therein with an admixture of more air and so assist the coking process, or they may be conveyed away and treated as in gas works, for the extraction of chemical products therefrom, and for use as heating gases. As the floor of the coking chamber, is inclined, and the doors GG^1 are as large as the end of the chambers, the charge, when finished, can be slid out as a coherent mass, with little or no breakage.

ROTARY PUMP.

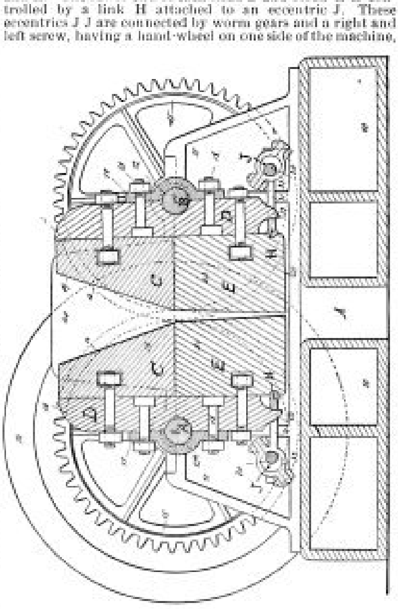
No. 448,335. Ellick H. Gollings, Lewiston, Idaho. *Patented March 17, 1891.* The body of this pump consists of a central ring C^2 containing the working chambers c^3 and two end sections C^1 which contain a series of ports or passages connecting the working chambers with the suction and delivery pipes. A belt is applied to the middle ring C^2 and the whole body or case revolves on the standing spindle 2. This spindle is hollow at the ends and has large ports B and B^2 which open on the under and top sides respectively. As the body revolves the passages c open one after another into these ports and so establish communication between the suction and those working chambers c^3 which are below the center line, and connect the working chambers above the center line with the delivery. A wrought iron shaft 4, 3, 4, is fastened to the end sections 2 by pins, as shown which hold it stationary. The body turns on rollers E which run on the parts 4 of the central shaft. The middle part 3 is eccentric, as shown in the cross-section in Fig. 1,



and furnishes a bearing for the winged wheel D which has wings d working within the chambers c^3 of the body C^2. Fig. 1 shows that the wings are in contact with the sides or edge of the working chambers only at 5, 6, and 7. These contacts continue only until the body or case and the wheel D have revolved far enough to bring the next wings into contact. The space enclosed between the case and the wings at 5 and 6 is much less than that enclosed between the points 6 and 7. It follows that the volume of the chambers gradually increase in rotating from the point 5 to 7, and as gradually decrease in passing from 7 to 5, consequently they will draw in water from the suction pipe on the lower half of their revolution, and will expel it through the delivery pipe during the upper half of the revolution. The case drives the wheel D by the contacts at 6. The action is continuous and no valves are required.

ROCK CRUSHER.

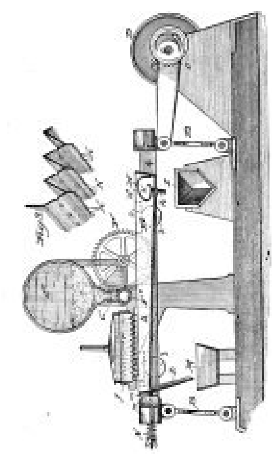
No. 450,489. William H. Howland, Bergenfield, N. J. *Patented April 14, 1891.* This machine has two driving shafts A and B, which are geared together as shown. Each shaft is formed with two eccentrics—each occupying half of the length between the journal boxes,—the throw of one eccentric being exactly opposite that of the other. Each eccentric carries a head D to which are bolted face blocks C and E. The lower end of each head D and block E is controlled by a link H attached to an eccentric J. These eccentrics J J are connected by worm gears and a right and left screw, having a hand-wheel on one side of the machine,



for adjustment. The driving shafts A and B are set so that their eccentrics are not exactly opposite, but those on one shaft are 90 degrees ahead of the other. The result of this arrangement is, that during a considerable part of the stroke, the jaws are moving vertically at different speeds or in different directions, thus exerting a powerful grinding action on the material between the jaws, in addition to the crushing force exerted while the jaws move toward each other. For grinding ores or rock, the blocks C and E are made of iron or steel, and for grinding softer material, the blocks E E are made of buhr stone, and for coffee, etc., end grain hard wood is employed.

CONCENTRATOR.

No. 451,926. Ryerson D. Gates, Chicago, Ill. *Patented May 12, 1891.* The pulverized ore is contained in the box G and is fed out through a slot in the bottom extending the whole width of the pan A. A double gate G^1 rests on the roller F^2 and regulates the feed. The roller F^2 is turned by gearing driven by a belt (not shown) from the main shaft S, and the stuff works out under the edge of the gate. For all ordinary cases the roller is made smooth. The pan A has lugs 2 on its sides, which rest on rollers 3 in the side frames 4 and is held against the end of the frame

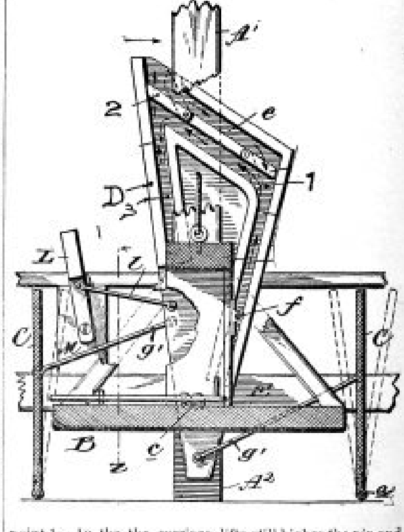


by the bolt and adjustable spring N. The frame is supported on rockers B and is moved back and forth by the eccentric C. The spring N serves to give the pan a sharp jerk or jar at each stroke. The bottom of the pan is inclined toward the discharge H. This plate is bent as shown, so that the water and gangue must work between it and the bottom of the pan and up over the edge b^1 to get into the discharge pipes b. The concentrates work up the inclined bottom and drop off at the plate L into the trough M. The water-box J has its bottom formed into V grooves, the sides of which are perforated as shown in Fig. 3. The lower edge of each V terminates in teeth K from which the water falls into the pan in drops, which are well distributed across the whole width of the pan.

MINE CARRIAGE.

No. 451,716. Isaac C. Welter, Luzerne, Pa. *Patented May 5, 1891.* The object of this device is to automatically operate the "fans" or platform stops, and unlatch the dogs which block the wheels of the car.

The fans C are connected by rods g^1 to a large triangular switch or cam board D, which rocks on a pin c attached to the shaft framing. The carriage is provided with a strong pin carrying a roller f on its outer end, which runs in the grooves formed in the cam board. When the carriage begins to come up, the cam board is tilted to the extreme left, and the fans stand leaning outward. As the carriage approaches the landing the roller on the end of the pin f, enters the groove in the cam and travels upward as shown by the arrows to the



point 1. As the the carriage lifts still higher the pin and roller pass to position 2, thus crowding the cam to the right and closing the fans sufficiently to receive the carriage as it descends, the roller passing a little ways down the groove 3, in so doing. When the carriage rises off the fans, preparatory to descending, the roller passes up through the latch 2, which is closed by a spring, and as the lowering begins the roller runs down the grove e, crowding the cam to the left and opening the fans. The roller passes on through the latch at 1 and down the groove by which it entered. The stop L is intended to trip the locking device employed to block the cars on the platform, and is moved into and out of position by the cam as it swings in obedience to the movements of the carriage.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 3. SCRANTON, PA., OCTOBER, 1891. WITH WHICH IS COMBINED THE MINING HERALD.

THE ECONOMIC GEOLOGY OF SILVER.

The Mineralogy, Mode of Occurrence, and Production of Silver.

BY H. A. WHEELER, E. M., OF ST. LOUIS.

The true silver minerals can be divided into two classes that differ quite widely from each other in their relative toughness, or into (*a*), the *sectile series*, or those which are tough enough as to be cut into shavings by a knife, and (*b*), the *brittle series*, or those which crumble into powder when whittled or scratched with a knife. The more important members of the first, or sectile class, are:

Native Silver, or metallic silver, which occurs quite frequently in nature as scales, crystals, wires, and rarely as nuggets or "float" silver, the latter being irregular, rounded masses that have been rolled along by stream action. Native silver, if untarnished, is a pure white colored, soft, very malleable metal that has a specific gravity of 10 to 11 or about half again as heavy as iron. It is seldom perfectly pure, usually containing a little copper and occasionally some gold. Except when freshly mined, its beautiful bright white color is very apt to be tarnished by a dark film of sulphide of silver, as sulphur has such a strong affinity for the metal that the small amount contained in the atmosphere of our cities or in the smoke from blasting powder used in the mines will, in time, combine with it as a dingy, dull, dark coating. Nearly all silver veins are apt to contain small amounts of native silver, at or near the croppings, or where the vein comes to the surface, and occasionally, as at Silver Islet, on the north shore of Lake Superior, and at the Batopilas mines, in Western Mexico, this is the principal ore mined.

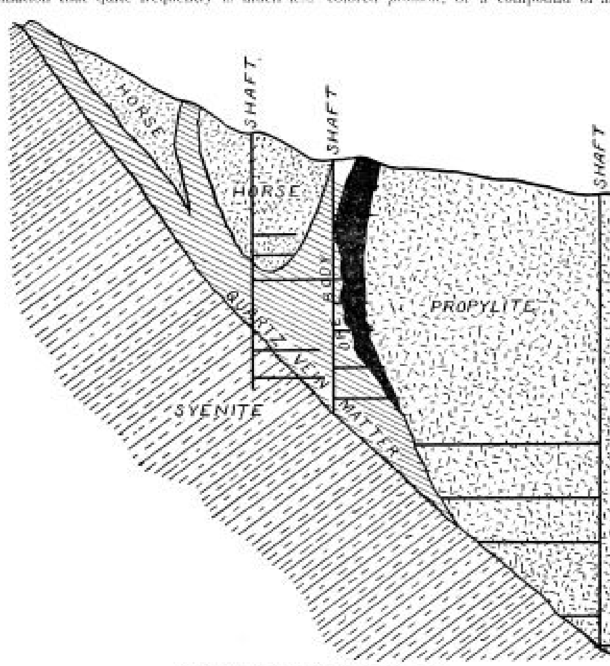
Argentite, or *silver glance*, is a sulphide of silver that contains about 87% of silver when pure. It is a soft, heavy, dull black mineral that can be cut as readily as the finger nails by a knife, while it will melt into a button of silver in the candle flame. It is quite a common mineral in some of the rich silver veins of Mexico, and frequently occurs in the high grade ores of the Western States and Territories.

Cerargyrite, or "*Horn-Silver*," or "*Chlorides*," is a chloride of silver that contains 75% of silver when pure. It is a soft, heavy, light to dark gray colored mineral with a dull waxy luster, and it can be cut or whittled as readily as horn, hence its common name of "horn-silver." It is not only one of the richest ores found, but as it is also easily milled, it is therefore justly prized by the prospector as this free-milling property enables very low grades ores to be worked, as at Silver Reef, Utah, where ores containing this mineral assaying only $5 to $10 a ton are worked at a profit. It is very frequently found at or near the outcrops of most of the silver veins of the West and occasionally it is found extending to depths of 300 to even 500 feet; but in the great majority of cases it soon runs into other silver minerals, as soon as any depth or the water-level is attained, that are more difficult to work and which are also often much poorer. It is an entirely too common experience in the West to find leaching works or pan-mills erected to work this ore which have perhaps no sooner got into regular running order when the chloride changes into a base silver mineral that necessitates roasting and even smelting to obtain the silver, requiring the rebuilding of the works or possibly their entire abandonment. Another very common error made in the West is to call all silver ores that are yellow-stained "chlorides," which quite often is correct, though in many instances such yellow-stained silver ores contain no horn-silver whatever, the silver being there in some other combination that quite frequently is much less tractable, while the yellow staining is usually due to oxide of iron.

Embolite, or bromide of silver, is a mineral that is identical in every respect with cerargyrite except that it is green-colored when freshly mined. This mineral is also very often misnamed by the Western miners and prospectors, who are apt to call all green-stained silver ores "bromides," when the green color is usually due to copper, and the silver is more frequently in some other less easily milling combination than as a bromide, which latter mills as readily as the chloride. Like the chloride, this mineral is usually found in the upper parts of many silver-bearing veins, and is apt to change into other combinations, especially with sulphur, as depth or permanent water-level is attained.

Of the *brittle* group of silver minerals, the more common ones are:

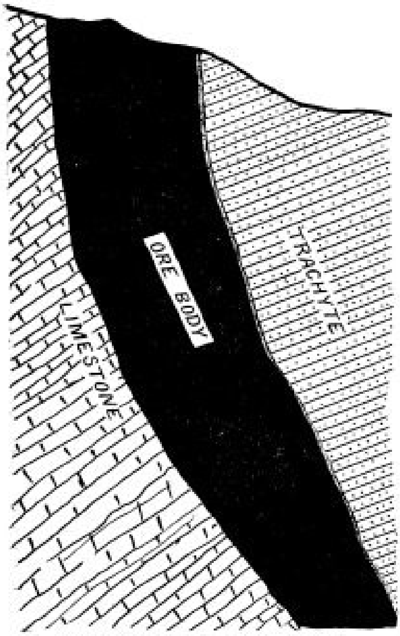
Ruby silver is a name applied to both the light-red colored *proustite*, or a compound of arsenic, sulphur, and silver, and to *pyrargyrite* or the dark-red to black colored compound of antimony, sulphur, and silver. They both give a red streak, are very brittle, and have a non-metallic luster, are heavy, and contain over 60% of silver. Ruby silver is the principal mineral of the famous Granite Mountain Mine, in Montana, and is very common in the Comstock Lode, of Nevada, while it is very apt to be present to a greater or less extent in most of the high grade silver veins of the West.



CROSS-SECTION OF THE COMSTOCK LODE.

Brittle silver, or stephanite, is a black compound of antimony, sulphur, and silver, that very much resembles the dark ruby silver in its properties, richness, and occurrence.

There are quite a number of other brittle silver minerals that are occasionally of local importance, like *polybasite*, at the Ontario Mine, Utah, *stromeyerite* at the Yankee Girl Mine, Colorado, but which are not of sufficient



CROSS-SECTION OF THE HORN-SILVER MINE.

general importance to deserve attention here, while all the gold ores, and especially the brittle telluride group, always carry at least some silver, but as its value is usually very much less than the gold, the silver is regarded as a by-product.

Silver ores which carry any of the above minerals are pretty certain to be profitable, and the only necessity of assaying them is to determine *how rich* they are; but there is another very valuable class of silver ores which give no reliable clue whether they are silver-bearing or not, and hence must be assayed to determine first *whether* they are argentiferous, and if so, then whether the silver is contained in profitable quantities. This class consists of the minerals of the base metals lead copper, iron, zinc, and antimony, which in certain districts are often found to be quite rich in silver, while in other districts they practically contain none; hence every new discovery of the base metal minerals should always be assayed, though usually they will not be found to contain silver or gold in profitable quantities in regions which are not already famous for their precious metals. The more important of these minerals that are liable to be silver-bearing are:

Galena, or the sulphide of lead, which is a very heavy, soft, bright metallic lead gray-colored mineral that almost invariably contains *at least some* silver, and in silver-bearing regions is nearly always a valuable silver ore. It seldom assays less than 1 or 2 ounces of silver per ton, and occasionally carries as high as 300 to 400 ounces. The very low grade galenas that do not contain enough silver to pay extraction (or less than 5 ounces per ton) are generally very coarse grained or split readily into cubes, while those galenas which carry silver in profitable amounts (or over 10 ounces per ton) are apt to be very fine grained or will not split into cubes. While the *grain* of the galena will thus give an idea in perhaps *most cases* as to its silver value, still there are *so many exceptions* to the rule that the only safe and proper way is to always assay every new galena and not put the implicit faith in the character of the grain that is so frequently done by Western prospectors.

"*Sand*" *and* "*rock*" *carbonates*, or the carbonate and sulphate of lead, are similar to galena in nearly always carrying paying amounts of silver in silver regions and very small and unprofitable quantities in districts like the Mississippi Valley, which is almost barren of silver veins.

"*Gray Copper*", or tetrahydrite, is a heavy, soft, gray-colored, metallic copper mineral that is often very rich in silver in silver regions, assaying as high as 2,000 ounces per ton, and is one of the most common and valuable silver ores of the West.

"*Yellow Copper*", or chalopyrite, is a heavy, somewhat hard, brass-yellow, metallic copper mineral that frequently carries paying amounts of silver, and is seldom entirely free from small quantities, but is more usually valuable for the gold that it is liable to carry than the silver. The other copper minerals (which are usually derived from this by alteration) are equally as liable to carry paying amounts of silver, and they probably are rarely free from small amounts or say ½ to 5 ounces per ton.

Blende, or "*Jack*", is a soft, yellow, brown to black colored, non metallic zinc mineral that usually carries some silver in silver regions, but frequently in amounts just too low to pay to extract on account of the difficulty in smelting such ores.

Pyrite, or "iron pyrites," is a heavy, very hard, light yellow, metallic iron mineral that frequently carries paying amounts of silver, though it is usually more valuable for the gold it is liable to contain in districts where the precious metals occur. The other iron minerals are also likely to contain some silver in silver regions, but are apt to be low grade.

Silver, as distinct silver minerals, or invisibly carried by argentiferous minerals of the base metals, occurs in nearly all classes of deposits. The class of silver deposits that are most highly prized and sought after by the Western prospector are the fissure vein, on account of the supposed permanence and reliability of this class of ore-bodies, and while this reputation is justly deserved in some cases, it has proved very unreliable in many other instances. One of the best known types of a silver bearing fissure vein is the *Ontario Mine*, in Parley's Park, Utah, which has been worked since 1872, and has paid in dividends the handsome sum of about $12,000,000 since the first was declared in 1877. The vein has a general east and west course or direction, and a dip of 70° to 80° to the north, though both the course and dip vary considerably; it has a width of 2 to 8 feet, with a vein filling of quartz carrying pay streaks of ½ to 4 feet in thickness. Both the foot and hanging walls are quartzite, though a dike occurs close to and nearly parallel with the vein in the hanging country. In the upper part of the lode (down to about 300 feet) the silver occurred largely in the form of horn-silver or chloride, but this has changed into polybasite and still deeper quite large amounts of smelting ore has made its appearance in association with blende, pyrite, and other sulphide minerals. The average value of the ore has fluctuated from $40 to $140 per ton, though some rich horn-silver ore from the outcrop ran as high as $1,000 per ton.

Another fissure vein that threatens to eclipse the brilliant record of the Ontario is the Granite Mountain, at Phillipsburg, Montana, which occurs in granite. The vein is almost vertical, runs nearly east and west, and has a width of 3 to 6 feet. Though the first dividend was declared in 1885, it has already paid over $11,000,000 to its stockholders and is continuing dividends at the handsome rate of $100,000 per month. The ore has run as high as $1,000 per ton in selected lots, and their milling ore has ranged from $60 to $150 per ton.

The most famous and heaviest producer of the precious metals thus far discovered in the United States is the Comstock Lode, at Virginia City, Nevada, on which the first claim was staked in 1858, and which has since produced over $350,000,000 in silver and gold, the latter metal making up 40 to 45% of this enormous amount. This lode runs nearly north and south, dips to the east at angles varying from 30° to 45°, has a foot-wall of syenite, and a hanging wall of volcanic rock, usually propylite. The vein varies greatly in width, from a few feet to as high as 300, and the vein filling is quartz and clay in which occur irregular bodies of the silver-gold bearing ores that vary from mere threads to over 200 feet in thickness. The large bodies of ore known as "bonanzas", occur very irregularly throughout the lode, being separated by stretches of barren quartz and clay, while they vary greatly in magnitude and value. As a result of this great irregularity in the occurrence of the ore-bodies, some of the numerous mines located on this lode have spent very large sums of money in prospecting or searching for them (from $500,000 to $6,000,000 each), which is here unusually expensive on account of the great width of the lode and the excessive heat encountered; whereas those few mines that have found them have been very profitable, while the bonanzas lasted, the famous consolidated Virginia having paid $40,000,000 in dividends, the Consolidated California over $31,000,000, and the Belcher over $15,000,000. The average value of the bonanza ore is not high, it ranging between $30 and $50 per ton, though picked lots of over $1,000 per ton have been obtained. The lode has been worked to a vertical depth of 3,200 feet, which is the deepest work thus far done in this country, while the mines adjoin one another for a length of over 5 miles. Great bodies of hot water are met with in this lode which makes the lower workings very trying to work in, as temperatures as high as 170° F. have had to be contended against by the free use of air currents, cold water led into the mines by pipes, a wholesale use of ice, and by paying wages of $4.00 for a 6 or 8 hour shift. The sketch shown of a section taken across the lode is at the Potosi Mine, after Hague.

A contact silver vein that has made an excellent record is the Horn Silver Mine, at Frisco, Utah, which since its discovery in 1877, has paid $4,300,000 in dividends. It has about a north and south course, dips about 70° to the east, and has a hanging wall of trochyte while the foot-wall is limestone and quartzite. The lode varies from 20 to 150 feet in width, and carries an almost solid body of ore that assays 30 to 90 ounces silver per ton, and 5 to 45% of lead. Some of the ore carried horn-silver, but most of it has been a sulphate of lead carrying 40 to 50 ounces of silver and 30 to 40% of lead. This mine was worked to the depth of about 1,000 feet before any water was struck, so that lead poisoning from the dust arising in stoping has been a very common complaint of the miners. After striking the water-level the ore has changed into galena, while the great width of the ore-body in the upper workings has been greatly reduced by the narrowing of the lode.

[TO BE CONTINUED].

THE JEFFREY STEAM STEVEDOER.

For Loading Coal, Grain, Lime, Ores etc., etc., on Board Vessels from Cars or Storage.

This machine consists of two hinged frames arranged to be supported upon the axles and wheels of a heavy truck, and to support the shafting, bearings, chains, guides, and buckets of an endless elevator.

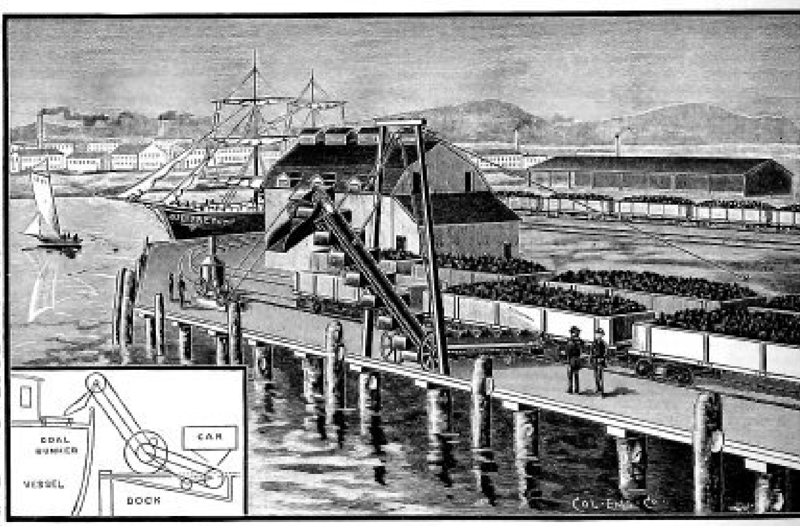
When not at work, the two portions of the frame are closed nearly together, the top portion resting upon a bolster trestle, the hinged end supported on axle and wheels, as shown in cut, the other end with bolster trestle on another axle and wheels, not shown. When folded and loaded as described, the whole apparatus with shears and guy wires, can be transported readily from place to place.

The illustration shows the machine ready for work to take coal from railroad transportation and deliver to vessel alongside of the dock.

The top of elevator is guyed in position and is driven by rope transmission from an ordinary dock engine connecting with worm and gear.

This machine can be placed, as shown, with the horizontal ladder running under and taking coal from the bottom of cars, or it can be placed at right angles to the position shown, with the horizontal ladder parallel to the railroad track, when a number of shovelers would load the passing buckets and a chute from the head would convey the coal or ore to the hatch of the vessel.

The wide field of usefulness of this machine is apparent at a glance, especially so to stevedoers at points where inland transportation on rivers, bays or canal, necessitates the use of barges, and where a capacity of



150 to 300 tons per hour at a moderate elevation of 25 to 30 feet is desirable. Its portability renders it as useful to the stevedoer or shipper as the hoisting engine.

This machine is manufactured by The Jeffrey Mfg. Co., who are well acquainted throughout the country as successful manufacturers of elevating and conveying machinery for handling material of all kinds. Their main office and works are at Columbus, Ohio, with a branch at 48 South Canal St., Chicago, Ill.

We have received from the Diamond Prospecting Company, of 15 and 17 North Clinton Street, Chicago, a copy of their new catalogue for 1891. It is a handsome and well-illustrated work, thoroughly describing their various types of diamond core drills, channeling machines, etc., etc., together with their two other important specialties, the Mitchell Coal Tipple and the Stanley Heading Machine. It will be sent free to mine owners, mining engineers and, mine superintendents on application, and it is a work that should be on file for reference in every mine office.

THE TRIPLEX ELECTRIC PUMP.

The triplex or three-cylinder pump, made by the Gould Manufacturing Company, possesses important advantages for combination with the Thomson-Houston Electric Motors. The pump offers absolutely even and unvarying resistance to the motor under all conditions, and consumes but a minimum power in friction of parts. Careful tests of the outfit complete have shown a high efficiency. The three-throw crank shaft, in the stroke of which there is no dead center, prevents jerking motion and vibrations. The pump and motor are mounted on one bed-plate, and are practically one machine, being thoroughly tested as such before going into active service.

In villages or cities where power can be had from electric light or power circuits, electric pumping offers relief from the discomforts of insufficient or hard and unfit water supply, and the hardly lesser trials of disagreeable, noisy, and dangerous pumping engines in vogue.

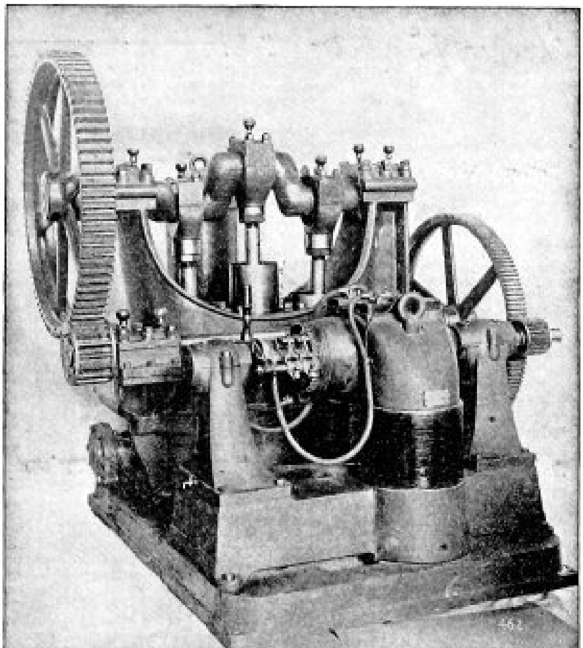
The triplex electric pump will take water from any source, as spring, cistern, or well, and force to upper supply tanks of residences, shops, warehouses, buildings, etc., or force city water to a higher point than its own pressure will carry it, as is often the case in the more elevated city districts or very tall buildings.

In such factories as large cotton mills, woolen mills, steel works, etc., and in fact, in any large establishment where work is distributed over a large territory, the employment of electrical transmission of energy for pumping can be used to great advantage.

The steam pump is in common use. Steam is generated in the boiler and transmitted through long lines of pipe to pumps where the work of pumping is performed. It has been found by actual experiment and demonstrated time and time again that these direct-acting steam pumps are most wasteful consumers of steam, using in the neighborhood of 25 pounds of coal per H. P. per hour. With electrical pumping outfits all this is changed.

One of the most troublesome questions in mining operations is the disposal of water. By the introduction of electricity for underground work the problem is greatly simplified. The necessity for long lines of steam pipe is removed, and in the place of hot steam pipes spreading dry rot in the vicinity, a small copper wire is suspended from wall or ceiling; or, the current may be taken from the trolley-wire if the mine is equipped with an electric haulage plant. In some cases, where transmission from the surface by steam or compressed air was utterly impracticable, and an underground steam plant seemed necessary, it has been found that the cost of excavating and drilling holes for the chimneys would exceed the total cost of the electric pumping plant.

The accompanying illustration shows a Goulds Pump and Thomson-Houston Motor, the combination which has met with such success in the applications mentioned above, and which is handled by the Thomson-Houston Motor Company for ordinary pumping work, and specially fitted for mining work by the Thomson-Van Depoele Electric Mining Company, for all mining, excavating, and metallurgical operations. Information on the subject of the applications of these pumping outfits, together with efficiencies and prices, will be furnished by the above companies upon request.



The Ingersoll-Sergeant Drill.

Mr. A. C. Douglas, who has recently completed two large tunnels in Pennsylvania, one at Ashland for the purpose of draining the Centralia coal basin, and the other at Park Place, for the purpose of draining another coal basin, has been given a contract by the Cataract Construction Company for canal and other rock excavation at Niagara Falls. Mr. Douglas has recently begun work, putting in new Ingersoll-Sergeant Piston Inlet Air Compressors and Ingersoll-Sergeant Drills.

Messrs. Rogers and Clements, the contractors for the main tunnel at Niagara Falls, have recently put in some Ingersoll-Sergeant drills, and are making rapid and satisfactory progress.

Indian Engineering states that the East Indian Railway collieries claim the deepest shaft in India, Jubilee Pit No. 2 having been already sunk to a depth of 450 ft., and a considerable distance having yet to be dug before coal is reached.

ON AN APPARATUS FOR THE LAYING OF COAL-DUST IN MINES.

BY MR. R. B. MAWSON.

[Transactions of the Manchester Geological Society.]

Mr. R. B. Mawson said: At the last meeting I was asked to read a paper on "Laying the Coal-Dust in Mines," but I have not been able to see my way to do it. There is nothing new about the system we use except the plugs at the end of the spray pipes, and though I am not prepared to read a paper upon the subject, I will endeavor to explain how we get over the difficulty of getting the spray fine enough at the Sovereign pit. The mine where we use the sprays is the Wigan 9 feet. The pit is 385 yards deep, and we get our water from the 7 feet lodges, at 200 yards from the surface. We have a pressure of about 240 lbs. The pipes from the lodges down the pit are 2 in. diameter. At the bottom of the pit we reduce them, and take 1½ in. pipes along the main level, east and west. We have about 500 yards of these 1½ in. pipes. At the bottom of each jig and the top of the down brows we have taps, and take the pipes about 30 yards into each district. At every 20 yards along these pipes we have ½ in. stand-pipes, to which the sprays are fitted. These stand-pipes have also taps, so that we can shut them or open them as we want, and have all or part of the sprays working. The system of pipes, &c., is the same as is carried out at a great many collieries now. The point I want to bring before the members being the lead plugs by which we get the sprays. When first we put the pipes in we tried No. 1 gas-burners, but these we found would not answer, as we could not get the sprays fine enough, and they always dropped and made the floor very wet for some feet around the bottom of the stand-pipes. This we could not do with, as the water caused the floor to lift, and had we continued with these burners we would soon have had the roads all upset. We next tried cane, which I had heard answered well at some places, but this would not do at all with our pressure, and the water simply came through in a jet. After this we tried everything we could think of and yet could not get the sprays fine enough, till Mr. Saint, one of Her Majesty's Inspectors of Mines, suggested lead plugs, which he said were used in South Wales. We, therefore, tried them, and after using them in various forms, at last hit upon our present form. We have now got the spray to the required fineness, and have had no trouble since. The lead plugs are simply screwed into the end of the pipe and then cut off, the length of the plug being about half an inch. We then drive a fine steel drift through the plug, which, besides making a hole through the lead, also swells out the lead in the pipe and makes it so fast that it will stand any pressure without blowing out. Upon turning on the water, if the spray is too coarse, we can get it as fine as we like by simply tapping the face of the lead plug with a hammer. We get the sprays just like a fog without any water dropping, and this fog traveling in the air renders all dust damp, so that if you take a handful and throw it, it drops straight down, and does not travel away in the air as dry dust does. The sprays are turned against the wind, and this breaks them up so that they act upon both floor, roof, and timber. You can trace this fog in the air from each jet for about fifteen yards, and we find by having them open about two hours per day we can render the dust damp enough and have no trouble with it. The plugs are very easily made, are inexpensive, and are not nearly so liable to get out of order as burners, which are very often stopped up by fine dirt getting in them.

DISCUSSION.

Mr. Hall. Do you find that these sprays have lowered the temperature at the face?

Mr. Mawson. In our case it has not done so, as our works are not extensive and are very cool. In some of the warm pits of South Wales, I am told, putting in the sprays has lowered the temperature from 8 to 10°.

Mr. Hall. Could you not get the same results by having shallow tanks full of water in the roadways?

Mr. Mawson. This might answer in warm workings where you could get evaporation, but except in warm workings, the tanks would have very little effect, unless the tubs were running through the water, in which case the wheels and links would carry the water to some distance and certainly prevent dust on the roads at those points.

Mr. McGreevey. Do you not find that these sprays cause the warrant to lift?

Mr. Mawson. We have no trouble in that direction now, as the sprays are simply like a very fine fog and have no effect on the floor of the mine. When we used gas-burners we could not get the spray fine enough, and always had more or less water dropping from the burners, which caused our floor to lift, and would have given us a good deal of trouble had we continued to use the burners.

Mr. Hall. How far does the fog travel in the air?

Mr. Mawson. That entirely depends upon the velocity of your air current. Our sprays are 20 yards apart, and you can distinctly see the fog for about 15 yards from the jet.

Mr. Robinson. Do you suggest it is practical to have them throughout the workings?

Mr. Mawson. Yes; I think so. It would be costly.

Mr. Dean. At Hindley Deep Pit we could trace the spray for 22 yards along the road.

Mr. Saint. There is another system of watering being tried in South Wales, the water being used in conjunction with compressed air. This means two sets of pipes, and also a compressed air engine, which greatly adds to the expense.

The President said the getting rid of dust in the main roads in mines was no doubt a very important matter, and one that had had a good deal of his attention. He had tried burners, but had experienced the difficulty of not being able to get the spray fine enough, and thus it upset his road. The lead plug seemed the right thing. It was very simple, which was a great point in its favor, and was not liable to get out of order. He certainly would try it. He thought a great deal might be done by improving the tubs used in the mine. Iron tubs were the thing, but when they came to consider the cost, it made them hold back. He was having his tubs improved by having the boards tongued and grooved and putting hoop iron in.

By this means he was making his tubs practically water-tight, and when he got all his tubs done, he expected to reduce the coal-dust in haulage roads to a very small item. They were about to try watering the top of the tubs before they started off from the bottom of the brow. Altogether, in one brow 900 yards long, by the means they had tried, they had reduced the quantity of dust made in twenty-four hours from eighteen tubs to three.

COST OF AMERICAN IRON.

The cost of production of iron and steel in this country is the subject of a report which the Hon. Carroll D. Wright, national commissioner of labor transmitted to Congress through the President on the 21st of February, 1891. This report is the result of several years of careful investigation, based upon an examination of the books of leading manufacturers and enquiries by expert special agents of the National Department of Labor. A comparison of the costs of materials used in the northern and southern states shows that the difference in favor of the south in the cost of ore and coal is very great. The ore used in the northern states costs per ton an average of 4·401 dols.; the cinder, scrap, &c., 2·031 dols.; and the coal, 2·035 dols. The ore used in the southern states costs per ton an average of 1·513 dols.; the cinder, scrap, etc., 1·031 dols.; and the coal, 1·565 dols. Figures of 118 establishments manufacturing pig iron are given.

The following table will show the comparative cost of making pig iron in different establishments in the United States and Europe. Each line represents the work of a separate establishment, and of the 118 given in the report those are quoted which fairly represent the highest, lowest, and average rates of cost of materials, labor cost, and total cost in each locality:

COST OF MANUFACTURING PIG IRON.

Locality.	Material.	Labor.	Total.
	Dols.	Dols.	Dols.
Northern	17·728	3·539	22·165
Northern	13·323	1·194	15·202
Southern	7·757	1·461	10·279
Northern	11·291	·955	12·584
Northern	11·663	1·344	13·133
Europe	9·559	·418	10·234
Europe	12·228	·912	13·434
Great Britain	9·230	·901	10·290
Great Britain	9·308	·743	10·729
Europe	14·219	·719	16·075
Northern	12·267	2·135	15·288
Northern	11·147	1·166	12·859
Southern	7·173	1·816	9·634
Southern	8·877	1·218	10·822
Southern	8·164	·595	9·622
Europe	9·885	1·414	12·070
Great Britain	9·529	·749	10·686
Europe	9·861	·731	11·107
Europe	7·327	·755	8·763
Great Britain	8·951	·608	10·163
Great Britain	9·236	·739	10·244
Great Britain	7·168	·710	8·175
Great Britain	6·844	·710	7·851
Europe	12·288	·912	13·436
Europe	10·256	·972	11·228
Europe	9·559	·835	10·394
Europe	8·333	·425	9·073
Europe	7·339	·461	8·639
Europe	7·182	·960	8·132

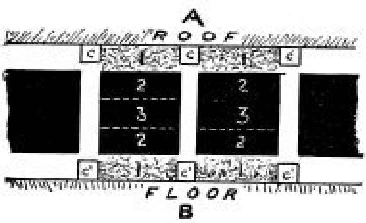
In each case the items of pay of officials and clerks, cost of supplies and repairs and taxes, constitute the excess of the "total cost" shown in the above table over the cost of material and labor. The establishments given under the head of "Europe" are situated in Germany and Belgium.

THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.*

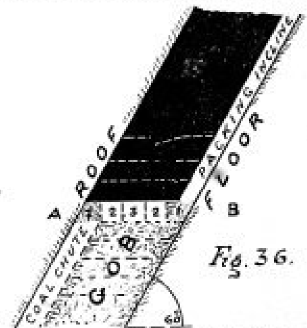
BY W. S. GRESLEY, M. E.

(Written for the Colliery Engineer).

Figs. 35 and 36. These do not appear to need much explanation, but it will be well to remark that they show a way of working a verk thick coal-bed on say a 60° pitch so that all the coal is removed. The close packing method is, of course, resorted to, because without it the whole of the seam could not be recovered by a very long way. As will be seen, the seam is first of all divided up into blocks or panels, and then worked away slice over slice, each one being mined on top of the gob or packing underfoot. The coal seam is thus worked away not parallel with its pitch or dip, but cut away systematically in horizontal slices or short lifts, each lift or slice being removed in the order of the numbers marked on plan Fig. 35 and each strip being packed tight and full as removed (see 1, 1; 1, 1, of each Fig). The coal is sent out to gangway down chutes c c c in the gob, next to the *roof of seam* or the *hanging wall* as it will be best to term it in such a system of mining. The material sent in for packing going in by way of other chutes, driven on the *foot-wall* (floor), c' c' c' Fig. 35. This method of working coal is a modified form of that illustrated in Fig. 34, applied to extraordinarily thick places in the seams.



PLAN Fig. 35.
Scale 40'



SECTION THROUGH AB Fig.
Scale 40'

Fig. 37 is a plan, and Fig. 37a is a section on the pitch, of a system of working thick coal in France, also on the close-packing method. It almost amounts to "Longwall withdrawing." In the illustrations here given, the seam has a 14° pitch. It is opened up in lifts, in descending order. Gangways and other headings are driven in on the strike about 60 feet apart with cross-headings driven on the slant or about half pitch at suitable distances (see Fig. 37 plan). When the back of the area of coal desired to be worked is reached the rooms or working-places are opened up, beginning at the uppermost heading in the section or lift, and continuing forward in such a way as to have each "place" properly "stepped" or in advance of the next one below it as to allow of the packing material being properly stowed behind the diggers as they come along. Each room, as will be seen from Figs. 37 and 38, which is an enlarged view of part of Fig. 37, is opened narrow or with a "neck" for a few feet and then widened out, and on the high side of each stump a stone wall or brattice is built square up to the next level or roadway. These "buildings" or walls serve to carry the roof coal and keep the packing in place. The top coal is taken down between and over the buildings behind the first stage of work going on in the rooms. The props and timbering are shown in Figs. 38 and 38a which sufficiently explain the details of the system. The slant roads are for lowering the cars to gangways. Practically all the coal is recovered. The air goes in on the bottom gangway G, works up hill through the various rooms, and then back to return aircourse on upper or old gangway G'. The refuse for packing is taken in along the level communicating with the upper end of each room. It comes either from the surface or else from some other part of the mine, and is mixed with the slates and refuse of the coal seam, in such a way as to completely fill the gobs and prevent serious subsidence, or danger to overlying workable beds of coal. Probably the large amount of yardage work (heading) constitutes the chief draw-back of this system.

Figs. 39 and 39a are plan and cross-section of a mode of mining a very thick and highly inclined bed of coal formerly if not still mined in France. The seam is worked in horizontal slices, each about 7½ ft. thick, from top rock to bottom rock (hanging wall to foot-wall as the metal miner would say) and altogether without reference to the natural stratification or bedding planes of the coal. About five cuts or slices are taken in each lift or section, and each is removed separately, the excavations being filled with rubbish as the work proceeds. The lifts are mined in descending order. Fig. 39 shows the uppermost one exhausted, the middle one in course of working, and the lowest practically untouched. It will also be seen that slices or cuts Nos. 1 and 2 have been completely worked out, while No. 3 is now being worked on top of No. 2 gob. Fig. 39a being a plan of it on one side of the inclines or planes, by means of which the coal is sent out and the packing materials sent in, the latter coming from above, and the coal going down through the timbered chute in the gob to the lowest hauling road or gangway level communicating with the shaft or hoisting slope. In this way, coal beds, no matter how thick, can be all worked out. Caves are avoided, squeezes can hardly occur, and everything is done with method and exactness.

[TO BE CONCLUDED.]

Forced Draught.

The Mining Journal, of London, in the issue of August 15th, reviews a paper read before the summer meeting of the Institution of Mechanical Engineers, at Liverpool, by Mr. Alfred Blechynden entitled "A Review of Marine Engineering During the past Decade." The views of Mr. Blechynden and of the members who participated in the discussion of the paper which followed its reading as to the relation between fuel consumption and forced draught are of special interest to fuel users who are interested in the burning of culm with forced draught. The *Journal* says:

"We do not think Mr. Blechynden is much above the mark when he estimates that the principle of forced draught means a saving of as much as 15 per cent. of coal relatively to power. Cheaper classes of fuel may also doubtless be used and a possible decrease of weight of boilers is also another advantage to the steam user. The author holds that it seems to be fairly well established that if the boilers are well constructed, and are provided with ample room to ensure circulation, their steaming power may without injury be increased to about 30 or 40 per cent. over that obtained on natural draught for continuous working, and may be about doubled for short runs. He proceeds to lay it down that such augmentation is accompanied in normal cases by an increased consumption per indicated horse-power; but he points out that, the same or even greater power being indicated, it may with moderate assistance of forced draught be developed with a smaller expenditure of fuel; providing that the grates and other portions of the apparatus are correctly proportioned. Doubtless, under certain conditions of weather, when with normal boiler proportions it would not be practicable to maintain steam for the ordinary speed with natural draught, the normal power may with forced draught be ensured. Strong confirmation of certain of Mr. Blechynden's views was forthcoming during the discussion, especially when Mr. F. C. Marshall pointed out that some steamship companies were using nothing but slack at 5s. 6d. a ton with forced draught stokeholes. The success of the application of forced draught was further remarked upon by Mr. W. Laird, who instanced some of the steamers running between Dublin and Holyhead. Nor was Mr. White far wrong when he observed that whatever discredit had fallen upon the forced draught system was in many cases due to the boilers to which it had been applied. From the remarks of Mr. Jeremiah Head, Mr. C. Cochrane, Mr. Macfarlane Gray, Mr. Ford Smith, Mr. Longridge, and Sir James Douglass, it appears that all the members of the institute who took part in the discussion are in favor of the principle inasmuch as full value can always be got out of the fuel no matter what are the atmospheric conditions. When gases from the funnel are used to heat the air proportionately, enhanced benefits are doubtless obtained."

COAL MINING IN THE BELLEVILLE SEAM, NO. 6, AT ST. CLAIR CO., ILL.

BY LEO GLUCK, E. M., MO. GEOL. SURVEY, JEFF. CITY.

The Belleville Seam, No. 6, of the Illinois series, was the first coal seam worked in the State, which is doubtless due to the fact that it outcrops along the Mississippi River bluffs in close proximity to St. Louis.

In St. Clair county, which is for the greater part underlaid by this bed, it is the principal seam worked.

Formerly this seam was mined extensively by drifts along the river bluffs; but the larger developments have been made from shafts in the interior of the county. It has quite a uniform thickness of 6 feet, varying generally between 5 feet and 7 feet, but reaching as much as 10 feet occasionally. At the Reinecke Mine, No. 1 (Consolidated Coal Co.), Birkner Station, St. Clair County, Illinois, which is a representative mine as regards thickness of the seam, method of working, output, management, etc., the writer had an opportunity to study the seam in detail, where the coal varies little, if any, from 6 feet in thickness.

The following general section, which includes a detailed section of the coal bed, shows the "partings and bands" in the coal, and the local names of the divisions:

20′ to 150′ loess.
150′ thin beds of limestone, shales and clay alternating and varying in thickness.
10′ shale.
5′ limestone.
5′ clay.
20′ to 25′ nodular, fossiliferous limestone (head rock).
1″ to 3′ slate.
12″ "top seam" or "blacksmith seam."
½″ "bone parting."
9″ "nine inch seam."
½″ "bone parting."
12″ to 14″ "drift seam."
½″ "clay or bone parting."
12″ "block coal."
½″ to 1″ pyritiferous or "sulphur" parting.
4″ "four inch seam."
½″ to 1½″ "bottom coal."
4′ to 16′ fire-clay.
Limestone (bottom rock.)

This coal is of the soft Bituminous variety, rather high in sulphur and ash, but its comparative great thickness, freedom from faults, its slight dip, and easy mining, make it compete favorably with other better Illinois and Ohio coals for steam and domestic use.

The impurities in this seam are pyrites and gypsum, which are found at irregular intervals throughout the seam, except in the Blacksmith which is remarkably free from them. The pyrites occurs, both as concretions, especially in the "Four-inch seam," and as flakes. The gypsum occurs as plates in the jointage planes.

The Blacksmith seam on account of its freedom from pyrites was formerly sorted out for blacksmith's use; commanding 2 cents more per bushel than the rest of the seam.

The plan of work adopted in opening up this seam is, as a general rule, the "Single Entry Room and Pillar" plan; which is continued until the workings become quite extensive, and then the "double or triple" entry plan is adopted and continued until the limits of the property are reached. Some of the larger mines are opened on the "double or triple" entry plan.

The pillars are left standing, and the coal is mined from the rooms to the extreme limits of the property before any trimming or robbing of the pillars is undertaken. If this precaution is not taken, the cracking of the roof would let in surface water, and by softening the "under clay" would cause "squeezes," even with pillars as thick as are used at present; increasing thereby the mining, pumping, and tramming expenses, besides making the mining operations more hazardous.

After the property limits are reached the coal in the pillars is regained by the "robbing system," retreating towards the shaft.

The following are the dimensions of the workings by the two different plans:

	Single Entry Plan.	Double Entry Plan.
	Feet.	Feet.
Rib between rooms	30	30
Rib between main entry and first room	60	60
Rooms started at	18 to 20	18 to 20
Rooms widen to	35 to 40	40 to 45
Width of entries	18	18
Distance between entries	300	
Distance between parallel entries		50
Cross cuts driven every		50 to 75
Distance between sets of parallel entries		600

There are two general methods of mining the coal practiced in this district; one by undercutting and shooting the coal down, the other by shooting out the coal in the solid. The former method is in general use, however.

At the Reinecke Mine the undercutting in the fire-clay was formerly done by hand; but coal cutters rapidly took the place of hand cutting, even though the former may have been temporarily cheaper.

The reason for this is that the frequent occurrence of strikes in this district, as can be seen from the coal statistics of Illinois, made the introduction of coal cutting machines almost a necessity; as with them a definite output of coal can be gotten without especially skilled labor. Any able-bodied man can become an expert machine man in a very short time. Thus giving the mine owner the advantage of placing large coal contracts with safety.

The Harrison machine, run by compressed air at 80 pounds pressure, making 220 revolutions per minute, is the mining machine used. It is operated by being placed on a board 10 feet long and 3 feet wide, inclined 9 inches in 10 feet towards the coal face.

The machine cuts along the width of the board; then it is shifted to another board, placed by the side of the first board, and it is then ready for another 3-foot cut. This is continued until the whole face of a room is undercut 3½ feet under, about 12″ high at the face, and 3″ to 4″ at the back. The undercutting is done in the fire-clay; but if the clay becomes too hard, or pyrites balls are encountered, or rolls in the floor, cut out the fire-clay, then the cutting is done in the coal.

Generally the cutting is done in part in the coal, and in part in fire-clay, cutting a wedge from each. About ⅙ of this coal is recovered as lump coal, the other ⅚ goes into the gob.

Each Harrison machine has a complement of six steel picks, two picks being generally in the blacksmith's shop for repairs. From six to eight picks are dulled by each machine daily. Each machine has five faces to work consecutively, thus giving the coal loaders opportunity to load the coal shot down.

The Harrison coal cutter in room work experiences in a day, of ten hours, the following delays:

10 bits or picks are changed @ 1½ minutes each, 15 minutes.
22 board shiftings are changed @ 3 minutes each, 66 minutes.

2 machine shiftings,	2 loadings @ 5½ minutes each,	11 min.
	2 " @ 6 minutes each,	12 min.
	2 trammings @ 4½ minutes each,	9 min.

Time lost by necessary delays, 113 minutes, or say two hours, 120 minutes.

Thus, in working a shift of 10 hours, 2 hours are lost by necessary delays, making the efficiency of the Harrison coal cutter under the best conditions 80% of the time of the working shift.

The labor required per machine is as follows:
1 machine runner.
1 machine helper.
1 blaster.
4 coal loaders.

The Harrison machine can cut on an average along 1 foot of face in 6½ minutes; as determined by the writer, from a long series of observations over a period of four weeks. Therefore, in a day of 10 hours, on this basis, assuming that no time was lost except as enumerated before, the Harrison machine can cut along 74 linear feet of face with an undercut of 3½′, which in a 6 foot seam amounts to 1,554 cubic feet, or 1,554 bushels of coal.

When a room is partially undercut by the coal cutters, then the blaster follows the machine and puts in holes for blasting down the coal with a geared auger drill, operated by hand, and attached to the coal face by expanding jaws inserted into a shallow hole made by a pick or jumper drill 3″ below the hole to be bored or drilled.

A kit of tools for the boring machine consists of two 2-foot, two 4-foot, two 6-foot augers, and two 18″ extensions. One set of tools are dulled every day, and require refacing by the blacksmith; although they are refiled by the blaster after each use.

In blasting down the coal, three and four holes respectively are used, of which one and two respectively are used in entry and room driving; all of which are usually started in the drift seam.

The following table gives the dimensions and speed of drilling the different kinds of holes:

	Entry Work.	Room Work.
Diameter of holes	2¼″ to 2¾″	2¼″ to 2¾″
Number of "breaking in" holes	1	2 (also incline to-
Inclination to the horizontal of "breaking in" holes	30°	30° wards each
Incl. to vert. of "breaking in" holes	15°	15° other.)
Length of " " "	5½′	5½′
No. of rib holes	2	2
Incl. to horizontal rib holes	20°	20°
Length of rib holes	3½′	3½′
Time taken to attach auger ready for drilling	4 m.	4 m.
Time taken to drill breaking in hole, (average)	15 m.	15 m. (average)
Time taken to drill rib hole	12 m.	12 m. "
Time taken to detach auger	1 m.	1 m. "

The loading of the holes is done by either of two methods the "Needle" or "Barrel" method, described in detail in the *Engineering and Mining Journal*, Feb. 22, 1890, by the writer, giving the several advantages.

It takes on an average 10 minutes to load a hole by the "Needle" method and one can load twice as fast by the "Barrel" method.

The "Breaking in" holes are fired first, and then the face is squared by the "rib" holes.

From a plot of the mine, the writer determined that 38% of the coal is left as pillars, leaving 62% of the coal to be mined.

The 4″ and 5″ of partings are lost, which is 9″ of 6′, or 12½% of the seam; again the amount of slack made by the mining of the coal depends greatly on the miner, but 5% will, without doubt, fully cover this loss, so that not more than 17½% of the 62% of the seam is the coal that is lost, or 62% − 17½% of 62% to = 51·15% is the coal that is hoisted.

By observation at the shaft landing it was determined that 81% of the coal hoisted went to the slack dump to be sold for practically nothing and part to be used as fuel at the mines. Therefore the marketable coal of the seam is only 40·89% of the total seam; but to this must be added about 25% of the 38% left as pillars, which is to be regained by robbing the pillars. Thus the total amount of the Belleville seam which is available as lump coal by the present methods of mining is 56·39% of the total seam.

THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.

The Probable Depth at Which Coal is now Being Worked in the British Isles.

A paper on this subject by Professor Hull is printed in the Transactions of the Manchester Geological Society, Volume XX. The author says:

"In connection with the duration of our coal supply, it is of interest to enquire into the average depth at which coal is being worked, and the rate of increase of that average. If at the introduction of steam winding engines about 1820 it be supposed that 100 yards was the average depth at which coal was mined; and that now, as a near approximation, the average depth be taken at 350 to 400 yards, then the rate of increase in depth is about 4 yards per annum if uniform, which it has not been. For the counties of York, Derby, and Notts the average depth at present is probably near 250 yards, while in Lancashire and Cheshire it is much greater—say, nearer 400 yards."

A DESCRIPTION OF THE ENDLESS ROPE HAULAGE AT CASTLE EDEN COLLIERY.

BY WALTER BELL.

[From the Proceedings of The British Society of Mining Students.]

As the engine planes for endless rope haulage must, of course, be wider than those for systems where single rails are used, the state of the roof has an important bearing on the choice of a system of haulage.

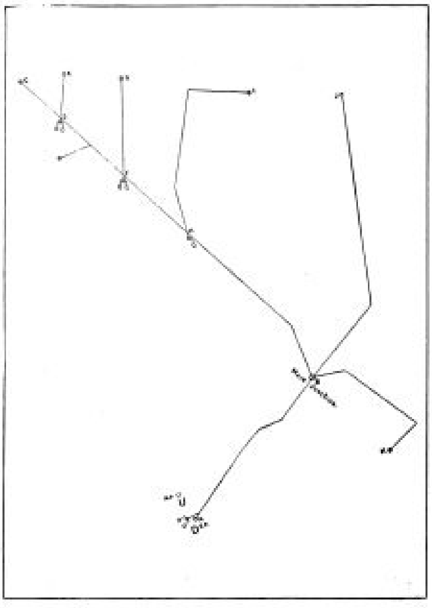

FIG. 1.

REFERENCE.

From A to B	814 yds.,	29·55	feet	rise.
From B to C	1991 yds.,	89·17	feet	fall.
From D to E	187 yds.,	6·94	feet	fall.
From F to G	418 yds.,	28·54	feet	rise.
From H to I	913 yds.,	40·85	feet	rise.
From B to J	1362 yds.,	166·94	feet	rise.
From B to K	682 yds.,	62·29	feet	rise.

The wagonways at Castle Eden are about 12 ft. in width, the gauge being 2 ft. in width, and 3 or 4 ft. being provided on one side of the road as a traveling way.

The height of the seam varies from about 3 ft. 6 in. to 4 ft. 6 in., and the top stone is "ripped" on one side to make height for the traveling way.

The hauling engine is underground, and was first fitted up for tail-rope haulage, but by adding gearing (7 to 1) it has been altered for slow motion. It is a condensing engine with two cylinders 16 in. diameter, 24 in. stroke. The drum is 9 in. wide. The engine is worked by steam or compressed air.

The driving-wheel for the rope is 8 ft. diameter and is of slightly conical form, the rope being passed around 3½ times, going on at the large diameter and coming off at the lesser, thus preventing friction of the coils against one another. The trod is lined with crucible cast steel so that it can be replaced when worn. This wheel is a duplicate of that shown in Figs. 4 and 5, without the friction-clutch.

Fig. 1 is a plan showing the number and direction of the wagonways where the rope is employed.

The rope runs underneath the tubs, and each tub is attached separately to the rope by means of a clip (see Figs. 2 and 3), rollers being placed about 10 yards apart for the purpose of preventing the rope from trailing on the ground, but low enough to allow free passage for the clips.

The system is worked by means of a main driving-rope 2⅞ in. circumference, which drives a wheel at the point B on Fig. 1, this wheel giving motion, by means of friction-clutches, to other wheels which drive the ropes leading into other districts, and each wheel can be separately put into or out of gear. By means of the friction-clutches the driving-wheels can be started gradually, thus relieving the ropes of any unnecessary strain.

The friction-clutch is the main feature of interest in the haulage. The driving-wheel A and friction-wheel B (see Figs. 4 and 5) are made to run loose on the shaft C when the clutch is out of gear. The strap as shown in plan is in three segments, each segment having projections *d* at the ends with screwed recesses in which work right and left-handed screws E. In the center of each segment there are holes F which receive pins passed also through the driving-wheel, as at H. On these right and left-handed screws are fixed levers K, connected with the arms L of the sliding box M, which is actuated by a screw and lever from above. When the sliding box is made to slide up, the screws bring the segments of the strap closer to one another and so gripe the friction-wheel, and the wheel revolves. This is tightened sufficiently to move the given load, and should the load become greater at any time the friction wheel slips and becomes stationary. If only the weight of coal is the cause of the heavier load, the sliding box can be pushed up still further, and the strap tightened.

In the wheel-pit, therefore, there is first the main driving-wheel, always running, then 3 sets of wheels and clutches below for the 3 different ways.

The wheels have false trods T of crucible cast steel, but show very little signs of wearing, although they have been on about 7 years.

The district B C is slightly dipping inbye, and tubs are taken off and hung on at 5 junctions. Three separate engines work the branch roads, H I, F G, and D E, which have compressed air as their motive power.

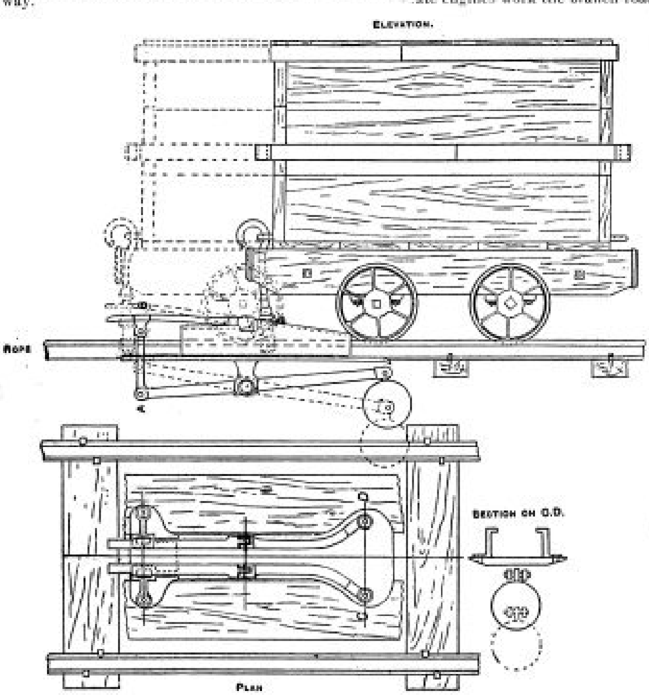

FIG. 2.

REMARKS.

The dotted lines drawn illustrating the "knock-off" in the elevation, show it in its natural position; where the tub is shown in dotted lines the clip is detached, the arms having been lifted up again by the ball and lever after being depressed.

The straight-on district B J rises inbye all the way, which does not put much work on the engine as the full tubs help to bring the empties up.

In the reference to Figure 1 the lengths and total rise or dip of the wagonways are given.

About 900 tons of coal pass over the main rope in tubs of 8½—9 cwt. capacity, and the rope runs 11 hours per day.

At the main junction B, the empty tubs are drawn up a "kip" to get an impetus to run into the other districts, in which there are "swalleys," where they are attached to the rope. In the same way on the full sides of the branch roads, the full tubs are brought on to a "kip," and when knocked off they run down to the main rope.

Speed. The rope travels about 3 miles per hour.

Curves. In passing round curves there is a series of bell-sheaves (those found to suit best are drawn to scale in Figs. 6 and 7), placed at equal distances around the curves and between the rails, which are so placed that a clip, when passing round with the rope, shall be in the center of the two rails, so when the rope is running alone it is a little out of the center. The clips having a firm grip of the rope, are easily drawn round the sheaves, and the tubs pass without jerks. The boxes of the clips must not be too low down, (which sometimes happens when the clips are worn) or, else they are liable to be lifted up and the clip become detached.

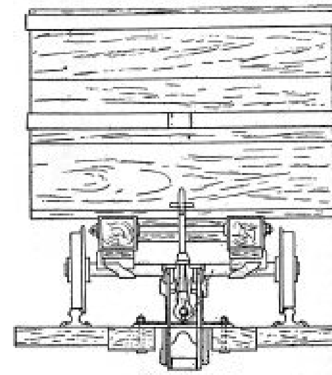

FIG. 3.

Swalleys. There being a greater tension on the full, than on the empty way, when passing "swalleys" the rope has a tendency to lift the tubs off the rails, but these "swalleys" are partially filled in on the full side. The tension not being so great on the empty way, the rope lies between the rails.

"Backs" or hills are in the same way cut through.

Gradients. The heaviest gradients on the outbye end or driving-rope is 1 in 9 on the full way, and 1 in 6 on the empty way.

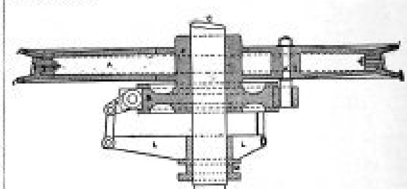

FIG. 4.

Tension Gear. Owing to the varying condition of the way, there are at different times and places, strains on the ropes which unless balanced to some extent, would throw the tubs off the rails.

To balance these the following method is applied: The rope is passed round a wheel supported on a sliding carriage on wheels, the carriage being attached to a chain at the end of which are placed weights, the chains passing over pulleys as in Figs. 8 and 9. The weights can be altered according to length of rope or

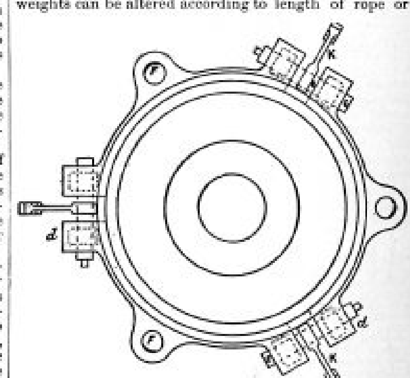

FIG. 5.

weight of mineral on road. These are placed on the trailing rope or empty tub side as near the driving-wheels as possible, so as to take up any slack after coming round these wheels.

Hanging on and knocking of the clips. The "hanging on" of the clips at first sight seems difficult, but the lads soon get trained to the work and can hang them on very quickly.

On the other hand, the "knocking off," when the tubs follow one another closely, and the clips being stiff at times, is attended with considerable difficulty, and should a tub miss, being detached near the return wheel, damage to the rope becomes serious.

To prevent such accidents an automatic "knock off," arrangement is placed at the terminus of the rope. Figs. 2 and 3 explain the working of it, which acts admirably.

Different sized clips are used for the different ropes. New ropes sometimes give trouble until they get stretched.

Size of ropes: Main road 2¼ in. circumference. Branch roads, 2¼ in. and 1¾ in. circumference.

Greasing. Automatic greasers are placed at various points throughout the mine which grease more effectively than in other systems where the tubs run at a greater speed.

Signals. Electric signaling is used throughout the pit, and the rope can be stopped within a few yards after the signal has been sent either to the engineman for the outbye end, or to the main junction for the other ropes (where a man is kept arranging the tubs into and out of the different districts) and any rope is immediately put out of gear.

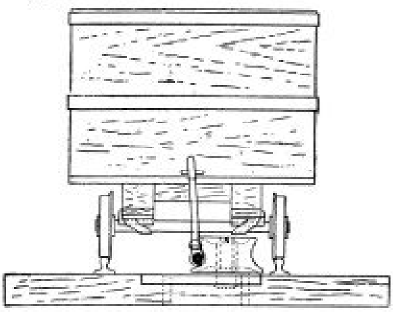

Fig. 6.

Bells are placed in circuit at all the junctions, so that those lads employed there can tell whether the ring comes from inbye or outbye.

Pumps can be coupled up to the return wheels the same as in other systems.

Compressed air is carried into the face of the district B C, and the branches on this road are worked by separate engines, as shown in Fig. 1.

The engine at H has one cylinder, 14 in. diameter by 18 in. stroke, geared 2½—1. The engine at F has two cylinders, 6 in. by 12 in. stroke, geared 6—1. The engine at D has two cylinders, 8 in. by 14 in. stroke, geared 8—1. The engine at H has lately had another cylinder added, namely, 20 in. by 20 in. stroke, and the gearing is to be altered to 6—1.

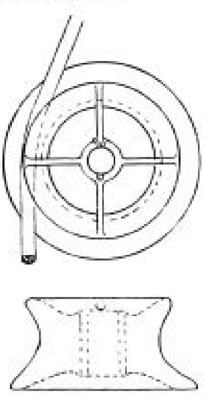

Fig. 7.

Naked lights are a great benefit at the junctions as they aid the lads much in hanging on the tubs properly, and where safe, open lights are used. At these stations, or about 20 yards both inbye and outbye, are fixed between the ways levers, which, when a tub passes over them, the axle pulls a bell at the junctions and warns the lads there of the approach of either full or empty tubs, according to the direction the ring comes from.

Advantages. Extensions of the rope can be made in very small distances, and consequently the putters or trammers put direct on to the rope, and so driving horses are done away with, which saves the cost of making the roads higher.

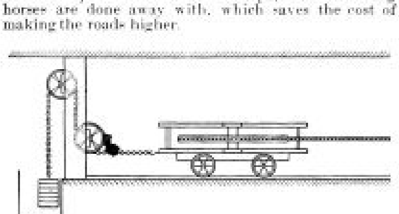

Fig. 8.

The strain and tear on machinery, trams, and ropes are a great deal less than in the tail-rope system, and if an accident does happen it is not generally of a very serious nature, as when a tub gets off the way the bow of the clip straightens out and leaves hold of the tub.

By attaching the tubs at equal distances apart, the weight of the rope is carried along with less friction on the ground and rollers.

A very regular supply of coal is brought to the shaft.

Over Endless Chain—less weight in the rope than in the chain, curves worked without any hand labor.

Over Quick-running Endless Rope—the clips being stronger and running in sets, the rope is liable to injury. No set-riders. Less liability to accident.

A rope lasts 4 years on the average.

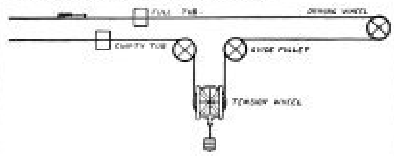

Fig. 9.

Costs. Maintaining way and all wagonway cost is about ·85 d. per ton, and cost of ropes about ·76 d. per ton.

The cost per ton for rope lads, *i. e.*, all lads taking off tubs and hanging on, is 1½ d. per ton.

The cost per ton per mile is about 3 d. Steam power and repair of tubs is not included in this. This is somewhat high on account of the rope being taken right into the "flats."

DEFINITIONS OF TECHNICAL TERMS.

KIP.—A level or gentle sloping roadway going outbye at the extremity of an engine plane, upon which the full tubs stand ready for being sent up the shaft.

SWALLEY.—A hollow in the road.

MINE INSPECTION IN THE TERRITORIES.

The Act for the Protection of the Lives of Miners in the Territories Passed by the Last Congress.

Be it enacted by the Senate and House of Representatives of the United States of America in Congress assembled, That in each organized and unorganized Territory of the United States wherein are located coal mines, the aggregate annual output of which shall be in excess of one thousand tons per annum, the President shall appoint a mine inspector, who shall hold office until his successor is appointed and qualified. Such inspector shall, before entering upon the discharge of his duties, give bond to the United States in the sum of two thousand dollars, conditioned for the faithful discharge of his duties.

SEC. 2. That no person shall be eligible for appointment as mine inspector under section one of this act who is not either a practical miner or mining engineer and who has not been a resident for at least six months in the Territory for which he shall be appointed; and no person who shall act as land agent, manager, or agent of any mine, or as mining engineer, or be interested in operating any mine in such Territory shall be at the same time an inspector under the provisions of this act.

SEC. 3. That it shall be the duty of the mine inspector provided for in this act to make careful and thorough inspection of each coal mine operated in such Territory, and to report at least annually upon the condition of each coal mine in said Territory with reference to the appliances for the safety of the miners, the number of air or ventilating shafts, the number of shafts or slopes for ingress or egress, the character and condition of the machinery for ventilating such mines, and the quantity of air supplied to the same. Such reports shall be made to the governor of the Territory in which such mines are located and a duplicate thereof forwarded to the Secretary of the Interior, and in the case of an unorganized Territory directly to the Secretary of the Interior.

SEC. 4. That in case the said mine inspector shall report that any coal mine is not properly constructed or not furnished with reasonable and proper machinery and appliances for the safety of the miners and other employes it shall be the duty of the governor of such organized Territory, or it shall be the duty of the Secretary of the Interior to give notice to the owners or managers of said coal mine that the said mine is unsafe and notifying them in what particular the same is unsafe, and requiring them to furnish or provide such additional machinery, slopes, entries, means of escape, ventilation, or other appliances necessary to the safety of the miners and other employes within a period to be in said notice named, and if the same be not furnished as required in such notice it shall be unlawful after the time fixed in such notice for the said owners or managers to operate said mine.

SEC. 5. That in all coal mines in the Territories of the United States the owners or managers shall provide at least two shafts, slopes, or other outlets, separated by natural strata of not less than one hundred and fifty feet in breadth, by which shafts, slopes, or outlets distinct means of ingress and egress, shall always be available to the persons employed in said mine. And in case of the failure of any coal mine to be so provided it shall be the duty of the mine inspector to make report of such fact, and thereupon notice shall issue, as provided in section four of this act, and with the same force and effect.

SEC. 6. That the owners or managers of every coal mine at a depth of one hundred feet or more shall provide an adequate amount of ventilation of not less than fifty-five cubic feet of pure air per second or thirty-three hundred cubic feet per minute, for every fifty men at work in said mine, and in like proportions for a greater number, which air shall by proper appliances or machinery be forced through such mine to the face of each and every working place, so as to dilute and render harmless and expel therefrom the noxious or poisonous gases; and all workings shall be kept clear of standing gas.

SEC. 7. That any mine owner or manager who shall continue to operate a mine after failure to comply with the requirements of this act and after the expiration of the period named in the notice provided for in section four of this act, shall be deemed guilty of a misdemeanor, and shall be fined not to exceed five hundred dollars.

SEC. 8. That in no case shall a furnace shaft be used or for the purposes of this act be deemed an escape shaft.

SEC. 9. That escape shafts shall be constructed in compliance with the requirements of this act within six months from the date of the passage hereof, unless the time shall be extended by the mine inspector, and in no case shall said time be extended to exceed one year from the passage of this act.

SEC. 10. That a metal speaking-tube from the top to the bottom of the shaft or slope shall be provided in all cases, so that conversation may be carried on through the same.

SEC. 11. That an approved safety-catch shall be provided and sufficient cover overhead on every carriage used in lowering or hoisting persons. And the mine inspectors shall examine and pass upon the adequacy and safety of all such hoisting apparatus.

SEC. 12. That no child under twelve years of age shall be employed in the underground workings of any mine. And no father or other person shall misrepresent the age of anybody so employed. Any person guilty of violating the provisions of this section shall be deemed guilty of a misdemeanor, and upon conviction thereof shall be fined not to exceed one hundred dollars.

SEC. 13. That only experienced and competent and sober men shall be placed in charge of hoisting apparatus or engines. And the maximum number of persons who may ascend or descend upon any cage or hoisting apparatus shall be determined by the mine inspector.

SEC. 14. That it shall be lawful for any inspector to enter and inspect any coal mine in his district and the work and machinery belonging thereto at all reasonable times, but so as not to impede or obstruct the working of the mine; and to make inquiry into the state of the mine, works, and machinery, and the ventilation and mode of lighting the same, and into all matters and things connected with or relating to the safety of the persons employed in or about the same, and especially to make inquiry whether the provisions of this act are complied with; and the owner or agent is hereby required to furnish means necessary for such entry, inspection, examination, and inquiry of which the said inspector shall make an entry in the record in his office, noting the time and material circumstances of the inspection.

SEC. 15. That in all cases of fatal accident a full report thereof shall be made by the mine owner or manager to the mine inspector, said report to be in writing and made within ten days after such death shall have occurred.

SEC. 16. That as a cumulative remedy, in case of the failure of any owner or manager of any mine to comply with the requirements contained in the notice of the Governor of such Territory or the Secretary of the Interior, given in pursuance of this act, any court of competent jurisdiction, or the Judge of such court in vacation, may, on the application of the mine inspector in the name of the United States and supported by the recommendation of the Governor of said Territory or of the Secretary of the Interior, issue an injunction restraining the further operation of such mine until such requirements are complied with, and in order to obtain such injunction no bond shall be required.

SEC. 17. That wherever the term "owner or manager" is used in this act the same shall include lessees or other persons controlling the operation of any mine. And in case of the violation of the provisions of this act by any corporation the managing officers and superintendents, and other managing agents of such corporation, shall be personally liable and shall be punished as provided in act for owners and managers.

SEC. 18. That the mine inspectors provided for in this act shall each receive a salary of two thousand per annum, and their actual traveling expenses when engaged in their duties.

SEC. 19. That whenever any organized Territory shall make or has made provision by law for the safe operation of mines within such Territory, and the Governor of such Territory shall certify said fact with a copy of the said law to the Secretary of the Interior, then and thereafter the provisions of this act shall no longer be enforced in such organized Territory, but in lieu thereof the statute of such Territory shall be operative in lieu of this act.

Approved March 3, 1891.

Testing Mineral Land.

So many mistakes have been made in the purchase or leasing of mineral lands, that it is now regarded as absolutely necessary that lands should first be tested by a diamond drill before the sale or lease is completed. Then, if the cores are carefully preserved and recorded, an almost perfect idea of the value of the minerals may be arrived at. Mr. H. P. Simpson, of Scranton, Pa., who for several years had charge of the prospecting business of Simpson and Watkins, has succeeded the latter firm, and the class of prospecting that he is doing is so satisfactory to the large coal companies of the Lackawanna and Wyoming region, that he has several drills constantly at work. Among his clients are the Hillside Coal and Iron Company, the Pennsylvania Coal Company, the Lackawanna Coal Company, Limited, the Parrish Coal Company, and others.

Mr. Simpson's facilities are such that he is prepared to contract for any number of test holes, and will guarantee good work and quick time. All records are kept strictly confidential. Those of our readers wishing to learn accurately the quality, position, and extent of strata in mineral lands, will do well to write Mr. Simpson for terms, etc.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.*

Siphon.

Editor Colliery Engineer :

SIR :—I submit the following in reply to "Miner," of Elizabeth, Pa., whose question appeared in the August issue:

Can a siphon have too much fall for its lift, and why?

I believe it can, as I have found by experience that there is a certain medium when the siphon will work best. If a siphon has a 30′ fall and is giving good results, by adding another length or more of pipe instead of making the flow of water better, it will hinder it. The quantity of water may not be much less, but the siphon will not run as long a time without charging as it did before the length was increased. Also in the 30′ fall the pipes will not be full of water, and in consequence there will be more or less of air in them, which in time will work its way to the summit and cut off the flow of water. If the fall is lengthened the room for air will be increased, and the flow of water will be cut off sooner, requiring it to be charged oftener. Also, the more the length of the pipe is increased the more friction there will be to overcome.

Yours, etc.,
JOSEPH CAIN.

Whitwell, Marion Co., Tenn., September 1st.

Certificated Mine Superintendents.

Editor Colliery Engineer :

SIR :—I have watched with much interest the articles which have been appearing in your journal for the past several months on "Certificated Mine Superintendents," and wish to add my views to the list.

Your journal has followed me to a large number of different States and places on this Continent, and at each of these mining places, of course, there were superintendents, and with the exception of one case I have not met with incompetent superintendents, so that my experience does not coincide with some of your correspondents. The one incompetent superintendent I refer to was met in the State of Alabama, and he only held the position for a short term.

Although the superintendents with whom I have come in contact are competent men well suited to the responsible positions which they hold before the people—not before the law so much—I think that even their standard of excellence could be raised by the law requiring that every official should have a certificate of competency, and this would bar out those who might by any chance desire to fill a position they are not fitted by education or practice to fill. We are aware that many incompetent men desire such positions, and we may thank the good judgment of general managers or executive committees for the selection in most cases of good men.

I am not of the opinion that superintendents should be required to have a special certificate but by all means let him pass the mine foremen's examination before he is considered eligible for the position of superintendent. This would, as I have just said, place a barrier strong enough to keep incompetent men out of the field and I think this is all that fair-minded mining men desire. Thus fitted out the superintendent will be a suitable man to adjust difficulties or give suitable advice or instructions at the proper time if called upon to do so. Being thus qualified himself he will also be the better able to select the best men to fill the positions of trust under him, and in the failure of mine bosses to do their full duty (some do not do their full duty) he can reprove in fitting language, knowing whereof he speaks.

Such a certificate would bring with it one other advantage, it would hush the voice of contumely and silence the crank, be he mine boss or a citizen in another walk of life.

Mr. Roy, by his simple remarks, started discussion on an important subject and I hope that the various candidly expressed opinions of the correspondents on this subject will aid Mr. Roy in the good work which so many years of his life he has been identified with.

Yours, etc.,
H. L. D. W.

Lethbridge, N. W. T., Canada, August 31st.

An Agricultural Phenomenon on Coal Land.

Editor Colliery Engineer :

SIR :—In Jefferson County, Ohio, there is a singular phenomenon which I would like to bring before your readers for explanation.

There are a great many apple orchards in that country, and on the hill-sides where the coal stratum comes to the surface, it has been noticed that above the stratum there is a large yield of apples, but below it there is not a single apple. This phenomenon exists in all of that section. In the spring, while the trees were in blossom, there was a heavy frost and the blossoms on the trees that did not bear were all destroyed. Now it is evident that the coal in some way protected the fruit trees from the frost by some inherent property, or chemical affinity that the coal possesses. I hope that some one will give a scientific explanation of the cause of this. It is also asserted that the frost destroyed all the delicate and tender plants and vegetable blossoms below the coal stratum.

Yours, etc.,

Pittsburgh, Pa., September 9th. W. W. CABLE.

Ventilation and Mining.

Editor Colliery Engineer :

SIR :—Please insert the following in answer to "A. L. G.," of Audenried, Pa.:

(1). In Wilson's book on mine ventilation the following formula is given to find the perimeter of an elliptical shaft:

$$\frac{\sqrt{\frac{A^2+a^2}{2}}+\frac{A\times a}{2}}{2}\times 3{\cdot}1416.$$

Please explain it by working it out fully.

For convenience we will take an elliptical shaft whose long axis is 10 ft. and short axis 5 ft., then $A = 10$, $a = 5$, then substituting their values in the formula and solving we have

$$\sqrt{\frac{10^2+5^2}{2}} = 7{\cdot}9,\quad \frac{10+5}{2} = 7{\cdot}5, \text{ and}$$

$$\frac{7{\cdot}9+7{\cdot}5}{2}\times 3{\cdot}1416 = 24{\cdot}19, \text{ perimeter.}$$

(2). In opening out a gangway to the width of a double track or turnout, how would you increase the length and diameter of your collars?

Assuming the gangway to be 8 ft. wide, using 8 in. collars, and it to be opened out to 12 ft., the collars being 3 ft. apart, each collar would have to be made 1 ft. longer.

The first collar on the turnout would equal

$$\sqrt[3]{\frac{9^2}{8^2}}\times 8^3 = 8{\cdot}653 \text{ in. diameter.}$$

The second collar on the turnout would equal

$$\sqrt[3]{\frac{10^2}{8^2}}\times 8^3 = 9{\cdot}28 \text{ in. diameter.}$$

The third collar on the turnout would equal

$$\sqrt[3]{\frac{11^2}{8}}\times 8^3 = 9{\cdot}9 \text{ in. diameter.}$$

The fourth collar on the turnout would equal

$$\sqrt[3]{\frac{12^2}{8^2}}\times 8^3 = 10{\cdot}482 \text{ in. diameter.}$$

(3). If there are two airways of the same length one being 12 ft. by 6 ft., and the other 9 ft. by 9 ft. what pressure applied to the former would give the same quantity of air that a pressure of 10 lbs. per sq. ft. gives to the latter?

Their perimeters and lengths being the same the pressure will be according to

$9 \times 9 \div 6 \times 12 = 1{\cdot}125$ = difference in size of airways and in velocity of air, being as 1 is to 1·125, then

$$\frac{1^2}{1{\cdot}125^2} : \frac{1{\cdot}125^2}{1} :: 10 : 14{\cdot}254.$$

Yours, etc.,

Hanna City, Ill., Aug. 22d. A. B.

[Solutions to the above questions were also received from "S. U. P.," of Red Bank, Pa., on account of their similarity they are not inserted.—ED.]

Answers to Miscellaneous Questions.

Editor Colliery Engineer :

SIR :—I wish to thank "R. M. S.," of Avoca, Pa., for his answers to my questions in the August issue of your journal. He asked for a calculation on the second question so that he might show where I was wrong. I would say that I solved the question myself after sending it to the THE COLLIERY ENGINEER.

As I am but a student in the theory of mining and having worked out the various fan questions given in your journal, and noticing that our District Inspector could always find more air at foot of upcast than the fan could exhaust, it rather puzzled me, I measured the airway, however, which I found to be 8′ 6″ × 9′ 4″ or an area of 79·4 sq. ft., and the anemometer showed a speed of 900 revolutions per minute, and 900 × 79·4 = 71,400 cu. ft. per minute. The dimensions of the fan are, diameter, 20′; width of blades, 7′; orifice 8′, and a velocity of 40 revolutions. Now by formula

$$(D + D) \times (D - D) \times {\cdot}7854 = \text{area, or}$$
$$20 + 8 = 28$$
$$20 - 8 = 12$$
$$28 \times 12 \times {\cdot}7854 = 263{\cdot}8944, \text{ area.}$$

And

$$263{\cdot}8944 \times 40 \times 7 = 73{,}890{\cdot}432 \text{ cu. ft. of air,}$$

then

$73{,}890{\cdot}432 - 71{,}400 = 2{,}490$ cu. ft. of air which the fan is displacing. I think this is nearly correct for the velocity will be much greater at blades of fan than at foot of upcast.

Yours, etc.,

Westville, N. S., Aug. 25th. JOS. QUIGLEY.

Ventilation.

Editor Colliery Engineer :

SIR :—I notice there is quite a difference in the answers to the questions asked by "Jim Trinket," in your April issue, arising out of a misconception of the principle involved. It is true air expands $\frac{1}{459}$ part of its volume for each degree of heat added *from zero up*, but the expansion must be computed from zero, or in other words take $\frac{1}{459}$ part of what the volume would be at zero for the expansion due to one degree of heat added, and this multiplied by the temperature will give the expansion. I think it can best be illustrated by taking an example for which we will use the same data given in "Jim Trinket's" question.

If 18,000 cubic feet of air at 55° be reduced to 0°, what then would be its volume? Again, if the volume found be raised to 180° temperature, what would the volume be? As air expands $\frac{1}{459}$ part of itself for each degree of heat added from zero, 459 must have expanded 55, and 459 + 55 = 514. The expansion, therefore, at 55° has been $\frac{55}{514}$ of the volume which equals

$$\frac{18{,}000 \times 55}{514} = 1{,}962{\cdot}07, \text{ then}$$

$18{,}000 - 1962{\cdot}07 = 16{,}073{\cdot}93$ which would be the volume at zero. Then

$$\frac{16073{\cdot}93}{459}\times 180^\circ = 6303, \text{ the expansion}$$

from zero, and

$16{,}073{\cdot}93 + 6303 = 22{,}376{\cdot}93$ equals the volume at 180° which is the same as

$$(459 + 55 = 514, \text{ and } 459 + 180 = 639)$$
$$514 : 639 :: 18{,}000 : 22{,}377.$$

Yours, etc.,
T. S. C.

Gardner, Ill., August 31st.

Effect of Gas on the Flame of a Safety-Lamp.

Editor Colliery Engineer :

SIR :—Please insert the following question in your journal:

What difference is observed in the flame of a safety-lamp when light carbureted hydrogen (CH_4) and air are mixed in the following proportions: 1 of gas to 13 of air; and 1 of gas to 5 of air?

Yours, etc.,
R. P.

Greensburg, Pa., September 1st.

Examination Question.

Editor Colliery Engineer :

SIR :—Not being satisfied with the solutions given in the August issue to my question in the July number, I herewith submit the following, being very desirous to be corrected if in the wrong. The difference at pressure between the downcast and upcast shafts is 5·2 lbs., now $\frac{5{\cdot}2}{5{\cdot}2} = 1$ inch water-gauge, and assuming water to be 833 times heavier than air, we find that

$$\frac{833 \times 1}{12} = 69{\cdot}4 \text{ ft. the length of the motive}$$

column producing ventilation. Let us now take the formula acknowledged by all authorities to be correct, viz.,

$$\frac{T - t}{459 + T} \times D = M, \text{ but as "T" is the un-}$$

known quality, we have only

$$\frac{(\ ) - t}{459 + (\ )} \times 400 = 69\tfrac{5}{12}, \text{ now let } X = T, \text{ the}$$

required temperature, then we have

$$\frac{X - t}{459 + X} \times 400 = 69\tfrac{5}{12}, \text{ or substituting the}$$

value of t it becomes.

$$\frac{(X + 40)\,400}{459 + X} = 69\tfrac{5}{12} \text{ clearing of fractions.}$$

$$400\,X - 16{,}000 = (459 + X)\ 69\tfrac{5}{12}, \text{ trans-}$$

posing and collecting we have

$$400\,X - 69\tfrac{5}{12}X = 31862\tfrac{1}{4} + 16{,}000$$
$$330\tfrac{7}{12}\,X = 47{,}862\tfrac{1}{4}$$
$$X = 144^\circ\ 47', \text{ or, say, } 145^\circ \text{ as the required}$$

temperature.

Proof,

$$\frac{145^\circ - 40^\circ}{459 + 145} \times 400 = 69{\cdot}53 \text{ nearly, same as}$$

above.

Yours, etc.,

Westville, Picton Co., N. S., Aug. 24th. J. W. S.

Ventilation.

Editor Colliery Engineer :

SIR :—I send the following in answer to "S. U. P.," of Red Bank, Pa.:

(1). In an elliptical shaft, whose diameters are 8′ and 14′ respectively, and whose depth is 600′, with a volume of 43,982·4 cubic feet of air passing per minute, what is the velocity?

The area is found as follows:

$14 \times 8 = 112 \times {\cdot}7854 = 87{\cdot}9648$, and the volume $43{,}982{\cdot}4 \div 87{\cdot}9648 = 500'$ per minute.

(2). Using Atkinson's coefficient of friction, what would be the pressure and water-gauge resulting?

Using Wilson's formula to find O,

$$\frac{\sqrt{\frac{14^2+8^2}{2}}+\frac{14+8}{2}}{2}\times 3{\cdot}1416 = 35{\cdot}18859 \times$$

$600' = 21113{\cdot}154$, or S, then

$$\frac{K\ S\ V^2}{a} = P, \text{ or}$$

$$\frac{21113{\cdot}154 \times 500^2 \times {\cdot}0000000217}{87{\cdot}9648} = 1{\cdot}302 \text{ lbs., pressure,}$$

and $1{\cdot}302 \div 5{\cdot}2 = {\cdot}25$ w. g.

Yours, etc.,

Connellsville, Pa., August 19th. SUBSCRIBER.

[Answers to these questions similar to the above were also received from "Miner," of Braidwood, Ill., "Taffee," of Fall Brook, Pa., Joseph Quigley, of Westville, N. S., "R. P.," of Greensburg, Pa., "T. S. C.," of Gardner, Ill., and "P.," of Whitney, Pa. As the solutions cover the same principles they are not inserted.—ED.]

Mensuration.

Editor Colliery Engineer:

SIR:—Will you kindly insert the following question in your Correspondence Department, that some of your readers may answer:

A tree 80′ long, 6′ diameter at butt end, tapers to 1′ diameter, how long a rope will it take to coil around it, the coils to be close together, also how long will the rope have to be, allowing 12″ between coils?

Yours, etc.,
TRACKMAN.

Reynoldsville, Pa., September 19th.

Pumping.

Editor Colliery Engineer:

SIR:—In answer to "Beginner," of Mount Pleasant, Pa., I would say that the pump placed in the pit 20′ instead of 5′ from bottom would require less power, because it would only have to force the water 80′ instead of 95′. The difference is caused by the fact that the suction would work just as well at 20′ as 5′, if the pipe, etc., were all tight. The difference in steam power would be

$$15 \times \cdot 434 = 6 \cdot 51 \text{ lbs.},$$

for every sq. in. of plunger area. Say, the area was 80″ the theoretical amount would be 520 lbs. less weight each stroke, which divided by area of steam cylinder would give the amount of steam pressure less per sq. in. needed.

Yours, etc.,
J. V.

Punxsutawney, Pa., September 21st.

Blasting.

Editor Colliery Engineer:

SIR:—In answer to Mr. Kane's question in the September issue, I am of the opinion that it cannot explode the powder for the following reasons:

It requires all of the air in close proximity of the needle-hole to feed the flame, and as the flame cannot exist without air, it is obvious that as the air is consumed as rapidly as it approaches the hole, it cannot enter the hole. It is impossible for the flame to enter where there is no air to feed it.

Yours, etc.,
JAY.

Gamble Mines, Ala., September 16th.

Ventilation.

Editor Colliery Engineer:

SIR:—In answer to "S. U. P.," of Red Bank, Pa., I submit the following replies:

Let $m\,c$ = motive column = 23·07′.

Let w = weight of 1 cu. ft. of downcast = ·079518 lbs.

Let P = pressure — 1·8351 lbs.

Then,

(1). $q = \sqrt{\frac{P\,a}{K\,s}} \times a = 15{,}700.$

(2). $m\,c = \frac{P}{w} = 23 \cdot 07$ ft.

(3). $P\,q = u = 28{,}811 = \cdot 89$ H. P.

(4). $\sqrt{9} : \sqrt{4} :: q^3 : q^3 = 10{,}466 \cdot 66.$

(5). The units of work in this case = 19,207·2; in first case 28·811. The cause of difference is due to the fact that the power is not all used in this latter case. The fact is that with furnace ventilation you cannot change length of airways of the same perimeter and area, unless you change the pressure. Had the power been all used up the pressure would have been greater and the quantity greater.

Yours, etc.,
J. V.

Punxsutawney, Pa., September 21st.

Ventilation.

Editor Colliery Engineer:

SIR:—I wish to thank "T. S. C.," of Gardner, Ill., for his correction of my reply to "R. R. S." On pages 52 and 53, of Mauchline's book, a similar problem is worked out on the same principle, which must be wrong according to method used by "T. S. C.," hence my error. It is simply a difference in authors. I have serious doubts whether either method would be correct, if properly tested in practice.

Yours, etc.,
S. U. P.

Red Bank, Pa., September 12th.

Pumping and Surveying.

Editor Colliery Engineer:

SIR:—Will some of your readers kindly answer the following questions:

(1.) How many imperial gallons of feed water per minute will be required to supply six boilers representing 288 nominal horse-powers?

(2.) In a heading which is S. 71° E., what must be the course of a cross heading at right angles to its north side?

Yours, etc.,
T. S. A.

Anita, Jeff., Co., Pa., September 14th.

Mining.

Editor Colliery Engineer:

SIR:—Please insert the following questions in your next issue:

(1.) What is the kinetic energy, and potential energy of a cage and load weighing two tons at the top of a shaft 600′ deep, also at the bottom?

(2.) Find the kinetic energy of a train of cars weighing 30 tons, moving at the rate of 10 and 20 miles per hour respectively.

(3.) The haulage rope letting a train of cars weighing 20 tons down an incline is suddenly broken, the train passes on to a level road with a velocity of 20 miles per hour. What distance will the cars travel before they come to a stop, the friction being $\frac{1}{75}$ of the load?

(4.) Suppose the train in the previous question instead of traveling onto a level road, the road should rise 1 in 20, what distance up the incline will it go?

Yours, etc.,
R. R. S.

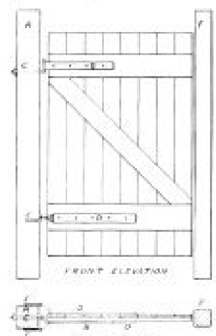
Winburne, Clearfield Co., Pa., Sept., 15th.

Mining.

Editor Colliery Engineer:

SIR:—I submit the following in reply to "Subscriber," of Lehigh, Ind. Ty.:

Will any of your readers kindly give plan and directions how to erect a door in a 4½′ vein to be opened by mules traveling both ways?



FRONT ELEVATION

GROUND PLAN

In the sketch A represents the post on which the door is hung, B a hinge made of leather, C a hook, which is fastened on the outside of the post with a nut, D D are strap hinges at the bottom of the door, and F a post which the door passes in opening either way by ½ inch. The bottom hinges should be not less than 3″ apart and hooks placed in the same post should be on a level and adjusted as required. The upper hinge should be strong, as all of the weight of the door rests on it. This door is not practicable where strong currents of air are passing, but are convenient for deflecting a weak current in another direction, or on steep grades where mules can go through both ways.

Yours, etc.,
SAMUEL KINSEY.

Glenshaw, Allegheny Co., Pa., September 12th.

Ventilation.

Editor Colliery Engineer:

SIR:—In answer to question of "S. U. P.," given in your August number, you published in your September number several solutions none of which agree. I enclose solution still different; which is right?

(1). Let

a = transverse diameter.
b = conjugate diameter.
x = 3·1416

Then

$a \times b \times x$ = area

substituting

$$\frac{14 \times 8}{2} \times 3 \cdot 1416 = 87 \cdot 9648 \text{ area},$$

And

$$43982 \cdot 4 \div 87 \cdot 9648 = 500' \text{ velocity}.$$

(2). We find that the circumference or perimeter by the following formula:

$$\sqrt{\frac{14^2 + 8^2}{2}} \times 3 \cdot 1416 = 35 \cdot 817 + \text{perimeter}$$

and 35·817 × 600 = 21,490·2 rubbing surface, and by formula

$$\frac{K\,s\,v^2}{a} = \text{pressure}.$$

Substituting

$$\frac{\cdot 0000000217 \times 21490 \cdot 2 \times 250{,}000}{87 \cdot 9648} = 1 \cdot 325 +, \text{ pressure}.$$

And

$$1 \cdot 325 \div 5 \cdot 2 = \cdot 254 + \text{w. g.}$$

Haswell is my authority for formula for finding area and perimeter of an ellipse,

Yours, etc.,
W. N. S

Falls Creek, Pa., September 12th.

Blasting.

Editor Colliery Engineer:

SIR:—I submit the following in reply to "J. T. G.," of Braidwood, Ill.:

There is a blast-hole charged with powder and tamped ready for firing. The needle is withdrawn and from the hole or orifice molded by the needle there issues fire-damp. When this fire-damp or gas is ignited at the mouth of the needle will it explode the powder at the end of the hole? State reasons, whether the answer is in affirmative or negative.

It will be impossible to explode the powder by firing gas issuing from the needle hole when the needle is withdrawn, for the reason that gas will not burn in its pure state, or not until it is mixed with oxygen. Gas issuing from a needle-hole or pipe is unmixed until it reaches the aperture, hence it will not burn but will extinguish fire. In this case the gas would burn at mouth of neeble hole the same as a jet, but would not burn in the needle-hole on account of lack of oxygen to support combustion. Also, the needle-hole acts the same as gauze on safety-lamps, *i. e.*, will cool the flame and extinguish it before it could reach the powder.

Any person that has seen gas burning either as a blower in a mine, gas jet, or from pipes, must have noticed that there is no flame at orifice, but the flame begins at a distance from the orifice, the intervening space being occupied by the gas in its purity and the flame begins at the point where enough oxygen has has been mixed with the gas to render it combustible. This space varies according to the pressure or amount of gas to be mixed in a given time.

Yours, etc.,
S. U. P.

Red Bank, Pa., September 12th.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in reply to "A. S.," of Wilkinsburgh, who asked the following question in your July issue:

Suppoeing we have two shafts of equal depth, 500′ each, and 5′ × 5′ area. The average temperature in the downcast shaft is 41°, and in the upcast or furnace shaft, 234·9°. What amount of air will this furnace power produce in an air course 1,000′ in length, and 5′ × 5′ area? And what amount of air will this same power produce in an air course of the same size, and 4,000′ in length? We will first find the weight of a cubic foot of air in both the downcast and upcast shafts and from that data compute the pressure, thus: for the downcast

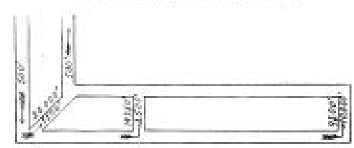
$$\frac{1 \cdot 3253 \times 30}{459 + 41} = \cdot 0795.$$

And, for the upcast

$$\frac{1 \cdot 3253 \times 30}{459 + 234 \cdot 9} = \cdot 0572, \text{ then}$$

$$\cdot 0795 - \cdot 0572 = \cdot 0223 \times 500 = 11 \cdot 15 \text{ lbs.}$$

pressure at the bottom of the downcast shaft.



We will assume the two shafts to be 500′ apart and an entry driven from one shaft to the other making the 1500′ pass 20,000 cu. ft. of air with 11·15 lbs. pressure per minute, then

$$11 \cdot 15 \times 20{,}000 = 223{,}000 \text{ units of work, and}$$

$$\frac{223{,}000}{\cdot 0217 \times 50{,}000} = 590 \times 25 = 14{,}750 \text{ ft. per minute},$$

$$\frac{223{,}000}{\cdot 0217 \times 200{,}000} = 372 \times 25 = 9{,}300 \text{ ft. per minute}.$$

Then the horse power for the 1,500′; 2,500′; and 10,000′ airways respectively are found thus to be 6·7 horse-power.

$$\frac{11 \cdot 15 \times 20{,}000}{33{,}000} = 6 \cdot 7 \text{ H. P.}$$

$$\frac{15 \cdot 11 \times 14{,}750}{33{,}000} = 6 \cdot 7 \text{ H. P.}$$

$$\frac{24 \cdot 2 \times 9{,}300}{33{,}000} = 6 \cdot 7 \text{ H. P.}$$

Yours, etc.,
HENRY NICHOLSON.

Cannonsburg, Pa., Aug. 10th.

Algebra.

Editor Colliery Engineer:

SIR:—I would say in reply to "A. B. C.," of Pittston, Pa., that in the question given, the value of x must be 2, and of y 3. Proof

$x^2 + y = 7$, substituting the values
$2^2 + 3 = 7$, or $4 + 3 = 7$, again
$x + y^2 = 11$, or
$2 + 3^2 = 11$, or $2 + 9 = 11$.

Yours, etc.,
T. S. A.

Anita, Jeff. Co., Pa., Sept. 14th.

[This question was also answered the same as the above by "Jay," of Gamble, Ala.—ED.]

Pumping.

Editor Colliery Engineer:

SIR:—Please insert the following in reply to "Beginner," of Mount Pleasant, Pa., in your August issue;

In a shaft 100′ deep a pump is placed with 5′ suction and 95′ discharge. Will it require more, or less power, if the pump is placed up the shaft with 20′ suction and 80′ discharge?

The power required with 5′ suction and 95′ discharge is found thus:

95′ × ·434, the constant give per sq. in. = 41·230 lbs. the power required.

For the 80′ discharge, using the same constant, we have

80′ × ·434 = 34·720 lbs., and 41·230 — 34·720 = 6·510 lbs., or it takes 6·510 lbs. less pressure for an 80′ discharge and 20′ suction.

Yours, etc.,
T. S. A.

Anita, Jeff. Co., Pa., September 14th.

Ventilation.

Editor Colliery Engineer :

SIR:—I submit the following in reply to questions by "S. U. P.," in your September issue:

(1). We can find the ventilating pressure per. sq. ft. by computing the difference of the weight of a column of air 1 sq. ft. in area and 100′ (which is the depth of the upcast shaft) long and at a temperature of 191° F. and a column of air of the same dimensions and at temperature of 41° F. (the temperature of outside air). Assuming a barometer of 30″, we have

$$\frac{1{\cdot}3253 \times 30}{459 + 191} \times 100 = 6{\cdot}117 \text{ lbs.} = \text{weight of}$$

column in upcast, and

$$\frac{1{\cdot}3253 \times 30}{459 + 41} \times 100 = 7{\cdot}952 = \text{weight of}$$

column of outside air.

Then

$7{\cdot}952 - 6{\cdot}117 = 1{\cdot}835 =$ ventilating pressure per sq. ft. We will assume that the shaft is the same sectional area as the airway, which being added will make the length 4100′, the perimeter being 32′.

Now

$$q = a\sqrt{\frac{P\,a}{K\,s}}, \text{ substituting the values given,}$$

we have

$$63 \times \sqrt{\frac{1{\cdot}835 \times 63}{{\cdot}0217 \times 4100 \times 32}} = 12{,}694 \text{ cu. ft per}$$

minute.

(2). The pressure is the weight of the motive column; and the pressure divided by the weight of a cubic foot of air of the outside temperature will equal the motive column.

Thus

$$\frac{1{\cdot}835}{{\cdot}07952} = 23{\cdot}076' = \text{motive column, or it can}$$

be found by the formula

$$D\,\frac{T - t}{459 + T} = \text{m. c., or}$$

$$100 \times \frac{191 - 41}{459 + 191} = 23{\cdot}076'$$

(3). The horse-power expended by the furnace equals

$$\frac{p \times q}{33{,}000} = \frac{1{\cdot}835 \times 12{,}694}{33{,}000} = {\cdot}706 \text{ H. P.}$$

(4). When the length is increased we have

$$a \times \sqrt{\frac{P\,a}{K\,s}} = q, \text{ by working out the formula}$$

we have

$$\sqrt{\frac{1{\cdot}835 \times 63}{{\cdot}0217 \times 9100 \times 32}} \times 63 = 8520 = q.$$

(5.) The h. p. expended $= \dfrac{8{,}520 \times 1{\cdot}835}{33{,}000} = {\cdot}473.$

The difference in horse-power is due to the fact that the quantity has decreased, owing to the increased length, while the pressure has remained constant, and as $p\,q = u$, the power must be less, because the quantity is lessened the pressure is the same.

Yours, etc.,
T. S. C.

Gardner, Ill., Sept. 12th.

Colliery Management.

Editor Colliery Engineer :

SIR:—I wish some of your correspondents would answer the following question to satisfy some of your readers:

Where and how can the best results be obtained from a furnace at a coal mine, whether at the top of outcast or at the bottom of outcast and state reason why?

Yours, etc.,
S.

Wilkes-Barre, Pa., September 10th.

Ventilation.

Editor Colliery Engineer :

SIR:—Please insert the following in reply to "S. U. P.," of Red Bank, Pa., who asked the following questions in your September issue:

A mine (drift opening) is ventilated by furnace. The outside temperature is 41° F., and the upcast shaft, which is 100′ in depth, has a temperature of 191° F., the dimensions of the underground airway are 7′ × 9′ × 4,000′.

(1). Using Atkinson's co-efficient of friction what will be the volume of air obtained under the above conditions?

(2). What will be the length of the motive column; (show method and formula by which length is ascertained)?

(3). What horse power will be expended by the furnace in producing this volume of air?

(4). Suppose the length of the airway is increased to 9,000′, what would be the quantity obtained, the area and pressure remaining the same?

(5). What will be the horse power expended, when the length is increased? Explain cause of difference in horse power, if any?

As the size of shaft is not given, we will assume it to be the same size as the underground airway. First, we will find the volume, as the depth, temperature, and length are given we obtain the area thus:

$2 \times 7 = 14$; $2 \times 9 = 18$, and $14 + 18 = 32 =$ O, and $32 \times 4{,}100$ (length) $= 131{,}200 =$ S, and to find the pressure

$$\frac{1{\cdot}3253 \times 30}{459 + 41} = {\cdot}079518.$$

And

$$\frac{1{\cdot}3253 \times 30}{459 + 191} = {\cdot}061167, \text{ then}$$

${\cdot}079518 - {\cdot}061167 = {\cdot}018351 =$ difference of pressure, which multiplied by the depth of the shaft, 100′, gives the total pressure, thus

$${\cdot}018351 \times 100 = 1{\cdot}8351 = p.$$

Now to obtain the velocity we use the formula

$$v = \sqrt{\frac{P\,a}{K\,s}},$$

substituting the given values we have

$$\frac{1{\cdot}835 \times 63}{{\cdot}00284704} = 40602{\cdot}25, \text{ and}$$

$\sqrt{40602{\cdot}25} = 201{\cdot}5$ the velocity, and this multiplied by $63 = 12{,}694{\cdot}5 = q$.

Second, we can find the motive column by the formula

$$D \times \frac{T - t}{459 + T} = \text{motive column,}$$

substituting their values,

$$100 \times \frac{191 - 41}{459 + 191} = 23{\cdot}077 \text{ ft.}$$

Third, the horse power of a furnace is found thus:

$P\,a \times q = u$, which divided by $33{,}000 =$ h. p.

$115{\cdot}6113 \times 12694{\cdot}5 = 147{,}627{\cdot}64 \div 33{,}000 = 4{\cdot}473$ h. p.

Fourth, by increasing the length 5,000′ the quantity is found thus

$$115{\cdot}6113 \div {\cdot}00631904 = 18{,}295, \text{ and}$$

$$\sqrt{18{,}295} = 135{\cdot}2 = v \times 63 = 8{,}517{\cdot}6 \text{ quantity.}$$

Fifth, to find the horse power

$115{\cdot}6113 \times 8517{\cdot}6 = 984{,}696{\cdot}4659 \div 33{,}000 = 29{\cdot}8275$ h. p. The difference in horse power is caused by not having as large a volume of air through increased surface without increased pressure and decreased velocity.

Yours, etc.,
J. K.

Connellsville, Pa., September 14th.

Examination Question.

Editor Colliery Engineer :

SIR:—Please publish the following in reply to "J. W. S.," of Westville, Picton Co., N. S.:

The weight of a cubic foot of air at 40° F. is found thus

$$\frac{1{\cdot}3253 \times 30}{459 + 40} = {\cdot}0797 \text{ lbs. nearly, and}$$

$$\frac{5{\cdot}2}{{\cdot}0797} = 65{\cdot}2' \text{ motive column. Now}$$

$$T = D\,\frac{459 + 40}{D - M} - 459 = 400 \times \frac{459 + 40}{400 - 65{\cdot}2} - 459$$

$= 137°$ temperature of upcast.

I notice "H. L. D. W." in answering this question proves one mistake by making another. The formula to prove it instead of being

$$M = D\,\frac{T - t}{459 + t}, \text{ should be}$$

$$M = D\,\frac{T - t}{459 + T}, \text{ and by using the latter we}$$

have

$$400\,\frac{137 - 40}{459 + 137} = 65{\cdot}1 = M.$$

Yours, etc.,
T. S. C.

Gardner, Ill., Sept. 12th.

Ventilation and Mining.

Editor Colliery Engineer :

SIR:—Will you please insert the following questions in your next issue for answer:

(1) Suppose a volume of 64,000 cu. ft. of air per minute is passing through a rectangular shaft, 8′ × 16′ and 500′ deep, what is the pressure?

If the shaft is partitioned off, *i. e.*, a brattice run from top to bottom making two 8′ × 8′ shafts, or air passages, what volume may be expected, pressure to be the same in both cases?

(2.) In case a serious breakdown should occur in the fan machinery or in the fan itself when the mine is very gassy and the fan should be stopped, would more or less danger attend the stoppage of an exhaust fan, or a blower, and why? In case a large fall should occur near the outlet where a blower is used, and another near inlet when exhaust fan is used, in which case would most danger arise? If the obstruction should be suddenly removed in both cases what would be the different effects on escape of gas from strata?

Yours, etc.,
S. U. P.

Red Bank, Pa., Sept. 15th.

German Coal Mining.

Our foreign correspondence has afforded some interesting information with reference to the richness of the great coal basin of the Sarre. This basin was formerly sought to be comprised in the French Empire, and it will be remembered that the Prince Imperial received his *baptême de feu* at Sarrebruck, at the commencement of the Franco-German War in 1870. It is now estimated that the Sarre basin contains the enormous quantity of 14,000,000,000 tons of coal. It is a generally recognized axiom that the country which possesses the most coal is destined to the greatest industrial future, and if Germany can maintain possession of the two provinces which she wrested from France in 1871 she ought to become one of the richest manufacturing nations in the world. Our foreign correspondence reveals the further important fact that the coal wealth of the Sarre basin is being at present worked upon an almost ridiculously small scale, the output being now only about 6,000,000 tons per annum. At this rate it is calculated that 2,333 years will elapse before the coal is the Sarre basin is exhausted. All kinds of fresh human combinations may be developed in the course of 2,333 years, but the probability is that the extraction of Sarre coal will proceed at an accelerated rate during the remaining years of the present century, and if it should be doubled by 1900, of course the calculation as to the 2,333 years over which the working of the basin may be expected to extend would at once fall to pieces. All calculations of this kind have a curious statistical interest rather than any real practical value; but, at any rate, the substantial fact remains that the war of 1870-71 left Germany in possession of a coal field of enormous value, from which the German Government may expect to derive an important revenue for a long series of years.

The extended working of coal in Germany is one of the most remarkable features in modern German life. If we go back to the commencement of the present century we find Germany the scene of fierce struggles for power between the French and the Germans, in which victory inclined at first to the side of the French, although they had to retreat within their original frontiers on the re-organization of Europe in 1815. But whether the Germans or the French were victorious during the first ten or fifteen years of the century, neither party appears to have paid any heed to the utilization of the coal wealth which lay buried beneath the soil over which the contending forces moved. An explanation of this is to be found not only in the preoccupation of the European mind with other matters during the Napoleonic wars, but also in the fact that the demand for coal was much less active then than it is now. Steam power had to be introduced upon a great scale before the dormant coal wealth of what is now the German Empire could acquire any substantial value But now that Germany has followed in the wake of Great Britain, Belgium, and France, and has developed numerous stationary steam engines, railways, and steamers, and now, also, that Germany has obtained what she sadly lacked in the early years of the century, viz., strength and security—she is beginning to work her coal wealth in earnest. The probability is that the output of Sarre coal will not only be doubled during the next fifty years, but that it will also be multiplied three-fold, or even five-fold.—*The Colliery Guardian.*

WESTERN PENNSYLVANIA MINING INSTITUTE.

First Bituminous District.

The following are the minutes of the meeting held in Knights of Labor Hall, Monongahela City, Pa., Saturday, September 5, 1891. Mr. Thomas S. Hutchinson presided.

Mine Inspector H. Louttit asked whether any one present was acquainted with fissures, fractures, or open spaces in the earth. Mr. Andrew Fraser said he knew of a fracture that had been made drawing pillars in the "Coal Valley Mine", the depth of the seam was 175 feet. Mr. Elijah Dainty, briefly described the fracture made in this district usually known as clay veins. Mr. Roger Rigby, of Elizabeth, gave an account of an experience he had had with faults in England. Mr. R. C Campbell, California, said that he had met with an open fracture in a mine in Tioga County, Pa., 250 feet from the surface, and that he had also seen one in Scotland, 75 feet beneath the surface. Neither of these spaces had any visible connection with the surface. The President mentioned a fracture he had met with in the Pittsburgh District which ranged in width from one to seven inches but was traceable for several miles. Mr. Statham, of Somerset County, related some experience with faults in England 30 years ago and said that at different times in his mining experience since he had noticed fractures or fissures with no connection with the surface above.

Mr. Jas. Louttit, Supt. of Brown's Mines, called attention to the fact that the dangers and difficulties attending mining were increasing, and that it was their duty as mine managers and mine officers to increase their efforts to save life and protect property. Referring to the numerous bore holes being put down for oil and gas which pass through the coal beds in the Pittsburgh District, Mr. Louttit said that he considered it the duty of every mine official whether a member of the Institute or not, to assist the operators and Mine Inspectors in preventing the sinking of bore holes or the plugging of them in the vicinity of mines. Mr. Adam Kyle, of McKeesport, endorsed Mr. Louttit's views and ernestly objected to plugging disused holes. After remarks on the subject by other members, the following resolutions were adopted:

"*Resolved*, that we, the members present, feel it our duty to state that if a Mine Inspector on visiting a mine finds such mine unsafe, or in a condition that if not at once removed may lead to serious disasters and jeopardize both life and property, that such Inspector should have, by virtue of his office, power to stop such mine working until the dangers are removed.

"*Resolved*, that we, the members of the Western Pennsylvania Mining Institute of the First Bituminous District, pledge ourselves to assist both operators and Mine Inspectors in every reasonable way, in the prevention of the loss of life and limb and in the preservation of property."

The meeting adjourned to meet in November.

A lump of coal was gotten out of No. 2 mine at Monongahela, near Fairmont, W. Va., recently, which measured 3x5x8 feet. It is large for a single lump of coal and weighs eight tons. It will be sent to the Pittsburgh Exposition, and it is the intention to forward it from there to the World's Fair.

THE PREVENTION OF ACCIDENTS IN MINES.

An Essay on Practical Means to Insure Safety in Coal Mines.

(The following paper of Mr. John L. Williams, of Shenandoah, Pa., Division Superintendent of the Philadelphia and Reading Coal and Iron Company, was one of the four essays recommended for publication by the committee of judges in the *Pittsburgh Times'* prize competition for $100 for the best essay on the "Prevention of Accidents in Mines." The prize was awarded to Mr. Austin King, formerly Inspector of Mines, but now in the employ of The H. C. Frick Coke Company. We shall publish the other two papers recommended for publication in due time.)

In order to treat intelligently upon the subject under consideration, it will be necessary to divide it into different heads or classes, which have a particular bearing upon the methods to be adopted. These, I am confident, would avert many of the great mine disasters.

In the first place employers should spare no expense in the erection of a safe and reliable plant; everything should be of the best possible kind, and especially adapted to the surrounding circumstances. All engines should be fitted more than equal in power to meet any and every contingency. The fans should be capable of producing a much greater quantity of air than is actually necessary in the present distribution. Then, in case any large and unexpected outburst of gas takes place, the fan or fans would be capable of diluting it and rendering it harmless.

MINE MANAGEMENT.

In the selection of a person to take charge of a mine great care should be exercised; his experience should be of the most practical and extensive kind, and undoubtedly he should possess tact and firmness in the management of his men. The more harmony that exists between master and men the more satisfactory results can be expected. The person in charge of a mine should be invested with power to choose his own subordinates and no restrictions should be placed upon him in the matter of procuring a sufficient number of officers to meet all emergencies. There should be a sufficient number of officers so that they could reach every working face before the men reach their work; and one or more visits should be paid each and every working face while the men are at work. This fact cannot be too deeply impressed. Whenever an order is issued, the person in authority issuing such order should see that it is fully and punctually carried out; a failure to do so results in loose discipline, which is often the cause of disasters. Whenever danger is found in any man's working face, there should be a sufficient number of officers to allow one of them to spend the greater part of his time in endeavoring to remove said danger, also to give the men the benefit of his superior ability and experience. Whenever an order that has been issued fails to be complied with by reason of negligence, then the person receiving such order should be immediately dismissed.

MINING.

Serious and mature consideration should be given to the matter of opening a new mine. The pitch of the vein, the nature of the top, hard or soft, brittle or pliable; also the indications of gas in great or less quantities would serve in aiding the person in charge in arriving at a conclusion as to the best method to be adopted in the system of mining the coal. Depending upon the depth of the shaft, etc., as to the width of the pillar that would remain intact, a wrong move in the outset has in certain cases resulted disastrously. A general squeeze covering the whole area of a colliery has been occasioned by leaving insufficient pillars. There should be a good and substantial pillar left between each breast, and every 100 yards there should be a reservation pillar of 50 yards in width. These should be left in every vein worked, and each pillar to overlie each other, so that the second outlet that I will again refer to, can be driven in every third reservation pillar, or in the second, if found necessary. This would enable us to rob the workings in different sections between the reservation pillars without affecting the safety of the gangway or general conditions of the colliery. Equally well you could first rob the breasts in the upper vein, between the reservation pillars, within a safe distance of the gangway; then proceed with the underlying veins in the same way. Thus the gangway could be kept intact until it reached the pillar line. By robbing the pillars in the manner described, no general squeeze of a large area could occur which has so often caused disasters and loss of life. In case the overlying top is of too hard a nature, and does not give way after the process of robbing has been completed between the reservations, I would suggest that this space be filled up with culm from the banks. This would avoid any concussions from heavy falls, that might cause disaster. This method of filling has been practically proved to be a success, as shown at Kohinoor Colliery, Shenandoah, Pa.

THE SECOND OUTLET.

I will now call attention to the second outlet as a means of safety for the men. In the Anthracite regions where the coal crops out to the surface, these second outlets could be driven in each and every vein to the surface, and if driven at the maximum distance of 300 yards between each and every one, if an accident should ever occur and close the men inside, the greatest distance they could be situated from the outlets as means of escape would be 150 yards. Such outlets as mentioned would ensure an easy way for rescue or escape. In the Bituminous region, where holes to the surface would not be always practicable, small shafts could be sunk at the distance mentioned, to serve precisely the same purpose. I would suggest that these outlets be maintained in good condition until the coal be all worked in the basin, gangways completed to boundary line and pillars robbed back to inside outlet; then all the pillars that have been retained to support the inside outlet can be robbed, and then the coal intervening between this and the next outlet can be dealt with in the same manner.

ENGINEERING DEPARTMENT.

The inside boss in charge should be provided with a correct map of his workings which should be kept posted once in three months at least. I would suggest that all air courses, main stoppings, and splits be marked on the map, in order that the directions of the currents be always present to his mind. This should be done before the map can be considered complete. All workings lying in close proximity to the colliery that is being opened out should be correctly surveyed and resurveyed, leaving no doubt in the minds of the employes and employers as regards the exact distances they can proceed with their workings without endangering a life. All abandoned workings should be marked on the maps, giving the relative positions of any two points that are desired to be known. If the abandoned workings contain any noxious gases or large quantities of water, or are supposed to contain them, a very wide margin should be left to insure safety, and even before reaching the margin laid out on plan, they should have bore-holes in advance of them, so that any and every precaution made will give you the satisfaction that lives are at stake and have been saved through the exercise of extra care.

LAMPS.

In a gaseous mine the miner carries his life in his hand. He is defenceless and open to be carried into eternity without the slightest warning if not provided with a good and reliable safety-lamp, a lamp that has been subject to the severest tests and has stood them. There are lamps in use that can be relied upon, as far as construction and principle are concerned. The lamp should be protected from too high a velocity of air, as danger is imminent when the flame pierces the gauze. It is not altogether from a defective lamp that mine disasters have originated, but from the careless and indifferent use made of them. In the first place, the lock of the safety-lamp should be so constructed as to defy a person to tamper with it that would not lead to detection. But a greater evil exists when illiterate and inexperienced persons are engaged who really do not know the danger that envelops them. Here is the point that should be pressed home. The miners, as a rule, are an educated class, but it cannot be disputed that there are a number of miners who need educating in the little duties and responsibilities that daily attend the full, practical, and safe execution of their work. Where blowers of gas are expected suddenly or have occurred, a safety-lamp should be provided that would surely be extinguished by the presence of gas inside the gauze. Any one found to have tampered with his lamp should be instantly dismissed, and prosecuted according to law.

VENTILATION.

This is no doubt the most important feature of a successful mine. By the word successful, I mean the mine which is practically free from all disasters that can be ascribed to the insufficient circulation of air. It is almost as impracticable to float a boat without water, as to imagine that a gaseous mine can be successfully operated free of disasters without the aid of a sound system of ventilation. Very often the quantity of air to circulate through a new mine is arrived at and based upon mathematical inferences or theoretically, which is not always reliable. It is desirable sometimes to take into consideration the condition of adjacent mines, worked under similar circumstances. Whenever such a basis is taken to work upon, care should be taken to allow sufficient margin. The ventilating power should be augmented. Then there are no risks. The fan engines should be regulated to meet different conditions as it is not always policy to have too strong a current of air. The miner's comfort commands our every consideration. I know of instances where the ventilating current is so strong that it impregnates the eyes and nostrils with dust, making it very uncomfortable. Experiments are numerous when, even after watering the roadway, the current has been so strong, together with the natural heat of the mine, as to make it impossible to keep the dust down.

THE DUST THEORY.

The theory advanced in support of the argument that coal-dust has been known to originate an explosion, I give no credence. All my experience proves to me that the explosion is only aggravated, intensified, and elongated, which is sufficient to impress upon us the importance of paying particular attention to the matter of keeping the dust down. By sections of pipes laid down the whole length of the main roadways, with jets at regular distances the water is thrown out at regular intervals, and thus the roadways are always kept damp. The distribution of air into splits cannot be too highly approved of, as each section of men receive an adequate quantity of pure air, and it is not charged with the air that men have inhaled in other sections of the mine. Each split of air is carried direct to the return and then to the upcast. Cases very often occur where explosive gases exist in small quantities, that the miner is provided with a safety-lamp to detect the presence of gas in his own working face, where it sometimes generates while he might be called away for a few minutes at a time. The fire boss examines during his prescribed time. This practice of giving a miner a safety-lamp together with his naked light "is absurd." That is where explosive gas is found.

Every year fresh evidences are chronicled in the mine inspectors' reports where men discard the safety-lamp, or accompanied their safety-lamp with a naked light, thus endangering the lives of hundreds of men. Anything that is done in a slipshod manner or by halves should be done away with. If good results are to accrue, then radical changes and improvements must be expected. All old and abandoned workings, that cannot be hermetically sealed, should be kept thoroughly ventilated and inspected at least once a week by the inside foreman or his assistants, and a correct report of the condition of the same be kept in the record book at the colliery office for the inspection of the mine inspector, and a copy sent to the district superintendent. There should be a duplicate fan kept at each and every colliery. In case anything happens to one fan, the other could be put in motion in a few minutes. I would also suggest that all fans should be so constructed that they could be changed in a short space of time from an exhaust to a propelling fan and *vice versa*. If so constructed the air currents could be changed in a short time in case of fires or explosions. Thus great disaster could be averted. I would also suggest that the air courses be of large dimensions, so that large quantities of air could be propelled through at a slow velocity. This would increase the ventilating current, by diminishing the friction. Every attention should be paid to maintain these air courses at any cost, in a first-class manner.

It is preposterous to presume that anything short of strict surveillance, careful and systematic management, and a sound system of ventilation, can prevent our hearths and homes being besieged and penetrated by tales of woe, of horrible explosions, and consequent desolation.

PROMINENT EXHIBITS AT THE PITTSBURGH EXPOSITION.

The Thomson-Houston Co.'s exhibit is a specially notable one. The sign displayed is an arrangement of incandescent lights forming the words "Thomson-Houston System." The display consists of one 30 H. P. generator which furnishes the power for all the motors in the building. There is also a 650 light alternating machine, one 100 light direct current insulated machine, and one 12 light arc machine. They also exhibit a beautiful new arc light, 23 inches high. It has no carbon rod, and no chimney. The carbon is in the form of a ribbon on a spool. As it burns, it is uncoiled, and will last for nine hours. They also show their automatic indicating instruments, which show at a glance, not only the energy supplied by the motor, but the amount consumed in the circuit. These machines took the first prize of 10,000 francs at the late Paris Exposition. Mr. H. F. Albright, Jr., a competent and affable electrical engineer is in charge of the exhibit, and he informed our representative that, owing to unavoidable delays, he had not been able to get their display of mining machinery to Pittsburgh in time for the opening of the Exposition, but he expects to have it on exhibition in a few days. Owing to the fact that the Thomson-VanDepoele Co. is very busy filling orders for mining machinery required at once, the display will necessarily be less complete than the Company would wish, but there will be enough shown to give mine owners, superintendents, and mining engineers an idea of its excellence.

Messrs. Arthur Kirk and Son, the agents for the Ingersoll-Sergeant Rock Drill Co., of New York, have on exhibition one of the Standard Sergeant Percussion Rock Drills, which attracts a great deal of attention from mining men.

The Shook-Anderson Mfg. Co., have on exhibition a couple of the celebrated New Pulsometers, manufactured by the Pulsometer Steam Pump Co., of New York. These pulsometers are in operation and practically demonstrate their superior qualities as a mine pump, where the lift does not exceed one hundred feet. Large numbers of these pumps are annually sold by the Shook-Anderson Mfg. Co. for use in mines, on coal and sand boats, and at paper mills.

The display of The Edison General Electric Co. is a specially fine one. The beautiful arrangement of incandescent lamps forming the words, "Edison General Electric Co.," attracts the visitors' eye at once. The display of electrical machinery is very fine, and the arrangement of lights in the enclosed space is artistic and beautiful. Two 20 H. P. generators furnish power for the lights, and the operation of motors. Prominent in the exhibit are two of the new Edison Single Reduction Street-Car Motors, one of 25 H. P. and one of 20 H. P. Standing side by side in happy contrast are a large 200 H. P. Motor, and one of the tiny motors used to run a sewing machine, a dentist's drill, or other light running machines. The display of electric fans, the switchboard, and new Edison arc lamps, are very fine. Mr. J. Calisch, of the New York office, is in charge of the exhibit, and he expects in the course of a few days to add one of the Edison percussion drills, and an electrical coal mining machine to the exhibit. Mr. Calisch is a pleasant and obliging gentleman, and visitors to the exposition will find him always ready to answer questions and give detailed information concerning the Edison exhibit.

Branch House.

The Lidgerwood Manufacturing Company, with headquarters at 96 Liberty street, New York City, have established a branch house in St. Louis for the sale of their standard hoisting engines, at 610 North 4th street, and 609 North 3d street, under the management of Mr. Chas. W. Melcher, a gentleman of well-known ability and enterprise.

The Lidgerwood Manufacturing Company is one of the busiest and most prosperous concerns in the United States, and have sold over 8,000 of their famous engines.

STATE GEOLOGICAL SURVEYS.

ONE of the most potent factors in enhancing the prosperity of any state or country is a comprehensive public knowledge of the mineral resources of the territory. Years ago, the fact that a certain section of country was remarkably fertile, was enough to attract settlers and a moderate amount of wealth, but this is not attraction enough now.

Capital has always regarded mineral lands and mining operations as the most desirable investments, and it is naturally attracted to such sections as can show expert evidence that they possess mineral wealth. The development of the mineral resources of a state, brings in its wake, and closely following, railroads and manufacturing establishments, collectively affording employment for large populations. These large populations must in turn depend on the agricultural community for food, and as the demand for agricultural products increases, the farmer naturally secures better prices for his crops, and the value of his land, for agricultural purposes alone, is enhanced. If the same land should, after careful geological examination, be found to contain mineral wealth, it becomes still more valuable.

Notwithstanding the fact, that a geological survey benefits the farmer more directly and in a greater degree than any other citizen, the greatest opposition to state geological surveys comes from this class of citizens.

A well organized state geological survey can gather and publish more information and data concerning the natural wealth of a state in one year than any other department of a state's government can in ten years.

In every state in the Union, there are hundreds of patriotic intelligent citizens who will cheerfully, and without expense to the state, assist in making such a survey a success. They will give information and data to a competent geologist or engineer, which they will not give to any other state official for publication, because they know that no one but a professional geologist can compile the information in such shape as to make it intelligible instead of ridiculous.

The primary work of a geological survey is necessarily very general in its character. Owing to local jealousies all portions of the state must be treated on in a general way at first, and to satisfy public clamor the report must be issued as soon as possible and in a hurried manner. Such a general report must necessarily be very incomplete, and will possibly contain errors that must be corrected in subsequent reports issued after more careful investigation.

However, such a report serves as a foundation on which to build a far more complete and elaborate set of reports that will publish to the world the mineral wealth of the state, corroborated by the most indisputable evidence.

After a first general report has been issued, the state can be divided into districts and one or more district at a time can be examined. Careful surveys, and researches among the notes and memoranda of local geologists and engineers, enables the geologist in charge to arrive at valuable conclusions, and to publish a comprehensive report on the geological structure of the district. Naturally it takes time and money to do this and do it with a certain degree of thoroughness, all over a state, but it pays to do it, and to do it well.

After a state has been entirely gone over in this manner, and the reports printed, the work should not cease. A small force under the charge of a competent practical geologist should be a permanent part of the state's government, so that more recent discoveries and the corrections of details made necessary by the use of the pick and drill, may be compiled and published as additional information regarding the state's mineral wealth.

No geologist that ever lived, can go over the whole territory of a state and from his own surveys and examinations produce an absolutely correct report. He may make a very close generalization of the matter, but he will necessarily be faulty in many of the minor details. Local geologists and others going over the same ground a few years later, when the strata is more exposed by railroad cuts, tunnels, or mining operations, will find the original report faulty, and if there is a permanent state geologist he will be informed of these facts, and thus be able to make necessary corrections or change conclusions that were arrived at by incomplete evidence.

A number of the states now have geological surveys in operation, following the example of Pennsylvania; but it is to be sincerely hoped that they will not follow Pennsylvania's example in calling the surveys finished when not much more than preliminary reports have been issued of the major portion of the state.

It seems, at this writing, as if the old fogy element had control of such matters in Pennsylvania. The survey will be called finished, and after a few reports and maps now in hand are published, all work will cease. In twenty or thirty years, a new generation will demand a geological survey based on broader and more comprehensive grounds. The detailed information made evident each year will prove, in course of time, that the last survey, while in the main correct, is very incomplete. Such a re-survey will be an expensive one, and if it is summarily ended as the previous one was, will also in course of time, be found incomplete.

Therefore, it will be wisdom for each state, and particularly Pennsylvania, to establish a permanent department of the state government, under the charge of a competent geologist, which shall annually issue a report containing the latest reliable data and conclusions regarding the geology of the state. These reports will be valuable supplements to those already issued, and they will add to the value of former issues by corroborating them in some parts and correcting unavoidable errors in others.

Most of the data necessary for this work will be collected by volunteers. All that is required of the state is the permanent employment of a small corps, and the publication of the reports.

In a recent letter, a prominent geologist makes the following pertinent remarks: "States should be brought to look upon a geological survey as a necessary permanent part of the government, and until they do this they will never derive full advantages from the work. The plan of having such surveys conducted intermittently is extremely wasteful and, in fact, in many cases a survey is not continued long enough for the facts which have been acquired to be made public, and they are seldom continued long enough for all the conclusions which have been deduced from these facts to be made available. It will be a great misfortune if the Pennsylvania survey is allowed to die out completely; but from all I hear, I fear this will be the case; unless some energetic movement is made to resuscitate it."

As we noted in our last issue, a national organization of government geologists was formed in Washington, D. C., on August 29th, and the influence of this organization will be great in establishing surveys in states which never have had any, and in securing their perpetuation in other states.

This National Association of Government Geologists is now in existence, and at the meeting at Washington, the Secretary, Mr. Arthur Winslow, State Geologist of Missouri, was instructed to draft a constitution and by-laws to be submitted to the committee at a meeting to be called in connection with the annual meeting of the Geological Society in December next, and he was also requested to notify all State Geologists of this movement towards organization and to invite them to be present at the next meeting.

Pennsylvania with her boasted intelligence and great mineral development should, without delay, establish a permanent department devoted to geological research.

THE COLLIERY ENGINEER MINING SCHOOL.

WE are presenting in our advertising columns a new plan for obtaining a mining education which deserves mention here.

There is no industry which is advancing more rapidly than coal mining. During the past twenty-five years the output has increased seven-fold, and the difficulties and dangers in procuring the mineral have increased at nearly as great a rate. This necessitates more careful working, a thorough knowledge of the practice and theory of mining, and a sound acquaintance with the allied sciences. This is proved by the legislation in different mining countries, having for its object, an increase in the standard of education among mine officials.

In mining, more than in any other occupation, the safety of all the workmen depends upon the individual knowledge of each and every separate person employed, and while this is true, there is no industry in which the facilities for technical education are so limited. This is chiefly owing to the fact that the number of those who see the necessity of such an education is so small as to prevent the employment of an efficient teacher for each mining locality.

That such is the situation is due principally to want of thought on the part of the miner himself, but it is often fostered by the scoffs of the older school of mine officials, who while possessing certificates of *service* themselves, profess to deride the so-called theory of mining.

We know instances where officials, secure in the possession of these service certificates, have been heard to say that THE COLLIERY ENGINEER in giving answers to questions, does so in symbols which are unintelligible to common workmen, and which require a college student to understand.

Now, the fact is, that a little time carefully and systematically spent, by anyone whose heart is in his work, will enable him to thoroughly understand all these seemingly formidable problems. We are glad to think, however, that such people are the exception, and that the service certificated men are on the whole only too glad to embrace any opportunity of increasing their knowledge.

The necessity of some method of education which will be thorough and cheap, and which will at the same time enable every student to enjoy its full benefits, no matter however isolated he may be from all other sources of knowledge, has been evident to us for a long time, but it is only lately that we have been able to see our way to a practical issue. Our readers will have observed an advertisement in the September number, of a Correspondence Class, by Mr. Alexander Dick, an efficient and experienced Mining Engineer and Colliery Manager. After the appearance of the advertisement we concluded that the Colliery

Engineer Company, as publishers of the leading Journal of Coal Mining in this country was the best agency for the successful conduct of such a school. We have therefore entered into an arrangement with Mr. Dick, whereby he agrees to carry on his system of education as Director of The Colliery Engineer School of Mines. Mr. Dick will devote his entire time to make the school a success. We will also give the work our personal attention so that he may have all assistance in pushing the students forward.

Our plan of Correspondence Lessons in Mining is no experiment, but is an elaboration of a system which has worked with great success in Europe for the past ten years. In the United States similar plans are now being conducted with complete success in almost every study with the exception of mining. We mention this as an answer to inquiries which have been made as to whether mining practice can be successfully taught by mail. If in England, with its compact population, such a method is necessary, and beneficial, how much more useful will it be here, where scattered and isolated districts preclude the possibility of separate teachers obtaining a sufficiently large class to warrant them devoting their time to teaching.

Having once gone into this matter we intend to make it a success. It may be that through want of a proper understanding of the system some will be deterred at first from entering, but the fact that there is a system should go far to reassure them. At present, a miner is debarred from the benefits of an efficient teacher, and if he wishes to study, goes plunging through the various subjects without aid or method. The secret of success in every study is system. Our school will guide the student to give the necessary prominence to each subject. It will help him to form habits of method. It will give him the advantage of a thorough periodical self-examination in each branch of his studies, and practice him in the art of expressing his ideas clearly upon paper, so that when he goes before the examining board for his certificate he may not be in the position of "knowing what the answer is, but not being able to put it in black and white."

The text-books will be chosen for their conciseness and cheapness, and will be adhered to strictly throughout the course.

In the classes of regular schools there are differences in the ability of the students, and the result is that, either the dull pupil keeps back the others, or the others drag the dull member forward at a pace greater than his capabilities will justify, so that his last state is generally worse than his first. This can not occur in the correspondence system, as each student begins the course when he likes, and, taking one subject, and one set of papers at a time, goes through them, and only when they are mastered does he obtain the next, and so on through the course. Each student is taught independently, and of two entering at the same time, one may finish months before the other, without either being interfered with. And then again, if any student feels, after he has gone through any particular subject, that he is not sufficiently informed, or if we consider further teaching in that branch necessary, he will receive a second instalment of work before he starts on the next part of the course.

No one need fear entering on the course from want of sufficient education, as we take every subject from the rudiments, and all we require is that each student shall have a few hours every week to devote to the work, with a purpose in view, and a firm determination to succeed.

To intending candidates for Mine Foremen's certificates, the School will henceforth be a necessity, and to those who may have already obtained that magic piece of paper, we recommend the course as a well organized means of keeping the theory of their profession fresh upon them, and maintaining their knowledge on a level with the times.

The Department for the actual practice of surveying and drawing, with instruments supplied by us for the use of the students, is an idea of our own which is not introduced in any similar method of instruction. We wish it borne in mind that this department is open to any student *without any additional fee*, if he will come and reside in Scranton for a week or two. It is not necessary that every student should do this to enable him to obtain a Mine Foreman's certificate (he can be taught all he requires to know by correspondence), but, as an auxiliary at the disposal of those who wish to go more fully into the course, we consider it will be welcomed by many of the pupils.

Our aim will be to conduct The Colliery Engineer School of Mines, so that those who may obtain its diploma will gain something more than a mere empty title cheaply gotten. On the contrary, the diploma, as it will only be secured after a hard examination, will be looked upon by employers as a guarantee of ability in those who possess it.

DISCIPLINE IN MINES.

IN many instances, the official investigation of the causes of accidents in mines leads directly to a lack of discipline. More accidents occur from either direct disobedience of orders, or carelessness, than from any other causes.

Mine laws alone will not bring about immunity from accidents. If the workmen will not use every precaution to ensure their own safety, the mere fact of certain laws being on the statute book will not help them.

Colliery officials owe it to themselves, their employers, and humanity, to enforce discipline in all cases. All violations of the mine laws, however slight, should be followed by a reprimand or suspension from work, and a repetition of the offence, should mean instant discharge.

The peculiar circumstances and changes, accompanied in many cases by sudden danger, which occur constantly in mines indispensably require thorough discipline as essential to safety. Whenever the source of danger is understood and can be avoided; neglect or lack of discipline resulting in loss of life or property is inexcusable, whether it be displayed by management or the workmen.

Discipline is just as essential in the working force of a mine, as in the army. Where the carelessness of one man may result in the death or injury of a dozen or hundreds, it is of no avail that all are careful and well disciplined men, but one. All must be subject to a rigid disciplinary system. A careful perusal of the reports of both the American and British Mine Inspectors, shows that the major portion of the mine accidents with their attending destruction of life and property are due to carelessness or disobedience of orders or in other words, to lack of discipline. The cause being known, it is the duty of those in authority to apply the remedy.

It may be impossible to wholly remedy this evil, but a strong and continuous effort should be made. Spasmodic treatment will not cure the evil. To use a familiar expression, "Eternal vigilance is the price of safety."

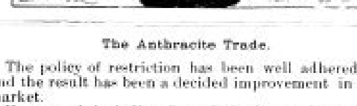
EDITORIAL NOTES.

PROF. M. C. IHLSENG, Professor of Mining in the State School of Mines, at Golden, Colo., writes us under date of Sept. 13th, as follows:

"It was purely accidental that I learned of your journal. Since I have subscribed and had opportunity to examine four numbers, I have been more and more pleased with it. And voluntarily, without any ulterior purpose, wish to say that to the mining man, it is the best, ablest and clearest journal published. I propose to recommend it to my students this school year, and hope you will gradually win the favor you deserve in this Western region.

With many wishes for continuance of the excellence, I am yours truly.

M. C. IHLSENG,
Professor of Mining.



The Anthracite Trade.

The policy of restriction has been well adhered to, and the result has been a decided improvement in the market.

Up to and including Sept. 20th the production of Anthracite coal for the year has been 27,058,225 tons, an increase of 2,815,153 tons over the production to same date last year. Notwithstanding this increase in production of nearly 3,000,000 tons, the stocks on hand at tide-water shipping points are lower than they were at the same time last year by nearly 120,000 tons.

The sales-agents held a meeting on the 16th ult. and ordered an advance of from 10 to 25 cts. per ton on all free burning coals, to take effect on October 1st. All the companies have pledged themselves to strictly adhere to these advanced prices. There was no advance made on Lehigh coal, but a proportional one will surely follow.

According to a previous agreement, all the companies on the 15th ult. cancelled all unfilled orders received previous to Sept. 1st. This action has materially strengthened the trade, and the action of the individual operators in continuing to supply coal at prices prevailing earlier in the season will not materially affect the trade. The demand is gradually getting stronger and all coal shipped is going into consumption. The outlook for the balance of the year is very promising, and the demand will certainly be heavy and prices naturally better than have been received at any time during the year.

The new railroad being built by Messrs. Coxe Bros. & Co. is being rapidly pushed toward completion as is also the Reading's line connecting it with the latter's system. As soon as the connection is made the transfer of tonnage from the N. J. C. and L. V. to the Reading Road will be made. Mr. Eckley B. Coxe, who is personally overseeing the construction of this road, is building one of the most substantial lines in the country. With all branches, it will aggregate about 60 miles in length, and will be finished in the course of a couple of months. When this transfer of tonnage is made, it is expected that there will be considerable trouble over the adjustment of the Reading's percentage for next year, but all parties are earnestly hoping for an amicable settlement of the question.

The Bituminous Trade.

The Bituminous trade is stiffening under the present condition of affairs. The demand for fuel is increasing, and while the production under ordinary circumstances could be kept to an enormously high point, but cars are scarce owing to the enormous grain production and the consequent heavy shipments. Prices are firm and will no doubt rule higher as the demand for coal, coupled with the grain shipments, is bound to be so great as to tax the capacity of most transportation companies, in the car line, beyond anything ever known before.

This naturally means an enforced restriction of production and it will have a beneficial effect on the trade.

The Coke Trade.

The coke trade is active and the demand is strong enough to warrant full time, though prices have not advanced beyond those of a month ago, or in fact for several months. Connellsville coke is still selling for $1.90 for furnace coke, $2.30 for foundry coke, and $2.65 for crushed coke, all for tons of 2,000 lbs. f. o. b. cars at ovens.

It is hard to foretell the prospects of the trade for the balance of the year. All will of course depend on the iron market, and the *American Manufacturer* declares that there is an overproduction of pig-iron, and as the semi-organ of the iron producers it is in position to pass a better opinion on the subject than any other journal. It is possible that its fears are groundless, for the country seems to be entering on a season of great business activity, and iron will naturally share in the benefits of such a condition of affairs.

At present the furnaces are making large outputs, and naturally are using large quantities of coke.

A Valuable Work.

We have received from the Mason Regulator Company, of Boston, Mass., the most complete work on steam engineering, designed for the use of practical men with limited educations, that we have ever seen. There have been many works published on steam, and the steam engine, which, although treating the subject in a comprehensive and scientific manner, have, nevertheless, failed to accomplish that which was intended (the education of the engineer), simply because the terms used by the writers, and the scientific character of the books, were beyond the comprehension of the great majority of the men who are expected to profit by their contents.

In this little treatise all terms and tables not easily understood have been avoided, and in the simplest language possible, the writer has briefly answered such questions as are likely to arise in the mind of an intelligent and practical engineer, using figures when necessary, in their simplest form, and only such illustrations as will be readily understood by any one with a common school education. Chapters I. to X. treat on air, water, fuel, steam, boilers, engines, engineers, belts, and shafting, speed of pulleys, tables, etc., respectively. These are all treated in a catechetical manner, so that this part of the work is really a thorough steam engineer's catechism. Part second treats on the combustion of coal, chemically and practically considered. It is handsomely bound in leatherette, and contains no advertisements. It is sold at the low price of thirty cents, and every colliery manager, engineer, and fireman in the country should have one. They can be procured by sending thirty cents, either postal note or stamps, to the Mason Regulator Company, Boston, Mass.

ANTHRACITE COAL STATISTICS.

Statement of Anthracite coal shipments, for month of August, 1891, compared with same period last year. Compiled from returns furnished by the Mine Operators, by John H. Jones, Chief of Bureau of Anthracite Coal Statistics.

	August 1891.	August 1890.	Difference.		For Year 1891.	For Year 1890.	Difference.	
From Wyoming Region,	1,669,625·04	1,749,217·06	Dec.	79,592·02	13,278,819·13	11,363,073·13	Inc.	1,915,746·00
From Lehigh Region,	509,640·17	578,370·17	Dec.	68,730·00	3,982,850·03	4,041,850·06	Dec.	58,999·03
From Schuylkill Region,	967,108·11	964,004·12	Inc.	3,104·19	7,641,198·18	6,562,780·13	Inc.	1,078,418·05
Total	3,146,426·12	3,291,652·15	Dec.	145,217·03	24,902,868·13	21,967,684·11	Inc.	2,935,184·02

The stock of coal on hand at tide-water shipping points, August 31st, 1891, was 648,900 tons; on July 31st, 1891, 703,634 tons; decrease, 54,734 tons.

THE NEW MINE INSPECTORS.

A Protest Against Their Appointment Filed With the Governor by Senator W. H. Hines, of Luzerne County.

We are indebted to the *Wilkes-Barre Record* for the following copy of the protest filed with the Governor against the appointment of Messrs. Blewitt and Roderick as Inspectors of the First and Second Mine Inspection Districts of the Anthracite coal regions.

WILKES-BARRE, PA., Sept. 18, 1891.

TO HIS EXCELLENCY, ROBERT E. PATTISON, GOVERNOR OF PENNSYLVANIA: I hereby, as attorney, file the following protest against the issuing of commissions to Messrs. Blewitt and Roderick as inspectors for the first and second districts of Lackawanna County under the provisions of the Act of Assembly approved the second day of June, 1891, assigning the following reasons therefor:

First, That previous to the passage of the aforesaid Act the First and Second Anthracite Coal Districts were included in one district of which Mr. Blewitt was mine inspector. That under the Anthracite law approved the 30th of June, 1885, the Judges of the Court of Common Pleas were authorized to appoint an Examining Board of the aforesaid districts.

That under and by virtue of said act of 1885 the Judges of the courts of Luzerne County appointed an Examining Board for said district and said Board appointed by the Luzerne Judges held the examinations and passed upon applicants for mine inspectors, and recommended the names of Messrs. Blewitt and Roderick for the aforesaid Anthracite mining districts. That the act approved the second day of June, 1891, repealed the act approved the thirtieth day of June, 1885; and therefore it was improper for this old Board appointed by the Luzerne Judges to examine applicants for mine inspectors in the First and Second Districts.

That so far as the undersigned knows, the Judges of Lackawanna County have not appointed a Board of Examiners for said first and second districts, nor have they any authority to do so under the act of 1891 until the first term of court held in 1892, therefore the aforesaid Board acted illegally and without authority in their recommendations of mine inspectors.

Second, That the Board above referred to were not sworn for several days after their appointment, and, in fact, were not sworn until the day they were to examine candidates for mine inspectors.

Third, that said Board of Examiners acted improperly in making up the percentages that should be allowed to candidates for questions answered. The said Board granting certain percentages to candidates for the positions they occupied, the kind of work they were engaged in, giving some high and others low percentage, thereby reducing the percentage of some entitled to more of a general percentage for questions answered relative to operating of Anthracite coal mines.

Fourth, That the act approved the 2d day of June, 1891, is not in full the act as it passed the Senate of Pennsylvania. The records of the Senate of Pennsylvania show that in section five, of said, act, all the words after the word "governor" down to the word "weekly," were stricken out, but the transcribing clerks without any authority inserted these words in the transcribed bill which was afterwards approved by the governor.

That said Board of Examiners in violation of the law that passed the Legislature have not forwarded to the governor the names of all the applicants for mine inspector qualified for the office. That several applicants who stood the examination and are qualified their names were not sent in to the governor.

That Mr. Roderick, whose name has been sent in to the governor as mine inspector, is not of legal age, and is therefore disqualified to hold the office.

That under and by virtue of the said act, approved June 2, 1891, the inspector for the new mine district created by said act cannot be recommended by any Board of Examiners until the first term of court, 1892, and by a Board then appointed by the courts of Lackawanna County. That if any vacancy exist until that time the only person who can have the power to appoint is the Governor of the Commonwealth.

I therefore ask, in consideration of what is above set forth, that no commissions be issued to Messrs. Blewitt and Roderick until such time as the matters hereinbefore set forth are properly adjudicated by the proper legal tribunal.

Truly yours,
W. H. HINES,
Attorney.

The objection against the appointment of Messrs. Blewitt and Roderick because they were passed and recommended by an Examining Board under the old law will hardly hold water. The Attorney-General has already decided that the Boards of Examiners for mine foremen, etc., appointed under the old law can legally perform their duties. It seems to us that the same line of reasoning through which the Attorney-General arrived at this opinion will apply with equal force to the Boards of Examiners for Mine Inspectors. The Attorney-General's opinion on this subject as published in our July issue is, "Under the terms of this Act, and especially Sec. 3, Article VIII., the appointment of the Board which consists of the District Inspector of Mines, two practical miners, and one owner, operator, or superintendent of a mine, or in fact any officers mentioned in this section is to be made at the first term of Court in each year." As this time is already passed in 1891, there could not be an appointment made under this Act until the first term of Court in 1892.

"It will be observed that this act repeals all parts of the act of 1885, inconsistent or in conflict with the provisions of this act. As the act of 1885 relates to the same subject matter, it is repealed by the act of 1891. Under the act of 1885 the appointments of the Board of Examiners for Mine Foremen, Assistant Mine Foremen, etc., as mentioned in your letter, were made for one year. It is my opinion these officers will continue and perform the duties under this act (which are essentially similar to those required by act of 1885) during the time for which they were appointed."

"The act of 1891 does not seem to have provided for the appointment of its officers for the year 1891, and therefore is not inconsistent with the continuance of the officers appointed or now holding office under the act of 1885. Under the act of 1891 no appointments can be made before the first term of Court in the year 1892. It would be advisable for the officers holding certificates under the act of 1885 to qualify under the act of 1891."

It is Section V., of Article 2d, of the new law that Senator Hines states is different in the copy of the law approved by the Governor from that passed in the Senate. In the copy signed by the Governor the Section reads "Whenever candidates for the office of Inspector are to be examined, the said examiner shall give public notice of the fact in not more than five papers published in the inspection district, and at least two weeks before the meeting, specifying the time and place where such meeting shall be held. The said examiners shall be sworn to a faithful discharge of their duties, and four of them shall agree in their recommendation of all candidates to the Governor who have answered 90 per centum of the questions. The names of the applicants, the questions asked, and answers thereto, shall be sent to the Secretary of the Commonwealth, and published in at least two local papers, daily or weekly, and shall recommend only such applicants as they find qualified for the office.

"Should the Board of Examiners not be able to agree in their selection and recommendation of a candidate, the Judges of the Court of Common Pleas shall dissolve the said board, and appoint a new board of like qualifications and powers."

"Upon the recommendation of the Board of Examiners as aforesaid, the Governor shall appoint such person or persons to fill the office of inspector of mines under this act, and shall issue to him a commission for the terms of five years, subject, however, to removal for neglect of duty or malfeasance in office, as hereinafter provided for."

Mr. Hines says that the words in the first paragraph after "Governor" down to and including the word "weekly" were stricken out of the law in the Senate, and should not have been incorporated in the copy sent to the Governor for his signature. At the time of the passage of the law we understood this was the case, and when we received a copy of the act signed by the Governor we delayed printing the same, and did not print it until we were informed, by what we considered good authority, that the law was likely to stand as signed by the Governor. We think the law (as Senator Hines says it passed the Senate) is as good if not better than it is as signed by the Governor, because it is less difficult to carry out, and will secure the appointment of as good officers. There is nothing to be gained by requiring the examining boards to favorably recommend all applicants who may answer 90% of the questions asked, nor can we see any benefit to be derived from publishing, at a very great expense, the questions and answers in two local newspapers every time an examination is held. It is enough to require the Boards of Examiners to report all the applicants whom they think qualified for appointment. The objection made to this arrangement is that the majority of a Board if they favor a particular candidate are likely to report the name of only a single person as qualified. Admitting that this objection is well founded, we think that it will be better for the majority of a Board to make an appointment than to leave the matter in the hands of the Governor, who will select, not the best man recommended, but the one among those recommended who has the strongest political pull. It is not safe to leave anything in regard to mining with the class of Governors we are having in Pennsylvania. The gentleman who now governs this State, with its mammoth mining interests, knows so little about the industry, and has such a poor opinion of its importance, that when the late World's Fair Commission was appointed, there were not enough mining men upon it to make a sub-committee of three. It was necessary to fill vacancies in the commission with miners to make up such a committee. This comes from selecting men who have spent their lives as clerks, and who have no idea at all of the industries from which the wealth of the Commonwealth is gained, as candidates for Governor. However, this has nothing to do with the new mine law. However much Mr. Hines may object to it, it is likely to stand as the Governor signed it.

Objection is also made to the examination the candidates were required to pass. The law says nothing in regard to the kind or standard of examinations that candidates shall pass. The whole subject is left to the judgment of the Examining Boards. Even if Mr. Hines' objections are pertinent they will have no weight, since the Boards of Examiners are the sole judges of the standard of examinations which candidates shall be required to pass. Objection is also made that Mr. Roderick is ineligible to the office, because he is not old enough. If Mr. Roderick is not eligible he cannot be appointed, but if this is a fact it is surprising that he was an applicant.

The dissatisfaction, which is voiced by this protest forcibly illustrates the folly of legislating upon mining subjects in a hurry. Senator Hines and his friends are responsible for the appointment of a thirty-five day commission to revise the mine laws. The time was utterly inadequate to study the important matters involved and report real improvements in the law, and as a consequence the new law is not as good as the old one.

The Litchfield Car & Machine Co., of Litchfield, Ill., has won an enviable reputation for good and prompt work, and mining machinery built by this company is now in use in almost every American coal field. A recent letter received from the general office of the company, informs us that they have sold and delivered a pair of hoisting engines to Messrs. Yoch and Brandenburger, of Belleville, Ill., and have just closed a contract for a pair of the Litchfield engines for the Kansas and Texas Coal Co. They are also building an engine and stock and box car loader for the Sandcoulee Coal Co., Sandcoulee, Montana, and among other inquiries which they attribute to their advertisement in THE COLLIERY ENGINEER, is one from New South Wales.

Mould's Hydraulic Coal-Getter.

For a considerable time past, Mr. E. Mould has been endeavoring to design a suitable mechanical contrivance that would take the place of explosives in dusty and fiery mines. He has produced screws and hydraulics of various forms, as well as a cylinder in the far end of the hole and water forced through a tube. But the bursting of the tubes was a nuisance. He then tried the cylinder outside, but this design was too heavy and cumbersome and others were inefficient. However, he now claims to have designed an instrument of a little over 60 lbs. in weight, to break loose almost any coal in the ordinary way of working.

This apparatus, which may be used as an ordinary hydraulic jack for any lifting purposes up to 10 tons, is thus described by the inventor: There are (1) the head, (2) the cylinder, (3) the mandrel, (4) the piston-rod, the side pieces and the pump handle. The side pieces and the pump handle are the only loose parts.

The head contains the pump, and in part answers the purpose of a reservoir.

The cylinder is simply a round parallel barrel, screw-threaded at each end, and is so connected to the head at the top end and to the mandrel at the bottom end. This cylinder is covered by a shell cylinder, leaving a cavity between the two—the inner and outer cylinder. The inner cylinder is perforated on the side at the bottom end, to allow the water to pass from the under side of the piston while it is being forced into the cylinder on the top side of the piston by means of the pump, thus supplying the pump during the operation of breaking loose the material in which it has been placed. As already stated, the inner cylinder is screw-threaded at each end. Now, while it is being screwed together, the outer shell is drawn into faced joints, both top and bottom end, and is so made water-tight, and becomes a portion of the reservoir for water. Thus there is ample provision in the head, the cylinder, and the cavity. This is to avoid the necessity of constantly refilling with water, which may be more or less unclean.

The mandrel is screwed into the bottom end of the cylinder, and so becomes a permanent joint. The mandrel is also provided with recesses, constituting inclined planes. In these inclined planes are placed side pieces or wedges, thus making the mandrel cylindrical in form, and is so placed in the hole prepared for it.

In addition to the cylinder and a piston, there is a piston rod. The rod passes from the piston in the cylinder through the mandrel, and on the bottom end there is placed a collaring, so as to enlarge the bearing, because this becomes the basis of pressure. It is very important that the machine should go to the far end of the hole, and to ensure this the drill should always be ¼ in. larger in diameter than the machine.

Now, supposing the machine is in the hole, quite at the far end, the moment pumping is commenced, the piston rod being against the far end of the hole cannot go forward, therefore, the machine moves outward, and the friction on the sides of the hole being greater than that of the incline planes, the said pieces become fixed and the machine moving outward, produces lateral pressure by means of the incline planes, thus forcing asunder the material in much larger blocks than when exposed to the shattering influence of an explosive; securing better results, and at the same time avoiding all the evils contingent on the use of explosives.

The merits claimed for this machine are: (1). Efficiency. (2). Portability, being a little over 60 lbs. when charged with water; the same is used over and over again, it may be for months, so that you see the pump is intact; and this is accomplished by the simple means of a thumbscrew. When the operation is completed, by turning a thumbscrew, the water returns to the underside of the piston. (3). Economy, being less in first cost, and less liable to get out of repair, its loose parts being so few in number—viz., side pieces and pump handle. (4). Simplicity—place the side pieces in the recesses of the mandrel, force it to the far end of the hole; if the coals are to be lifted up or forced down the side pieces must be top and bottom. But if the coal is to be forced sideways the side pieces must be right and left. Then commence pumping, and in about five minutes the coals will be down or on the sprags, ready for dropping, as required.—*The Colliery Guardian.*

Keep Up with the Procession.

In this day of close competition and small profits, it is necessary for every mine owner, superintendent, mining engineer, and mine foreman, to avail himself of all improved mechanical appliances that tend to reduce cost and enhance the value of his products. To do this he must watch carefully the new devices constantly being set before the mining public. Therefore we advise our readers to

Send for the circulars, catalogues, etc., of The Harrington & King Perforating Co., Nos. 222 to 226 North Union St., Chicago.

Send for the circulars, catalogues, etc., of The Reliance Gauge Co., 736 Ontario St., Cleveland, Ohio.

Send for the literature on self-oiling mine car wheels, mine cars, etc., published by Messrs. Hockensmith and Wagoner, Irwin, Pa.

Send for the handsome catalogue of The Goulds Steam Pump Co., Seneca Falls, N. Y.

Send for "Steam," a very handsome cloth and gilt bound volume treating on steam production, care of boilers, pipe covering, etc. It is really a text-book on the subject. Babcock & Wilcox Co., 30 Cortlandt Street, New York.

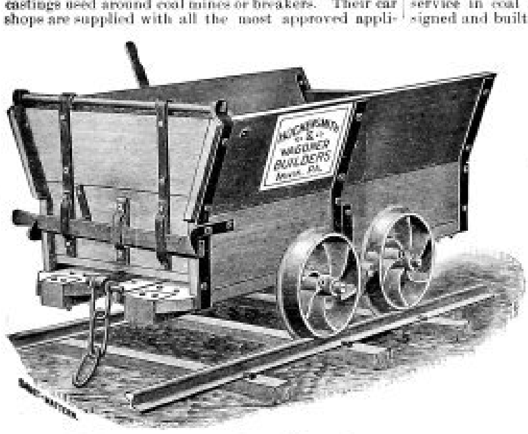
Send for "Key to Steam engineering," a simple and convenient catechism on steam engineering, completly covering the subject, and including also a treatise on combustion of fuels. Price 30 cents post-paid. Address The Mason Regulator Co., Boston, Mass.

All the above but the last will be sent free. The latter is fully worth the nominal price charged for it. When writing mention THE COLLIERY ENGINEER.

A GOOD MINE CAR WHEEL.

The strongest proof of the excellence of any specialty, whether mechanical or otherwise, is secured when the sales to parties eminently qualified to judge of its merits rapidly increases in a regular ratio, and when each purchaser repeats his order. This has been the case with the "Common Sense Mine Car Wheel," manufactured by Messrs. Hockensmith & Wagoner, of Irwin, Pa. This firm is composed of two young and energetic men whose whole business life and natural inclination eminently fit them for the business in which they are engaged. The "Common Sense Wheel" is the invention of Mr. Frank C. Hockensmith, who for over twenty years has been actively engaged in mechanical pursuits, having started at the early age of seventeen years. After much thought and study, and numerous experiments, he invented and patented the wheel of which we give a sectional view herewith. The points of advantage in this wheel are: (1) It has no loose parts to get out of repair. (2) The device for oiling the back part of the journal effectively, where the hub and axle collar come in contact, which it is important to keep well oiled, is perfect. (3) It effects a saving of from 50 to 75 per cent. of oil. (4) The bracket in the oil chamber prevents the oil from being thrown out when running on curves. (5) The oiling arrangement only adds 4 lbs. to the weight of the old style wheels. (6) Its simplicity and cheapness of first cost and durability and efficiency. Since the formation of the firm of Hockensmith & Wagoner and the purchase of the Irwin shops, in 1886, the firm has, beside its other business, sold over eighty thousand of these wheels. They are in use in every American coal field, and sample sets are sent on approval to responsible parties. If not satisfactory they can be returned at the manufacturers' expense.

In addition to the car wheel foundry, Messrs. Hockensmith & Wagner are prepared to make all kinds of castings used around coal mines or breakers. Their car shops are supplied with all the most approved appliances and their mine cars substantially and conveniently constructed. They make all sizes and styles of mine cars and equip them with either "Common Sense" or plain wheels. The present capacity of their works is six hundred car wheels and fifty mine cars per week. In 1886 when they started under the firm name of Hockensmith & Wagoner, they employed five men. The superiority of their products soon won for them a reputation, and the number of hands employed was gradually increased till now they employ fifty, and they will continue increasing as rapidly as their business demands it. They realize that two things are necessary to secure and hold trade, and that they are ready to furnish both. These are superior goods, and prompt filling of orders. It will pay colliery owners and colliery officials to write to Messrs. Hockensmith & Wagoner for circulars.



Remington Brothers' Newspaper Manual, 1891.

We have just received the fifth annual edition of the Newspaper Manual of Remington Bros., of Pittsburgh, Pa., which appears in a greatly enlarged form, and is now one of the most concise, convenient and reliable works of its kind. The general arrangement of this useful book remains unaltered, but important and valuable additions have been made, thus increasing its value to the general advertiser as a reference work and in the compilation of his list.

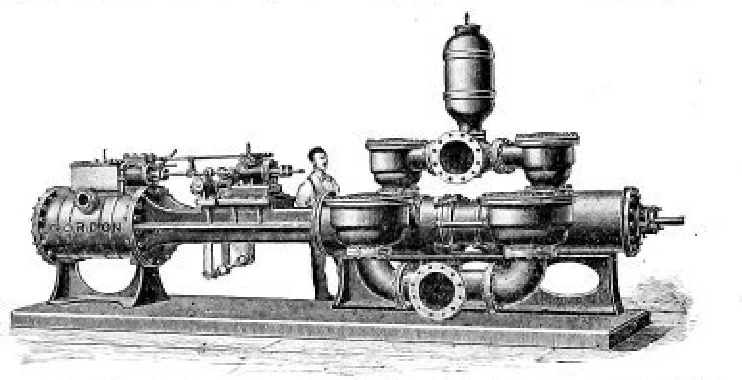
The contents include complete lists of all newspapers in the United States and Canada, with their days of issue, politics, and circulations, and properly classified list of the principal Dailies and Weeklies, and the best Agricultural, Religious, Scientific, and Trade publications and leading Magazines. All the lists are catalogued by towns in alphabetical order, and in the general list the population is given of each town and of the county in which it is located

The photo-engraving, on page 3, of Remington Bros.' extensive and handsome main office at Pittsburgh will give some idea of the extent of their business transactions.

We have tested the accuracy of the Manual and find it singularly free from errors. To advertisers especially it must prove invaluable, containing as it does every particular necessary for the general description of each newspaper, and so arranged as to admit of the readiest reference.

A SUPERIOR MINE-PUMPING ENGINE.

In this issue we present to our readers an illustration of a large mine pumping engine, which is one of a number of its kind constructed by the Gordon Steam Pump Co of Hamilton, Ohio. This particular machine has a steam cylinder 24″ in diameter, water plunger 15½″ in diameter, and a stroke of 36″. The water cylinder with all valve chambers, valves, plunger, and plunger-rods, suction and discharge connections are cast of a high grade of composition, and the amount of this metal in the pump end is a little over seven tons, the total weight of the engine being in the neighborhood of twelve tons.



This pump engine is particularly adapted for the hard service in coal and other mining practice, being designed and built especially for this class of work.

One of the leading and peculiar features of this engine is the cataract and self-governing device. The combination of these secure results which entitle it to the well-known characteristic of Isochronal or equal spaces in equal times; that is the strokes of the piston are all equal in length and are made at equal times, being unaffected by variations in the steam pressure, or in the resistance against which the engine is working. The isochronal valve-gear not only neutralizes the bad effect of the sudden change in the steam pressure or the load of the engine, but also secures other advantages of the greatest value. By means of the cataract the movements of the main steam-valve are automatically graduated and controlled, so the speed of the piston is reduced as it nears the end of the stroke, allowing the valves to seat themselves gently and quietly and the moving column of water to come to a gradual and easy rest. In fact, the cataract is an ever watchful and never-tiring engineer, always promptly adapting the movements of the engine to the external conditions of the work.

Large columns of water may be raised to great elevations or forced against heavy pressure from without shock or jar of any kind and with entire safety to the machinery and connections.

The Isochronal pumping engine is especially adapted and conveniently fitted for draining out mines, furnishing rolling mills, iron furnaces, or any establishment requiring a large supply of water. This engine is built in all sizes and for all duties, and is also built either compound, compound-condensing or high pressure, both duplex or single, as the case may demand.

Parties contemplating the purchase of pumping machinery would do well to open a correspondence with the Gordon Steam Pump Company and investigate their engines.

PERSONALS

MR. WILLIAM J. WATKINS, formerly connected with the Oregon Improvement Co., has assumed charge of a new mine at Blue Canon City, Whatcom Co., Washington.

MR. WILLIAM J. MCDOWELL, of Snowshoe, Center Co., Pa., has accepted the position of Superintendent of the O'Shanter Mines at Clearfield, Pa.

MR. JOHN H. JONES, the well-known compiler of coal trade statistics, has been appointed General Manager of The J. B. Sanborn Company for the territory east of the Ohio river. We predict that under Mr. Jones the Agency will be brought up to a high state of efficiency.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since our Last Issue.

Russell Coal and Mining Company,	Russellville, Ark.
Ophir Mining Company,	Butte, Mont.
Marengo Gas, Mineral, and Mineral Water Co.,	Liberty, Indiana.
Columbian Lead and Zinc Co.,	Chicago, Ill.
The International Railway Supply and Improvement Co.,	Chicago, Ill.
Chancy Creek Mining Co.,	St. Paul, Minn.
The Wylie Mining and Milling Co.,	Denver, Colorado.
The Calender Mining and Milling Co.,	Denver, Colorado.
Almeda County Improvement Co.,	Oakland, California.
The Peck Montana Co.,	Chicago, Illinois.
Eastern Oregon Development Co.,	Portland, Oregon.
Cleveland Gold and Silver Mining Co.,	Sierra City, Cal.
St. James Mining and Mineral Paint Company,	East St. Louis, Ill.
The Fanny Rawlings Mining Co.,	Colorado Springs, Colo.
New York and New Jersey Mining Company,	New York, N. Y.
The Castle Mining Co.,	Denver, Colorado.
The Willow Mining and Milling Co.,	Denver, Colorado.
The Ruby Mining and Milling Co.,	San Francisco, Cal.
Marion Iron Ore Company,	New York, N. Y.
Silver Horn Mining Co.,	Neihart, Mont.
The Clear Creek Mining Co.,	Springfield, Ill.
The Austin Mining Co.,	Jersey City, N. J.
Dry Fork Mining Co.,	Barker, Montana.
Bear Valley Mining Co.,	San Bernardino, Cal.
The Garabaldi Mining and Smelting Company,	Chicago, Ill.
The Dodson Lead and Zinc Co.,	Bethlehem, Pa.
The Chicago and Florida Phosphate Company,	Chicago, Ill.
The May Queen Lode Mining Co.,	Pueblo, Colorado.
Yellowstone Mining Co.,	White Sulphur Springs, Mont.
Blackbird Coal Co.,	Unionville, Mo.
The Dufont Mining Co.,	Camden, N. J.
Westmoreland Fire Brick Co.,	Pittsburgh, Pa.
The Gaylord Coal Co.,	Martins Ferry, Ohio.
Bone Valley Phosphate Co.,	Portland, Me.
The Anglo-American Cotton Milling and Coal Mining Co. (Amended),	Kansas City, Kansas.
Montezuma Improvement Co.,	St. Louis, Mo.
Acme Coal and Coke Co.,	Opekiska, W. Va.
Principio Furnace and Rolling Mill Company,	New York, N. Y.
American Land Co.,	Louisville, Ky.
Kentucky Land and Improvement Company,	Louisville, Ky.
Montgomery Marble and Mining Co.,	Montgomery City, Mo.
The Milan Land and Coal Mining Co.,	Milan, Mo.
Ozark Mineral Land and Mining Co.,	Carthage, Mo.
American Mining Company of Kansas City,	Kansas City, Mo.
The American Tin Plate Co.,	Elwood, Ind.
The Kaufman Gas Co.,	Arcadia, Ind.
The Crown Mining and Milling Co.,	Denver, Colorado.
Chicago Carbonate Mining Co.,	Anaconda, Mont.
The Bandora Mining and Milling Co.,	Colorado Springs, Colo.
Kenova Coal and Timber Co.,	Kenova, W. Va.
The Saratoga Mancos Gold Mining Company,	Mancos, Colorado.
The Boulder Comstock Mining Co.,	Helena, Mont.
Little Nellie Zinc Mining Co.,	St. Louis, Mo.
Montague Coal Mining Co.,	Fort Worth, Texas.
The Anchor Mining Co.,	Kansas City, Mo.
The Springfield and New River Development Co.,	Springfield, W. Va.
The Hammett Mining Co.,	Jersey City, N. J.
The Indiana Mining Co.,	Butte, Mont.
The Mexico and Central and South American Mining and Colonization Company,	Denver, Colorado.
The Francenia Mining Co.,	Leadville, Colorado.
The Vesuvius Mining and Milling Company,	Leadville, Colorado.
Silver Queen Mining Co.,	Ardmore, Ind. Ter.
San Domingo and Hay Tunnel Mining Company,	Oshkosh, Wis.
San Mateo Mining Company,	Oshkosh, Wis.
Eureka Gold Company of West Virginia,	Philadelphia, Pa.
Lone Mountain Mining Co.,	Silver City, N. M.
Ophir Mining and Milling Co.,	Great Falls, Idaho.
The Sapphire Mining Co.,	Victor, Mont.
The Buckwheat Coal Co.,	Lewiston, Ill.
Gold Mountain Mining Co.,	San Francisco, Cal.
Sacramento Mexican Mining Co.,	Sacramento, Cal.
Mount Morian Quartz Mining Co.,	Downieville, Cal.
Bonner Oil Company,	Los Angeles, Cal.
The Bituminous Consolidated Mining Company,	San Francisco, Cal.

DEATH OF HON. WM. L. SCOTT.

Hon. Wm. L. Scott, of Erie, Pa., one of the largest individual owners of coal land in the world, and heavily interested in other business enterprises, died at Newport, R. I., shortly after midnight on the 20th ult.

Mr. Scott was a typical self-made American, and his rise from poverty to great wealth and prominence in both the business and political world was marvelous, and was due entirely to his great mind and his aptitude to foresee chances that are evident to most men when such chances become things of the past. In our November issue we will publish a portrait of Mr. Scott, and a synopsis of his life more in keeping with his character as a man, a patriot, and a philanthropist than is possible in the limited space at our disposal in this issue.

THE PROGRESS IN MINING.

Reviews of the Important Papers Relating to Mining Published in the Proceedings of the Mining Institutes and in the Mining Publications of Europe, United States, and Canada.

Coal Cutters. — A paper recently read before the Mining Institute of Scotland, by Mr. Robert Martin, descriptive of the working of Mechanical Coal Cutters by compressed air, has been fruitful in eliciting a few experiences from the members present. The case in question was where one of Rigg & Micklejohn's patent machines holed a face of work 126 yards long. The seam was 4 ft. thick, with an even holing, and the depth holed was 30 inches. The air was compressed on the surface and conducted underground 700 yards in pipes. The cutters were of "titanic" steel, and worked like a horizontal circular saw. The machine which worked at night was manipulated by three men, two of whom looked after the cutters, whilst the third cleaned the dirt from the holing and set the sprags and props to sustain the coal until morning when a staff of nine fillers with three drawers and four brushers came to load it out. The machine, barring accidents, traveled the whole length of face (126 yards) in a night, and the cost in fuel at the boilers for this work was five tons. The fuel was dust, passed through a ½" screen.

It requires training to make the men competent to work the machine, and difficulty is sometimes met in obtaining them. The general expression of opinion by the members seemed to be, that the only material saving was in the smaller percentage of small coal made by the machine as compared with hand labor, and so far as Scotch mining is concerned, it has only been where men are scarce that the machine has been adopted. The initial outlay is always great, and the amount of machinery involved demands an increased staff of skilled mechanics. To secure favorable results there must be a plain, unvarying holing, free from occasional ironstone nodules, the presence of which generally results in stripping the cutters and placing the machine *hors de combat* for several days.

Longwall.—Balgonie Colliery, in Scotland, was troubled with gob fires. The seam worked is seven feet thick with a parting of stone a few inches thick in the middle. For the purpose of preventing spontaneous combustion, Mr. Alexander Jamieson, the manager, introduced a new method of Longwall, and as it has been successful in abolishing these fires during five years, it has been described in a paper read before the Mining Institute of Scotland, by Mr. Robert McLaren. The working is divided into sections by parallel heading roads driven to the rise, and from these headings branch roads are turned level course 12 yards apart. As they advance the bottom leaf of coal, three feet thick, and the stone parting above it, is all excavated, and the stone utilized for building roadside packs. To make height, the roadways are brushed up to the top of the vein (7 feet). Care is taken to build the roadsides tight, and when the brushing &c., is not sufficient to do so, old slabs and coal-dross are utilized. This working progresses until the next panel or section of the pit is reached, when the miners start back, excavating the upper leaf, and using the old roads for drawing the coal which were used in the first working. Mr. Jamieson claims that by this method he has a cheaper and safer working, better ventilation, and perfect immunity from gob fires. Formerly both halves of the seam were worked in the same direction, one behind the other.

In discussion before the Institute the question was raised as to what percentage of the entire seam was necessary for efficient brushing. In the section in question the percentage of rubbish was 30% of the entire area excavated, and a member who had investigated numerous instances throughout Scotland, stated that experience proved that the best results were obtained where there was 40% of rubbish.

Propping.—A paper on this subject recently read before the Scotch Institute, by Mr. Robert Martin, whilst containing nothing striking in the way of novelty, drew from the president the very trite remark, that, in the West of Scotland, where he is Government Mine Inspector, while 40 per cent. of the entire accidents were due to falls, the majority of these were in places where the roof had obtained a good reputation. At collieries where the roof was *notoriously* bad, timber could be seen put up as close to the working force as possible, and consequently accidents were very rare; but if a roof was generally good the miner seemed to turn careless, and while one might see the traveling roads beautifully timbered, at the same time, the working places, where the men spent all their time, would be devoid of wood for 10 or 12 feet from the face. Familiarity breeds contempt!

Oil Shale Mining.—During the past few months the Mining Institute, of Scotland, has had under discussion a series of papers descriptive of the methods of mining as practiced in the oil shale industry in the East of Scotland, and whilst a few extracts may be interesting, it might also be well to recount in a few words the circumstances which led to the founding of an industry which, in all its ramifications, gives employment to thousands of the workers in the Scottish mining and chemical industries.

Somewhere about thirty years ago a discovery was made of oil exuding from the rock in a Derbyshire mine. A sample was sent to James Young, a Manchester chemist, who found that it contained chemical properties which made it valuable as a burning oil. The circumstances under which it was discovered led him to the conclusion, that, before such an oil could exist, there must have been some mineral from which by natural distillation the oil was procured, and he made it his life study to find that mineral. Ultimately his quest was successful in the discovery, in the Lothians in the East side of Scotland, of a series of seams of Bituminous mineral, somewhat akin to Cannel coal, and amongst which was the famous Boghead or Torbanehill gas coal, the cause of one of the greatest law-suits that ever excited the mining world; and from the discovery of those seams arose the paraffine oil shale industry which now gives employment to many thousands of Scotland's industrial army, and transformed the quondam Manchester chemist into a millionaire.

In the geological section the oil shales lie below the Hurlet limestone which is the base of the legitimate coal field of the great Lanarkshire basin. The workable seams of shale were originally six in number, as follows: Dam Shale, Mungle Shale, Grey Shale, Fell's Shale, Broxburn Shale, and Dunnet's Shale, and the base of these was the Burdiehouse or Campe Line.

In recently published sections, however, there is another seam shown as existing below the Burdiehouse Line, and which is named the "Pumpherston," from the only locality in which it has been found. Peculiarly enough, however, where the Pumpherston shale is found there is some geological disturbance to prevent the geologist from inspecting the Dunnet, and *vice versa*. Of course this may not be so strange in a district where the field is so overrun with faults, that the student is sometimes at a loss to say whether he is in a stratification of seams interspersed with faults, or in a conglomerate of faults, besprinkled with oil shales. Be this as it may, however, there seems reasonable cause for doubting the positive existence of two separate seams, more especially as each has many features in common, and some, well versed in the section, are inclined to say that the Dunnet and Pumpherston are identical.

A few months ago we were in conversation with a mining engineer who has earnestly studied this district for many years, and he said: "Let me illustrate "the problem by a story: A man who had come into "an estate, arrived to take possession, and noticed that "the butler and gardener were extremely like each "other. He arranged upon several occasions to have "them both together, but when the time arrived something was sure to turn up to prevent him from seeing "them side by side. Ultimately he succeeded, by "thorough investigation, in finding out that they were "one and the same person, taking advantage of his "inexperience to draw a double salary. So is it with "these two seams, where Dunnet is Pumpherston is "absent, and where Pumpherston is, Dunnet is not."

The general method of mining the oil shales is explained in a paper read by Mr. Alexander Faulds, on "Shale Mining at Oakbank."

In this seam, the Dunnet, the section is as follows:

Roof.	Fakes.
Second Working	Shale 3 ft.
Brushing.	Blaes 3 ft. 5 inches.
First Working	Shale 3 ft.
Pavement.	

The system is Longwall. The length of each working face is 15 yards, and as the roof is tender it is found advisable to have each face a "fall" in advance of the one next on the "inbye" side. Oil shale labors under this disadvantage, that it is sometimes extremely difficult in the pit to distinguish between good shale and the blaes, or dirt, which in every case, lies either over the seam or intermingled with it in layers of varying thickness, and it will be observed that in this case a band of 3 feet 5 inches intervenes between the two portions of the seam. The lower leaf is first holed under and blasted down for a distance of 9 feet in from the face, and after this is loaded the timbers supporting are drawn, and the overlying strata, to the top of the upper leaf, is then dropped. The shale being uppermost is now put into the cars, and then the "blaes" is used for building the roadsides. The roadways, which run directly to the rise, rarely exceed 300 ft. in length, being cut off periodically by slope roads or levels driven from the main incline. Each of these working faces of 15 yards long is worked by two miners, and a drawer, the duty of the latter being to run the cars, which hold half a ton each, down the roads to the gangway. These three men use 3 pounds of gunpowder per day, and put out 5·37 tons, or an average of 1·79 tons per man.

The Fall Meeting of The American Institute of Mining Engineers.

The sixtieth meeting of the American Institute of Mining Engineers will be held at Glen Summit, a beautiful mountain resort near Wilkes-Barre, Pa., beginning Tuesday evening October 6th.

The following provisional programme is announced by the Secretary:

Tuesday evening, Opening Session.

Wednesday morning and afternoon, sessions for the reading of papers and discussions.

Wednesday evening, "Camp Fire," on the grounds of Gen. Paul A. Oliver, at Oliver's Mills.

Thursday, Excursion in the Wyoming region; luncheon at Harvey's Lake.

Thursday evening, Final Session.

Friday, excursion in the Lehigh region, including visit to the iron breakers of Coxe Brothers & Co., and to collieries where large Anthracite seams are worked by stripping off the overlying strata.

That the sessions will be interesting is evidenced by the announcement of the following papers to be read:

Electricity in Mining, as applied by the Aspen Mining and Smelting Company, by M. E. Holt, Aspen, Colorado.

Electric Locomotives in German Mines, by Karl Eilers, Berlin, Germany.

The Manufacture of Liquid Sulphurous Acid in Upper Silesia, by Karl Eilers, Berlin, Germany.

A Chinese System of Gold-Milling, by Henry Louis, Singapore, Straits Settlements.

The Utilization of Puddle-Slag for Paint-Stock, by Axel Sahlin, New York City.

The Florence Oil Fields, Colorado, by George H. Eldridge, U. S. Geol. Survey, Washington, D. C.

A Survey of the Planches de Plata Mines, Sonora, by Henry M. Stanley and Henry O. Flipper, Nogales, Arizona.

Co-ordinate Surveying, by Henry O. Flipper, Nogales, Arizona.

Cord-wood in the Matting Blast-Furnace, by Herbert Lang, Mineral, Idaho.

The Bendigo Gold-Field, by T. A. Rickard, Allemont, Isere, France.

Apparatus for the Manipulation of Iron and Steel Plates during the Process of Finishing, by Gram Curtis, Pittsburgh, Pa.

The Handling of Ingots and Moulds in Bessemer Steel Works, by Gram Curtis, Pittsburgh, Pa.

Centrifugal Ventilators, by R. Van A. Norris, Wilkes-Barre, Pa.

Tandem Tanks for Hoisting Water from Flooded Slopes, by J. H. Bowden, Wilkes-Barre, Pa.

The Utilization of Anthracite Waste by Gasification in Producers, by W. H. Blauvelt, Philadelphia, Pa.

The Use of Magnetic Concentrates in the Port Henry Blast-Furnaces, by N. M. Langdon, Port Henry, N. Y.

Special discussions are also expected on the following topics:

The Preparation and Utilization of Small Sizes of Anthracite Coal, and The Practical Uses of Concentrated Iron Ores.

Mr. Norris' paper on Centrifugal Ventilators will naturally be one of great interest, and there will no doubt be considerable discussion of this important subject.

McARTHUR-FORREST PROCESS OF GOLD EXTRACTION.

BY J. S. McARTHUR.

(In the Journal of the Society of Chemical Industry, Vol. IX., Abstracted by A. L., of the Mining Institute of Scotland).

The author describes briefly a number of the different mechanical and chemical processes hitherto in use, by which the metal has been separated from the ore. After experimenting on ores from all parts of the world, the inventors adopted the following process, which may be stated in the author's words: "The ore is ground to about the fineness of sand. If, instead of ore, we are working tailings from the amalgamation process, these are generally not re-ground, but treated as delivered. The finely-divided material is mixed with a solution of cyanide, say cyanide of potassium, containing on an average 0·4 per cent. of cyanogen as the cyanide of potassium or other alkali or alkaline earth. The ore and solution are stirred together for six hours, more or less; and when the gold is known to be dissolved, the pulp is discharged into an ordinary filtering tank, where the filtration may, if necessary, be assisted by suction, and where the ore is washed by water or by the waste cyanide solution from a previous operation. The ore, after treatment with cyanide solution, is unchanged to the eye, as almost nothing but the imperceptible proportion of gold present has been removed. The gold now being in solution, the next object is to get it precipitated, and here we encounter a serious difficulty. Gold and cyanogen have such a strong mutual affinity that it is difficult to get any substance that will separate them. The gold cannot be precipitated by any ordinary method, such as the use of ferrous sulphate or oxalic acid; even sulphureted hydrogen and sulphide of sodium will not precipitate gold from its cyanide solution, though they precipitate silver. We had noticed, however, by experiment, that zinc precipitated gold very feebly, and tried this in the same way that copper is precipitated from its ordinary solutions by scrap iron, but scrap zinc had no effect; then granulated zinc was tried, with a most imperfect and disappointing result; then heating in presence of scrap and granulated zinc, but this had only the effect of forming urea, and assisting the precipitation very little indeed. Further, we tried zinc dust, but still there was no success. Finally, we prepared some zinc in a form like sawdust, porous, and with a large surface of bright metal. On allowing the cyanide of gold solution to trickle through a mass of the zinc, we found that it trickled out gold-free, and, better still, we found that the action became more vigorous and pronounced after a portion of the gold had been precipitated on it, doubtless as gold and zinc formed together a more powerful electro-chemical precipitant than zinc by itself. An arrangement of a porous mass of zinc like a sponge formed a chemical filter, which at once precipitated and collected the precious metal; indeed, so like an ordinary water-purifying device was this zinc filter that many non-technical visitors formed and held tenaciously to the idea that the gold was in suspension in the cyanide solution, and the zinc was used merely because of its durability. Improvements in detail were made in the direction of increasing the surface, and decreasing the weight of the zinc, till now we have it in threads, 1 lb. of which occupies about two gallons measure. The zinc in this form is possessed of enormous chemical activity, of which the strongest and most direct evidence is the fact that it burns in the air like thin shavings of wood. When the gold has been deposited, it is necessary to separate it from the excess of zinc present. The filiform structure of the zinc, and the exceedingly fine powder, as which the gold is deposited, render this an easy matter. The filiform mass of zinc, with gold powder adhering, is vigorously shaken in water, and the gold falls off, and the fibrous particles of the zinc may be collected in a sieve. The gold settles easily, is collected, and fused directly into bullion."

PRIMARY EDUCATIONAL DEPARTMENT

FOR CANDIDATES FOR

MINE FOREMEN'S CERTIFICATES

AND FOR

STUDENTS OF MINING.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the sciences related to mining and to learn how to answer the questions in ventilation, surveying, and mechanics which are asked at the examinations for mine foremen's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine foremen and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and many calculations are worked out at length for the benefit of those who are not familiar with figures.

CORRECTION.

Some of the readers of this department in the last month's issue of THE COLLIERY ENGINEER, were doubtless confused by Fig. 2, page 42, which was through a mistake of the pressman printed upside down.

PENMANSHIP.

The capital letter E is generated by the same elements as the other letters. It will be seen that it consists essentially of two ellipses, the upper and the lower, the major axes not only being parallel, but when correctly drawn, lie in the same straight line; the loops and scrolls are generated in just the same way. Figs. 18

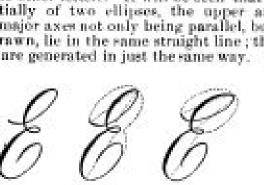


FIG. 18.

and 19 furnish illustrations of the correct principles on which this letter is produced, and also show how any divergencies from the correct elliptical arrangement produce deformities. Beginning at the left hand side of Fig. 18 the first letter is correctly drawn; Letter 2 illustrates the development of the letter by the laws of penmanship, it shows the axes of the two large ellipses to be parallel, and the upper loop is shown as a development of an ellipse whose major axis is inclined at an angle of about 20° from the major axis of the large ellipse. The little or intermediate loop is shown to be developed by the interlocking of the two large ellipses, and the scroll consists of two ellipses having their axes parallel.

In Letter 3 the major axis of the upper ellipse is not parallel to the major axis of the lower ellipse, hence the letter appears as a manifest deformity.

Letter 1, Fig. 19, shows that the proportions between

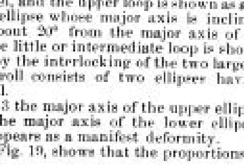

FIG. 19.

the upper and the lower ellipses are not correct, the major axis of the upper ellipse being too short. Letter 2 manifests the same disproportions in an opposite way, namely, the major axis of the upper ellipse is excessively long contrasted with the major axis of the lower ellipse. Letter 3 shows that the major axis of the ellipses that generates the loop is inclined too little from the major axis of the upper ellipse.

Figs. 20 and 21 illustrate the development of the capital letter F. Letter 1, Fig. 20, beginning at the left

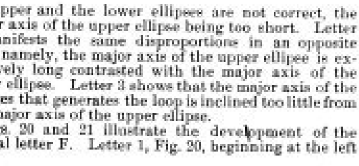

FIG. 20.

is drawn on correct principles, and is in conformity with the general laws of penmanship. The second letter illustrates the development of the Fig. by the first four laws of penmanship. Letter 3 shows two causes of deformity; first, the involved lines of the scroll are not parallel, and the letter is crossed below the middle of the stem, producing a deformity painful to the feelings.

Letter 1, Fig. 21, shows that the stem of the letter is crossed at too great an elevation, hence arises a deformity as manifest as that of the former. In Letter 2 the initial curl of the letter violates the first laws of pen-

FIG. 21.

manship, namely, all strokes shall be parallel, hence the offensive feature in this letter, which renders it repellant to the feelings.

ARITHMETIC.

FRACTIONS.

There is nothing difficult in arithmetic, the difficulty lies in ourselves, we study rules and incorrect principles, all the while forgetting that rules are only ordinary arrangements arising out of principles. Numbers may be said to express things in whole or things in part, one or more wholes may be expressed by ordinary figures, and a part of a whole must be expressed as less than one, therefore, this part is called a fraction, a piece or particle taken from a whole, or remaining after a portion of a whole has been taken away. To understand this is to have clear views of concrete, or complete things, and fractions, or portions of a thing. Again, we might speak of one foot as a unit of length, and as far as that unit of length is concerned one inch is only a twelfth of one foot, because there are twelve inches in a foot; let us for a simple illustration imagine a strip of paper twelve inches long, if eleven inches be cut off that strip only one inch will remain, and this one inch will represent the $\frac{1}{12}$ of the original foot, or the eleven inches cast away may be represented as $\frac{11}{12}$ of a foot, so that we say we have cast away $\frac{11}{12}$ and retained $\frac{1}{12}$ or, in other words the whole of anything is equal to its parts, then the whole foot must be equal to $\frac{1}{12}$ of the foot and to $\frac{11}{12}$ of a foot, and these two portions conjoined produce the original whole. An inch may be considered itself to be a whole inch. Having a strip of paper one inch long, if one-fourth of its length be removed three-fourths remain, that is to say we cast away $\frac{1}{4}$ of an inch of the paper and retain $\frac{3}{4}$; again, the whole is equal to all its parts for if $\frac{1}{4}$ be added to $\frac{3}{4}$ we recover or restore the original whole, viz., a one inch strip of paper.

From what has been here said it will be seen that even the term fraction has a relative rather than a positive meaning in many cases, for instance, one foot may be itself equal to a whole, but one foot as related to a yard is only one-third of the yard, because there are three feet in a yard, in the same way one inch may be considered a whole, but related to a foot it is only a twelfth, or related to a yard it is only a thirty-sixth, because there are 36 inches in a yard, if however, we speak of an apple, a half of the apple can never be a whole, because one apple is the largest expression that can be made in relation to the mere thing without breaking it, anything less than an apple then is a fraction of an apple. This reasoning may appear to be very elementary, and to some it may even appear unnecessary, but we often come across men that are fairly expert in the use of figures, but totally fail in the solution of some problems, simply because they have neglected to furnish their minds with right ideas of the relative values of expressions such as we have been adverting to.

CHEMISTRY RELATING TO MINE VENTILATION.

HOW THE GASES ARE PRODUCED BY NATURAL AND ARTIFICIAL PROCESSES.

Hydrogen. Small quantities of this gas are given off by active volcanoes, but it is seldom found in nature in a free or uncombined state. It is always a constituent of fats, oils, and resins, consequently wherever the resinous remains of vegetable matter are found, there we find methyl hydride, or marsh gas. In the autumn of the year, decayed leaves and vegetable tissues, fermenting in pools and stagnant ditches, give off this gas abundantly, but this is not pure hydrogen, but $C\,H_4$.

Hydrogen can be produced by artificial means, and we advise the student to make himself practically acquainted with the processes. Mere reading will never enable him to cultivate the observing faculty by which alone he can hope to succeed in his studies.

Hydrogen can be prepared in two ways:

First. When steam is passed through a red hot iron pipe containing small scraps of iron we have H_2O + Fe; but to obtain a complete multiple number, we proceed with four molecules of water and three atoms of iron, or four volumes of water and three volumes of iron, and thus obtain magnetic oxide of iron and free hydrogen, thus

$$4\,H_2O + 3\,Fe = Fe_3O_4 + 8\,H.$$

If the remaning steam and hydrogen be passed through cold water, the steam is condensed, and the pure hydrogen may be collected by an inverted jar filled with water.

Second. If a bottle be charged with a few pieces of thin sheet-zinc cuttings, and half filled with water containing one-sixth of its volume of strong sulphuric acid, the acid and the zinc will form new combinations, as follows: One molecule of sulphuric acid, and one atom of zinc, $H_2SO_4 + Zn = ZnSO_4 + H_2$ so that two volumes of hydrogen are set free. By putting the shank of a tobacco pipe through a cork in the bottle neck, the hydrogen may be collected in a bladder for future experiments.

Oxygen occurs free in the atmosphere mixed with nitrogen.

The best way to prepare oxygen artificially is the following: Get powdered potassium chlorate, 2 oz., mix with clean sand, 1 oz., and put the mixture into an iron pipe with one end closed, connect the other end by some means with a bladder, and insert the closed end in the fire; very soon pure oxygen gas will be given off. The gas will cause the most intense ignition if any lighted body be placed in it. To show the experiment, a bottle should be filled with it, and if very fine iron wire with a lighted thread on the end, be plunged into the gas, the iron will burn with the most beautiful scintillations.

Fill a bladder with one-third oxygen and two-thirds hydrogen; taking great care to have a suitable small brass pipe with a tap inserted in the neck of the bladder, and to keep yourself away from all lights while you hold the bladder. Now blow a little of the mixed gases into a dish containing soap water "milk warm," and after carefully removing your bladder, throw a lighted piece of paper into the foam produced by the injected gases, when a violent explosion accompanied by a loud report will ensue.

In this way, and by no other, can you have proper ideas of explosive mixtures. You will here see that by taking one-third by volume of oxygen, and two-thirds by volume of hydrogen, you have formed water which is made up of three atoms, H_2O.

It has been noticed that nearly one-fifth of the air we breathe is oxygen in a free state. Five volumes of air would give up one volume of oxygen and that added to two volumes of hydrogen would be an explosive mixture. It will be here seen that the four volumes of nitrogen do not assist in the explosion, and remain unaffected by the chemical action set up.

Nitrogen occurs in a free state in the atmosphere mixed with oxygen, and is easily prepared as follows: Take a large glass jar full of air, and having inverted the jar suspend in it a piece of burning phosphorus, taking care to then place the mouth of the jar (which is now downwards) in water; white fumes at first seem to fill the jar, but these are soon absorbed by the water, leaving almost pure nitrogen in the vessel.

This gas is the principal constituent of after-damp in mine explosions. It is not poisonous, as has been shown, and its function with regard to the animal economy and ordinary combustion is to dilute the oxygen, otherwise pure oxygen would burn up the tissues of the living organism, and the iron bars or other fittings of the fire-places and furnaces would burn and melt like wax in the flame of a candle.

Methyl hydride, a compound gas produced in nature by the decomposition of decaying vegetation, and given off by coal seams in quantities varying with the conditions of the strata and coal where it is found. It can be produced artificially by the following process:

Heat the following mixture in a retort, and collect the gas after passing it through water: Acetate of soda, 2 parts; caustic potash, 2 parts; and quicklime, 3 parts.

Hydride of ethyl. This gas is one of the paraffin series, and is produced in the neighborhood of petroleum springs and oil shales overlying coal seams.

Carbon dioxide, or carbonic acid, is very abundant in nature. The atmosphere contains by weight no less than 300,000,000 tons of this gas, and yet the proportion in the air is only 4 in 10,000 parts. It pours in enormous volumes out of the craters of volcanoes; it is produced wherever animal and vegetable matter is decomposed; it is exhaled by animals, and produced wherever carbon is burnt in air; water holds it in solution, and it is chemically combined with lime, magnesia, etc., forming carbonates.

For experiments it can be produced with great ease, all that is required for the purpose being a bottle with a pipe inserted through the cork and about a yard of india rubber tubing. Having connected the tubing with the pipe, put into the bottle some pieces of chalk, or lime, or marble, but best of all some common washing soda. Now pour on to the carbonate of lime or carbonate of soda dilute sulphuric acid, when the gas will come off and soon fill another jar into which you convey it with the tube. Here you can extinguish lights, and show its great density or weight by pouring it on the flame of a candle, and make many other such experiments as the future articles will suggest.

Carbon monoxide is produced when carbon is burnt in a limited supply of air. It can also be produced for experimental purposes by passing carbon dioxide through an iron tube kept at a red heat and containing red hot coke. The lambent flames on a coke fire are produced by carbon monoxide burning in air, here $C\,O$ takes an O from the air and becomes $C\,O_2$ or carbon dioxide. Carbon monoxide is a poison, and will not of itself support combustion. It will, however, burn in air when lighted like gas at the open end of a pipe.

Hydrogen sulphide is produced in nature chiefly by the decomposition of sulphates in the presence of organic matter.

Watery vapor is absorbed by the atmosphere when the temperature of the air is raised, and on the air being lowered in temperature it delivers up its surcharge as dew, rain, hail, and snow.

To understand this natural operation a few examples may be noted.

Steam under pressure in a boiler is an example of water taking the gaseous form, when like most other gases it is invisible, and obeys the laws of expansion and contraction, in short it fulfills Boyle's law, namely, "the pressure is inversely as the volume," and its capacity for heat at constant volume and at constant pressure is the same as in a gas under like conditions.

Let it be carefully noted that the boiling point of water varies directly as the pressure.

For example: When the barometer shows a pressure equal to 30 inches of mercury at the sea level, at such level water boils at 212° F., while at an elevation of 600 feet boiling point is at 211° F., and at an elevation of 1,200 nearly, the boiling point is 210°. Now as 600 feet is equal to 100 fathoms, it follows, that the boiling point will rise directly as the depth, increasing 1° F. for every 100 fathoms of descent. An excellent example of this law may be found in a simple experiment. Take a Florence flask and boil in it by the aid of a spirit lamp, a little water, let the water boil until all the air is expelled; suddenly insert a cork and remove the flask from the lamp, when it will cease to boil. Now pour a little cold water on the sides of the flask, when it will begin to boil again, and as the result of the contained steam being condensed, and the pressure being thereby reduced.

Explosive mixtures of fire-damp and air ought to be properly understood by the mining student. It has already been noticed that two volumes of hydrogen and one of oxygen, when ignited, combine with explosive violence. It is also true that one volume of marsh gas or fire-damp, when mixed with two volumes of oxygen and ignited, generates an explosive force nearly twice as great as the afore-mentioned mixture. Now, as has been shown, two volumes of oxygen mixed with one volume of marsh gas makes the maximum explosive mixture; therefore one volume of marsh gas mixed with 9·52 volumes of air, makes what is known to the miner as the maximum explosive mixture of fire-damp and air.

CH_4 is the chemical formula of marsh gas, which is a chemical compound of two elementary bodies, whose united atomic volume is equal to the volume of two atoms of hydrogen. Now the carbon atom will require for complete combustion two atoms of oxygen, and the four atoms of hydrogen will require for complete combustion two atoms of oxygen also, making altogether four atoms of oxygen; but as we have already noticed, the five atoms on chemically combining would be condensed into the volume of two. Now divide the four atoms by two, and there remains two volumes of oxygen to completely burn up one volume of marsh gas. But the oxygen in the air is only ·21 of its volume; therefore, $\frac{2}{21} \times 100 = 9·52$, the volumes of air required to completely burn up one volume of marsh gas.

After an explosion of one volume of fire-damp mixed with 9·52 volumes of air, the resultant gases would be carbonic acid CO_2, watery vapor H_2O, and nitrogen N, the whole constituting that deadly atmosphere called after-damp, making, the moment after the explosion, the following mixture:

Nitrogen or N	=	71·48 per cent.
Watery Vapor or H_2O	=	19·01 per cent.
Carbonic Acid or CO_2	=	9·51 per cent.
		100·00

But the watery vapor will immediately condense, leaving the after-damp as a mixture of nitrogen and carbonic acid of the following proportions per volume, per cent.:

Nitrogen or N	=	88·26
Carbonic Acid or CO_2	=	11·74
		100·00

Perhaps these proportions would be better retained by the memory, by saying after-damp is a mixture of 88 per cent. nitrogen and 12 per cent. carbonic acid.

At the moment of explosion 70 per cent. nitrogen, 20 per cent. steam, and 10 per cent. carbonic acid. It would perhaps be safe to say that in no case in an actual mine, an explosion has occurred with a true chemical mixture of 9·52 of pure air and one of marsh gas.

There are a great number of explosive mixtures ranging from 4·76 of air to one of gas to 14·28 of air to one of gas. The explosive range, might, however, be stated to lie between 5 of air and 15 of air to one of gas; the meaning of this statement will require further explanation. The student must for a moment consider that one of gas and one of air could not in any sense, constitute an explosive mixture; and here it would be wise to notice what we mean by the term explosive mixture. We mean then, such a mixture of gas and air as would, if ignited, produce *instantly* a volume of flame filling the space occupied by the mixture. Now, with a mixture of one of gas and one of air even ignition cannot take place, because there is not sufficient oxygen in the air to burn up the hydrogen constituent of the fire-damp, the heat of combustion being instantly absorbed; or if the flame was to be set up in any one point it could not extend beyond that point, because the heat absorbed by the unburnt gas and the nitrogen of the air would keep the heat permanently below the temperature of flame. With a mixture, however, of five of air and one of gas, ignition of the whole mixture would just be possible, or to put it more clearly, the heat developed by the hydrogen burnt with the oxygen present would just be able to raise the temperature of the hydrogen and the unburnt carbon to the lowest possible temperature of flame. Combustion under these circumstances would develop unburnt carbon as soot, steam, and free nitrogen. With a mixture of 7·14 of air and 1 of gas, we would just have sufficient oxygen to convert the hydrogen of the fire-damp into steam, and the carbon of the fire-damp into carbon monoxide. With 14·21 of air and 1 of fire-damp we reach the extreme limit of an explosive mixture when air is in excess. Practical illustrations of such mixtures would have to be sought for under peculiar conditions. For instance: A mixture of 5 of air and 1 of gas would have to be sought for in a gob fire, or where a seam was on fire. The maximum explosive mixture, viz.: 9·52 of air and one of gas in an ordinary goaf, but it is extremely probable that nearly all explosions of fire-damp in mines originate where the mixture is between 9·52 and 14·28 of air to one of gas.

To summarize these conclusions, the after-damp under three marked conditions of mixture would be constituted as follows: In round numbers, where the explosive mixture was 5 of air and 1 of gas:

Nitrogen	66 per cent.
Steam	34 per cent.
	100

or, when the steam was condensed the after-damp would consist of pure nitrogen, the soot of the unburnt carbon having been deposited as a solid. Here it will be well to notice that wherever fire-damp is burnt in a very deficient supply of air carbon as soot is deposited.

Second form of after-damp. When the mixture consists of 7·41 of air and 1 of fire-damp, the resultant gases are:

Nitrogen	79 per cent.
Steam	14 per cent.
Carbon Monoxide	7 per cent.
	100

or after the steam is condensed:

Nitrogen	92 per cent.
Carbon Monoxide	8 per cent.
	100

and the maximum explosive mixture as given before.

MECHANICS AND MINING.

PUMPS (CONTINUED).

The use of the balance bob. Where a single set is worked by a double acting engine it is necessary to balance the engine with a counterpoise, because on the upstroke the engine is lifting both water and spears; consequently on the down stroke the counterpoise should be equal to the weight of the spears plus half the weight of the water.

Where a forcing and lifting set are employed the engine can be balanced by a proper adjustment of the lengths of the two columns, and this is often done by giving a lift of 240 feet to the lifting set, and a force of 360 feet to the forcing set, or the balance may be stated in the form of an equation. Let E = the power of the engine, W = weight of column, S = weight of spears, then W + S = E in the case of the lifting set and for the forcing set W = S + E.

Special pumps are used whenever the conditions are favorable. They have many advantages over the spear pumps, being cheaper in the first erection and less expensive in repairs; besides they have another great advantage, viz., the ascending column moves at a nearly uniform velocity, and thereby economizes the force that is wasted on inertia, when the movements of the column are intermittent, as in ordinary lifting and forcing sets. The special pump is fixed near the bottom of the shaft, and works a pair of rams or plungers so arranged that either one or the other is constantly in the act of forcing. The velocity of the column is kept uniform by a spring air cushion in the form of what is called the air vessel. The most serious difficulty in the use of this class of pumps arises out of ignorance in the management of the glands of the plungers; the glands ought never to be perfectly water-tight, a little play with the gland, not too tight, and the pump will give comparative satisfaction. When special pumps are used to force water to higher elevations than 600 feet practical difficulties of a serious nature always arise, such as broken joints, fluting of the skin of the plungers, and the constant failing of the packing and glands.

Pumping water out of dip workings has been accomplished by many different applications of energy. The oldest methods employed would undoubtedly be by buckets and kibbles and the ordinary lift pump. Even yet in many cases, the common lift pump is employed, but this is quickly being superseded by plunger force pumps sometimes worked by manual labor. At other times a gin is set up to work plunger pumps by horse power. These pumps are also frequently worked by passing tail ropes round a grooved wheel, the rope being kept round the wheel by binding sheaves. This mode of working pumps is expensive in consequence of the damage done to the ropes, and sometimes a large engine is kept running to work these pumps when the ordinary work of the mine does not require the use of the engine. One of the best motive powers recently used for pumping water out of dip workings is the hydraulic pump, this arrangement being very effective when the pumps are not situated very far from the shaft, arising from the circumstance that the hydraulic motor is worked by a column either taken from the tubbing in the shaft or from the main pumping set. It will thus be seen that a long range of pipes for the motive column would often be required. But for the expense of these long ranges of pipes, often of considerable diameter, perhaps no better motor for pumping water from dip workings could be found. It is a class of pumps that requires very little attention, and has worked for months when entirely submerged. To understand its mode of action the motor consists of an ordinary cylinder with piston and piston rod, the diameter of the piston being regulated by the height of the motive column. The percentage of useful effect being only about 30, which is relatively small, the area of the motor piston is often about one-third of the pump plungers. The water of the motive column is alternately admitted to each end of the cylinder, and the exhaust water is discharged into the delivery pipe of the pump. It will thus be seen that a motive column, about ten times greater than the elevation to the shaft sump, will often be required; or let the modulus be ·3, and the elevation from the pump to the sump at the shaft bottom be 40 feet, then if the area of the piston of the motor be one-third of the sectional area of the plungers, $\frac{40}{·3} \times 3 =$ the motive column in feet, or 400 feet of motive column. A later innovation is compressed air for working pumps in dip workings. This form of energy is applied through the medium of an engine, precisely similar to a steam engine.

MECHANICAL PROBLEMS.

Q. 1.—What are the most severe and damaging strains to which haulage ropes are subject?

A.—The most severe and damaging strains to which haulage ropes are subject, arise out of the carelessness of the brakeman or engine man. The heavy drums, or rope rolls, and the moving parts of the engine are possessed of considerable inertia, when started at a comparatively high speed with a slack rope. Now the inertia due to the heavy cars is so great, that the rope is subjected to a severe strain by the quick starting of the engine, so much so, that often some of the wires, or one of the strands, or the rope itself, is broken, or a socket is drawn, or some of the coupling chains of the coupling bars of the cars are broken by this cause. The engine ought to be started with a creeping motion, until the rope and all the coupling chains of the cars are tight, then the speed may be quickened with comparative safety.

Q. 2.—An incline rising to the shaft at the rate of two inches to the yard is 3000 yards long, the engine is required to haul sixty cars of ten cwt. up this incline; required the strain on the rope.

A.—The cars would be half the weight of the coal, and the coal will weigh thirty tons, and the cars fifteen tons. Jointly the cars and coal will weigh forty-five tons. Let us first proceed to find the strain on the rope due to one ton of the load, which will arise from two causes, first, gravitatio ; second, friction due to traction. As the co-efficient of traction can only be determined in each special case by experiment, we will assume it to be thirty pounds to the ton, which is the average for pit cars; next proceed to find the strain due to gravitation per ton. This is found as follows: Multiply the pounds in one ton by the inches of the rise per yard, and divide by thirty-six the inches in a yard, as follows:

$$\frac{2240 \times 2}{36} = 124·4,$$ Now to 124·4 add 30, which is equal to 154·4 pounds the strain on the rope per ton moved. Now if 154·4 pounds be multiplied by 45, it will equal the strain on the rope in pounds, and is found as follows: 154·4 × 45 = 6948. Now if 6948 be divided by 2240, we have the strain on the rope in tons, namely, 3·1.

Q. 3.—What horse power of an engine will be required to haul 500 tons of coal per day of ten hours along an engine plane of 3,000 yards long, the average rise to the shaft being 2½ inches to the yard?

A.—The cars are always half the weight of the coal they carry, consequently the load on the engine will be 750 tons. The resistance due to gravitation per ton is found as follows: First, multiply the pounds in a ton by 2½, the inches rise per yard, and divide that product by 36, the inches in a yard, and the result will be the resistance in pounds due to gravitation, as

$$\frac{2240 \times 2·5}{36} = 155·5 \text{ lbs.}$$

Now the average co-efficient of traction per ton in cars is 30 pounds, consequently 155·5 + 30 = 185·5 lbs. per ton power required to haul each ton along the road. Again, 750 × 185·5 × 3,000 × 3 = the units of work to be done, but that is the units of work to be done per shift of ten hours. The engine, however, by the main and tail-rope system will only be engaged in hauling coal one-third of the time, that is, 200 minutes; consequently, the units of work will be found as follows:

$$\frac{750 \times 185·5 \times 3,000 \times 3}{200} = \text{the foot lbs. due to haulage.}$$

If these foot pounds be divided by 33,000, the foot pounds in one horse-power, the result will be the theoretical horse-power of the engine required, but we require the indicated horse-power, therefore if the modulus of the engine be taken at ·7 to make due allowance for the friction due to drums, ropes, and rollers, the size of engine required will be found as follows:

$$\frac{750 \times 185·5 \times 3,000 \times 3}{200 \times 33,000 \times ·7} = 271 \text{ H.P.}$$

Q. 4.—What should be the speed of the rope to haul to the shaft the tons of coal mentioned in question 3?

A.—The speed of the rope should not exceed ten miles per hour.

Q. 5.—At ten miles per hour, what would be the strain on the rope for the work done in question 3?

A.—If the units of work in the indicated h.p. of the engine be divided by the speed of the rope in feet per minute, the result will be the strain on the rope in pounds. The speed on the rope in feet per minute will be found as follows:

$$\frac{5,280 \times 10}{60} = 880 \text{ feet per minute.}$$

Therefore the foot pounds in 271 h.p. will be found as follows: 271 × 33,000, but the foot pounds in 271 h.p. divided by the speed of the rope in feet per minute, will be the strain required

$$\frac{271 \times 33,000}{880} = 10162·5 \text{ pounds strain on the rope.}$$

Q. 6.—How many ten cwt. cars could this engine haul out at once, that is, the engine to do the work of question 3?

A.—First find the strain required for one car. According to the solution in question 3, 185·5 lbs. strain were required to haul one ton up the incline; now a 10 cwt. car and its coal will weigh 15 cwt., or three-quarters of a ton; therefore—

$$\frac{185·5 \times 3}{4} = 139·1 \text{ lbs.}$$

Therefore, if the total strain on the rope be divided by the strain due to one car, the result must be the number of cars in one set, as—

$$\frac{101625}{1391} = 73 \text{ cars.}$$

SCIENCE RELATING TO MINING.

THE BAROMETER.

In all ages mankind have been addicted to the same practice of trying to satisfy their craving for knowledge by giving names to things they do not understand.

FIG. 1.

Matters pertaining to the barometer have been treated in precisely the same way, and are even treated so now. It is a misfortune, however, to invent names and excuses for ignorance. He is the best of all men that dare say "I don't know," and make an honorable retreat.

Up to the year 1643, the action of a common pump was not understood, and the reason assigned for water rising up through the tail-piece of a pump was sagely given by saying "Nature abhors a vacuum," or in other words: "Nature hates a vacuum." Now if nature hated a vacuum, nature could think and feel like a man, and if nature hated a vacuum, the very statement gives to nature and vacuum two distinct personalities, which is absurd.

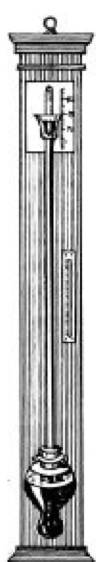

FIG. 2.

The pupil of the great Galileo, whose name was Torricelli, began to think that the oft-repeated statement of nature abhorring a vacuum was foolish and untenable, for it had dawned on his mind that the atmosphere exerted considerable pressure, and that a vacuum was a space void of air, and, therefore void of the pressure peculiar to air, and to prove these conclusions he made the first barometer. Happy will it be for every reader of this article who has not hitherto made a barometer, if he proceeds at once to construct one precisely the same way as Torricelli did. In the left hand portion of Fig. 1 a glass tube is shown closed or hermetically sealed at the lower end, and filled to the top or open end with mercury. Torricelli tightly fixed his thumb over the open end, and by this means both ends of the tube were closed. Now, in this manner he turned the tube upside down, dipping the open end with his thumb pressing tight on it into a cup of mercury, as shown in the right hand side of the figure, when the mercury fell to a height as shown in the right hand tube, corresponding to the pressure of the atmosphere. Now the weight of what we call a cubic inch of mercury would correspond to some other volume and weight of mercury peculiar to Italian weights and measures, and by this means Torricelli was enabled to determine the pressure and weight of the atmosphere.

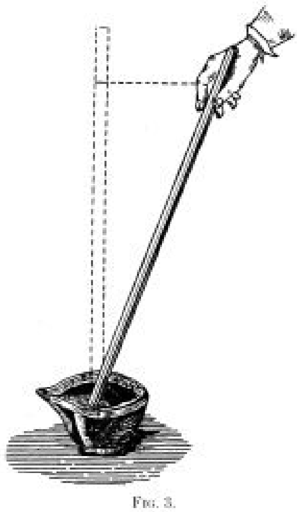

FIG. 3.

A cubic inch of mercury weighs ·4908 of a pound; now, if this be multiplied by the height of the mercury column above the level of the mercury in the cup the pressure of the atmosphere can be determined according to English units. Suppose this height to be 29·7 inches, then 29·7 × ·4908 would be the pressure of the atmosphere under these conditions, or 14·59676 pounds on the square inch.

Fig. 2 illustrates a barometer as supplied by makers; Fig. 3 is intended to illustrate that the length of the column of mercury in the glass tube is shortest when in a truly vertical position, and if the tube be canted to one side from a vertical line the relationships will be that of the radius to the cosine of the angle. It will be seen when the tube is canted the column is longer than when in a vertical position, as shown by the dotted line, or in other words, the vertical height of the length of the mercury in the tube from the level of the mercury in the cup is unalterable while the atmospheric pressure remains the same.

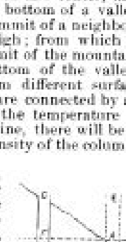
EXAMINATION QUESTIONS ANSWERED.

QUESTION 10.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

What causes natural ventilation? Explain fully. Also explain the various means by which mine ventilation may be produced.

(This question was answered several month ago, but for the benefit of new subscribers we republish the answer.)

ANSWER—In order to understand the theory of natural ventilation, it must be remembered that the height of the atmosphere does not follow the undulations of the earth's surface, but that its outer edge is everywhere equi-distant from the earth's center, and that if it is 50 miles high from the bottom of a valley it will only be 47 miles from the summit of a neighboring mountain which is 3 miles high; from which it follows that the pressure at the summit of the mountain is always less than it is at the bottom of the valley. Hence if two shafts are sunk from different surface levels to the same level seam and are connected by an airway, and there is a difference in the temperature of the air inside and outside of the mine, there will be a current of air created, because the density of the columns of air in the two shafts will differ.



To illustrate this, let A B be a shaft 100 ft. deep, and C D another shaft 200 ft. deep, connected at the bottom by the heading D B. Suppose the air inside to be the warmer, as in winter, and for example let the air inside weigh one-half ounce per foot of shaft per square yard of section, and the outside air weigh three-fourths of an ounce for the same bulk; then the relation between the two shafts would stand thus:

Shallow shaft, 100 ft. at ½ oz. per ft.	50 oz.
Outside column from A to E at ¾ oz. per foot, and 100 ft., equal	75 oz.
Total	125 oz.
Deep Shaft, 200 ft. at ½ oz. per foot	100 oz.
Difference	25 oz.

The balance in favor of the shallow shaft, 25 ounces, will make the shallow shaft the downcast by a pressure equal to 25 ounces per square yard of section. If the temperature outside were the highest, as in summer, this result would be reversed. The difference of weight between the air in the deeper shaft from F to C, and the imaginary column A E is the pressure producing ventilation.

In the case of a drift driven into the side of a hill with an air-shaft opened to its summit under similar conditions the same results are produced. The difference in the weight of the air in the shaft and of an imaginary column in the opening air, from the mouth of the drift, to the level of the shaft, is the pressure producing ventilation. In winter, when the temperature inside the drift is warmer than the air outside, the current will be up the shaft, but in the summer, when the outer air is the warmer, the current will be reversed, and the direction will be out the drift. When the temperatures inside and outside are equal there will be no current. Natural ventilation, on account of its feebleness and liability to derangement by change in the temperature of the atmosphere, at the surface, is inadequate for operations of considerable extent, and recourse must be had to artificial ventilation.

The different modes of producing mechanical ventilation are by furnace, water-fall, steam jet and mechanical ventilators.

In furnace ventilation, a furnace is placed at the bottom of the upcast, which heats and rarifies the air, thus increasing the difference of weight in the two columns in the upcast and downcast shafts. This, of course, acts in assistance of the natural warmth of the earth; this kind of ventilation is much less liable to disturbance from atmospheric changes, although far from exempt from their influence.

The waterfall is not generally used, but is a useful auxiliary for driving air into a mine after an explosion. It causes a current by cooling and increasing the density of the air in the downcast, and also has a tendency to displace considerable air in falling.

The steam-jet acts in a manner totally different. It is a mechanical force applied to propel the air through the shaft. When the jet of high pressure steam is blown into an atmosphere at a state of rest, it produces a violent disturbance in that fluid. The particles of steam are in rapid motion; and since the first law of motion is, that a body in motion continues to move for ever or until stopped by something else, when stopped it communicates its force to the body stopping it. The force of the jet of steam is expended on the air on which it strikes and through which it passes; and this force is applied to the air as fully as if it were applied to a piston in a steam engine. Thus by this method we have the steam power applied directly to the object we require to move, avoiding all the friction of an engine. The force thus obtained is used in forcing the air up or down the pit, or both, according to requirements, and is under more perfect control, and is a more powerful agent when properly employed than the furnace; the furnace not producing above three inches of disturbance of the water-gauge level, the jet has been shown to produce fifteen inches of mercury, which is equal to 15 feet of the water-gauge. It requires no machinery, but a simple pipe in connection with the steam.

Mechanical ventilators are either large air pumps, or exhaust or blower fans. Fans are now justly regarded by all mining engineers as the best means of producing ventilation, and the majority of the leading mining authorities prefer the exhaust fan. There are, however some high authorities that advocate the use of blower fans. Fans produce an air current either by drawing the vitiated air out of the upcast, or by blowing fresh air down the intake.

QUESTION 11.—Asked at the Examination for Certificated Mine Foremen of the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In mines where large quantities of fire-damp are given off, what are the requirements of the mine law?

ANSWER.—In addition to the general requirements intended for all mines, the law requires that the following rules shall be observed in all mines generating explosive gas:

All accessible parts of an abandoned portion of a mine in which explosive gases have been found shall be carefully examined by the mine foreman or his assistants at least once a week, and all danger found existing therein shall be immediately removed. A report of said examination shall be recorded in a book kept at the colliery for that purpose and signed by the person making the same.

In mines generating explosive gases, the mine foreman or his assistant shall make a careful examination every morning of all working places and traveling roads, and all other places which might endanger the safety of the workmen, before the workmen shall enter the mine, and such examination shall be made with a safety-lamp within three (3) hours at most, before the time for commencing work, and a workman shall not enter the mine or his working place, until the said mine or part thereof, and working place are reported to be safe. Every report shall be recorded without delay in a book which shall be kept at the colliery for the purpose and shall be signed by the person making the examination. The person who makes said examination shall establish proof of the same by marking plainly the date thereof at the face of each working place and all other places examined.

A station or stations shall be established at the entrance to each mine or different parts of each mine, as the case may require, and the workmen shall not pass beyond any such station until the mine or part of the mine beyond the same has been inspected and reported to be safe. It shall be the duty of the fire boss to remain at the danger station until relieved by some person authorized by himself or the mine foreman, who shall stand guard until said mine or part of mine shall be reported safe, and he shall not let any person pass without permission from the fire boss.

If at any time it is found by the person for the time being in charge of the mine or any part thereof that by reason of noxious gases prevailing in such mine or such part thereof, or of any cause whatever, the mine or the said part is dangerous, every precaution shall be used to ensure the safety of the workmen. And every workman, except such persons as may be required to remove the danger, shall be withdrawn from the mine or such part thereof as is so found dangerous until the said mine or said part thereof is examined by a competent person and reported by him to be safe.

In every working approaching any place where there is likely to be an accumulation of explosive gases, or in any working in which danger is imminent from explosive gases no light or fire other than a locked safety-lamp shall be allowed or used. Whenever safety-lamps are required in any mine, they shall be the property of the owner of the said mine, and a competent person, who shall be appointed for the purpose, shall examine every safety-lamp immediately before it is taken into the workings for use, and ascertain it to be clean, safe, and securely locked, and safety-lamps shall not be used until they have been so examined, and found safe, clean, and securely locked, unless permission be first given by the mine foreman to have the lamps used unlocked.

No one except a duly authorized person shall have in his possession a key or any other contrivance for the purpose of unlocking any safety-lamp in any mine where locked lamps are used. No lucifer matches or any other apparatus for striking light shall be taken into said mine or parts thereof.

No blast shall be fired in any mine where locked safety-lamps are used except by permission of the mine foreman or his assistant, and before a blast is fired the person in charge must examine the place, and adjoining places and satisfy himself that it is safe to fire such blast, before such permission is given.

QUESTION 12.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In opening up a new mine where the veins or seams have an average dip of 15°, it is proposed to work three seams or veins. State how you would open the slope, and fan way, and other openings, and how you would conduct your air current?

ANSWER.—I would sink a double track slope in the middle vein, as near the center of the track as possible. I would drive tunnels to the other veins near the inside end of the slope turnouts, one tunnel on each side of the slope. I would drive my fan way also in the middle vein, and use the slope for the downcast until I could get airways driven to the surface from each of the other veins. As soon as I could get this done, I would arrange my ventilation so as to draw fresh air into each vein through its own airway, and would split it so that each of the six main sections of the mine should have proportionally the same amount of air. I would also, if feasible, make the second outlet from the slope vein the downcast instead of the slope so as to prevent freezing the slope in winter.

QUESTION 13.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In which case in your opinion does the greater necessity exist for timbering, in a shaft sunk through measures pitching 70 degrees, or in a shaft sunk through the same measures pitching 5 degrees?

ANSWER.—In the shaft sunk through measures pitching 70°, because there is more likelihood of slips or slides in the various strata of rock, or mineral passed through.

QUESTION 14.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

When a mine is passing 20,000 cubic feet of air, with a pressure of four pounds per square foot, what will be the pressure when the mine passes 40,000 cubic feet of air per minute?

ANSWER.—The pressure varies as the square of the quantity, therefore

$$20{,}000^2 : 40{,}000^2 :: 4 : (\ ) \text{ or}$$
$$2^2 : 4^2 :: 4 : (\ ) \text{ or 16 pounds per sq. ft.}$$

QUESTION 15.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Describe the plan or system of mining at some colliery at which you have worked, and state how the same was ventilated?

This question must be answered according to individual experience and is intended to draw out the candidate's power of observation, experience, etc.

QUESTION 16.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Suppose you were approaching an abandoned mine, filled with water to a vertical height of 300 feet, vein or seam 30 feet thick and coal free. How much pillar would you leave to prevent the water from bursting in?

ANSWER.—At least 50 yds. In certain portions of the Anthracite region it is customary to leave line pillars of 20 yds. on each side of a land line (40 yds. in all) to protect the workings from floods or fires in adjoining collieries, but as the seam in this case is very thick, and the coal free it would be better to leave 50 yds.

QUESTION 17.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

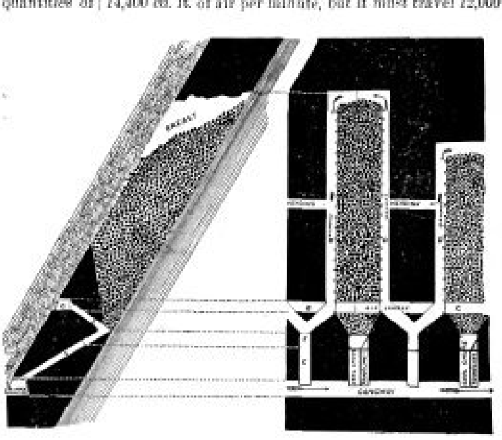
What are the duties of a mine foreman, and what should be the exten. of his knowledge to best fit him for the position?

ANSWER.—The duties of the mine foreman are to see that the process of mining is conducted in an economical and safe manner. To see that the ventilation of the mine is fully up to the requirements of the law, to enforce discipline in the mine, and to generally supervise the underground workings and secure the largest possible output of coal at the least cost consistent with safety to the employes. He should have a good practical knowledge of ventilation, the different systems of mining, should be able to keep his time book, etc., in a correct and legible shape, and he should possess sufficient executive ability to have all his orders obeyed without causing trouble among those of his subordinates who are too ignorant to understand why he wants certain things done contrary to the way they think they should be done.

QUESTION 18.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In a mine where the vein or seam is 30 feet thick, and pitching 50 degrees, and where large quantities of fire-damp are given off, state how you open gangways, chutes, headings, and breasts, and how you would conduct your air-current?

ANSWER.—In a vein of this character I would drive the gangway, along the top of slate, to give greater security to the gangway and also to allow the chute to be at such a grade as will permit the coal to be under the control of the loader in its passage from the breast to the wagon. I would drive the air course C, against the top above the gangway and connect it with the manways E E, between each breast, by the passages F F. When the breasts are in operation the air course or "monkey gangway" C, is not used, the arrows indicating the course of the air, the gangway, of course, being the main intake. The great advantage of this system is that it secures a permanent return for the air after the breasts are exhausted.



The coal made along the manways D, may be drawn from the manways E. The main chute, marked "coal chute," should be driven 9 ft. wide with a traveling, way on one side to allow a man to attend to the drawing of the coal. I would have a separate current for each section of four or less breasts, and would endeavor to prevent the coal "rushing," and thus liberate gas in larger quantities than the air current could safely cope with.

QUESTION 19.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

What system or plan of mining would you adopt where the vein or seam is inverted, and how would you sink the slope and make other openings?

ANSWER.—I would proceed the same as if the seam was lying in a natural position with a similar inclination, but as inverted seams are often faulty, I would be reasonably sure that it would be a paying operation before spending much money on dead work.

QUESTION 20.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

What in your judgment should be the difference in the thickness of pillars left to support the overlying strata of a mine between that of a 10-foot vein or seam and that of a 30-foot vein, and which should be the largest pillar on a pitching or horizontal vein?

ANSWER.—Approximately, the strength of pillars vary inversely as the square of the thickness of the seam, all things being equal. Then, as the square of the thickness of the thin seam is to the square of the thickness of the thick seam, so is the fourth power of the side of the pillar in the thin seam to the fourth power of the pillar in the thick seam, and the fourth root will, of course, be the length of the side.

Thus

$$10^2 : 30^2 :: 1^4 : (\ )^4 \text{ or}$$
$$100 : 900 :: 1 : (\ )^4 \text{ or } 9.$$

Then the fourth root of 9 is 1·732. Therefore the sides of the pillar in the 30-ft. seam should be 1·732 times the length of the sides of the pillar in the 10-ft. seam.

SPECIAL QUESTIONS AND ANSWERS.

By request we answer Questions 14, 18, 20, and 21, given at the Iowa Examination for Mine Inspectors, on April 9th, 1890.

QUESTION 14.—If a water-gauge shows a difference of reading of twelve inches between the intake and return of a certain portion of a mine, and the anemometer indicates a velocity of ten ft. per second, size of entries, 6 ft. × 8 ft. what effective horse power has been expended in that portion of the mine?

The difference of twelve inches in the reading of the water-gauge shows that to overcome friction a pressure of 12 × 5·2 lbs. or 62·4 lbs. per square foot has been required; and as the velocity is 10 ft. per second in an entry of 48 square feet sectional area there is a current of 10 × 60 × 48 or 28,800 cu. ft. passing. Then the rule to obtain the effective horse power is to multiply the pressure per square foot by the volume of air passing per minute and divide by 33,000.

Thus

$$\frac{62{\cdot}4 \times 26{,}800}{33{,}000} = 50{\cdot}7 \text{ — H. P.}$$

QUESTION 18.—In what part of a mine should observations with the anemometer be taken and why?

ANSWER.—Observations with the anemometer should be taken at the inlet and outlet airways, at or near the face of each main heading, and at the nearest heading to the face of the inside and outside chamber, where men are employed. That is, the reading should be taken at such localities as will give the velocity of the current in each split or section of the mine.

QUESTION 20.—In the section of the mine mentioned in Question 14, which we will designate as "Section A," the air travels 6,000 ft. of entry including return. In "Section B" of the same mine there is required 14,400 cu. ft. of air per minute, but it must travel 12,000 ft. of entry including the return, how would you arrange the regulator, or in what proportion would you split the air for these two sections to equalize the ventilation currents in them, size of entries in both sections the same?

ANSWER.—As both sections have the same sectional area and differ only in length, and the total volume of air passing is 26,800 cu. ft. (see Answer to Question 14) plus 14,400 cu. ft. = 41,200 cu. ft. The question resolves itself into the following:

Given two airways of equal sectional area, one of which is twice as long as the other, how would you split the air to ensure an equal current in each? The answer naturally is, by placing a regulator in the shorter airway. Now as to the size of this regulator. Most persons in calculating the size of regulators, use the rule to find the areas of airways of different lengths to pass the same amount of air. It must be evident to every practical man that this cannot be right, because a regulator is an obstruction and obstructs the free passage of the current suddenly. Its rubbing surface is entirely different from the rubbing surface of an airway. It is in fact simply a gate valve which regulates the flow of a fluid called air under a certain pressure, through an underground tube. The only way in which the correct size of the regulator can be determined is by experiment. If it is possible to equalize the current by making one air course longer, and the other shorter it is a much better plan than using the regulator, because the power necessary to overcome the resistance offered by a regulator to a current of air is a waste of energy, and every regulator placed in a mine means an expenditure of work that would otherwise be available for increasing the total quantity of air in the mine. Of course it is often impracticable to avoid the use of regulators, but when they can be dispensed with they should be.

In the case under consideration the regulator must offer a resistance equal to the resistance offered by the entire rubbing surface of "Section A," and it should be placed at or near the point where the current joins the main return current. If an approximate rule is necessary to find the size, the following will be as close as any:

$$\sqrt[3]{12{,}000} : \sqrt[3]{6{,}000} :: 48 : (\ ) \text{ or}$$
$$\sqrt[3]{2} : \sqrt[3]{1} :: 48 : 38 + \text{sq. ft.}$$

QUESTION 21.—How would the friction of the air current in "Section A" compare with the friction of the air current in "Section B."

ANSWER.—As both airways have the same sectional airway, and differ only in length, the frictional resistance before putting in the regulator would only be ½ as much in "Section A" as in "Section B." The use of the regulator is resorted to, to increase the resistance in "Section A" to an amount equal that in "Section B" which has twice as much rubbing surface.

Scientific Advancement

Vital Force—What Is It?

At a recent meeting of physicians and surgeons at Chicago, a paper was read by Dr. H. J. Treat, entitled: "Vital Force the Surgeon's Best Friend," upon which quite a lengthy discussion was held, from which we extract as follows:

Dr. Hasty thought the paper a most excellent one. Had no criticisms to offer, and but one query to make, and that was with reference to an "intelligent force" that has to do with the respective process in surgery or medicine. The vital force had been talked of as an intelligent independence or an independent intelligence, an independent entity, an intelligent entity, etc. He thought that the matter should be well considered, in order not to make ourselves ridiculous in the eyes of intelligent, thinking men and women. He did not for one moment question the existence of a vital force, but that it existed as an independent intelligence he did seriously question. Vital force in his opinion was a property of matter. He thought that Dr. A. Curtis was not far from the truth when he said that "whatever always exists in connection with matter, but has no existence without it, is called a property of matter." Inasmuch, therefore, as "vital force" always exists in connection with living matter, and has never been found to exist outside thereof, or independent thereof, it must be a property of living matter, and we can know nothing about vital force aside from living matter.

Dr. O. P. Fletcher queried: "What is vital force?" He had never yet heard it defined, and would like to know what it was. Had thought at times that it was intelligent. If you can find any force, not intelligent, that could bring together bones, muscles, nerves, blood vessels and all the various parts of this human machine, and put it in working order and maintain it in that condition 50, 60, or 100 years, he would like to know its name and to know more about it. In college he was taught to believe that chemical force was not to be thought of as producing any of the results witnessed in the animal economy. It seemed to him now that life could not exist without chemical action.

Dr. Pechuman remarked that our bodies are mysterious. Life and soul are used as synonymous terms by some. If the soul is the life, it is different from matter. The body is the house, the soul is the occupant. When life goes out, the house is left to decay. The bioplasm of plants and animals are, so far as can be ascertained by chemistry and microscopy, the same. Some of these bioplasts go to make bone, some form muscle, others form serous membranes, some skin, and so on through the whole body. When the man dies, his body is liken to Mr. Jones' house—empty—something has gone out of it. The house still contains all the elements that were found in it during life, but there is something gone. This something is not a property of matter, but, as he viewed it, an intelligence—a something separate from the living matter.

Dr. Treat concluded that we can tell what vital force is as well as we can what life is, as well as we can tell what electricity is, as well as we can tell what gravity is. They are all known by their effects upon matter. It is only a play of words to say it is a property of matter. We know it is independent by its effects.

Dr. W. A. Harris remarked that the question put him in deep water. If a bone be broken, the vital force goes to work to repair the injury and reunite the parts. It looks and acts like it was intelligent. As to its being independent, I have nothing to say. It seems to have power to resist chemical force.

In reply it was said: A tree gets bruised by the woodman's ax. The living matter, by virtue of the inherent force in it, heals the injury. Is there an intelligence there?

Dr. Treat says there is a force or forces that overcome vital force—if it were not so, we would not die. Vital force is limited in its capacity to resist chemical force.

Dr. Scroggy said if the process of digestion be chemical and there was no vital force to resist it, the stomach itself would be digested.

Dr. Pechuman said that many in the profession hold that all changes that take place in our bodies are due to chemical force, yet some of these thinkers are changing their minds in this respect. When the vital force leaves the body, the chemical forces go to work to decompose it. The natural heat of the body is produced by chemical action of changing fluids into semi-fluids—all chemical action is attended with changes of temperature.

Unsolved Problems of Chemistry.

So simple-looking a substance as the white of an egg is yet a most stupendous mystery to our science. It and all the albuminoids are awaiting this very light. The fever and pain, discomfort and delirium of disease are now known to be due, in many cases, to ptomaines manufactured by bacteria. They are believed to break down albuminous substances by aid of the ferments they secrete. We want to know the nature of these ferments. Until such knowledge is acquired we can not really say that we know how nitric or acetic acids, and all the nitrates and acetates, are made as common and cheap as they are. Micro organisms produce them. The bread problem of the future is believed to carry its solution in this same question.

From cellulose to starch is a very short step, but we can not take it in the proper way. By a crude process long known, sawdust can be converted into an exceedingly coarse article of bread, the catalytic body being sulphuric acid. We await the discovery of the proper organic contact action body to do perfectly what can now be roughly done. The world may yet see deal boards transmuted into the whitest kind of starch. We can and do now change starch into that kind of sugar called glucose. Let us next find how to make it into levulose, and then discover how to unite these two, and we will have cane sugar. Hundreds of chemists have worked at this problem. The man lucky enough to solve it has an enormous fortune awaiting him. We have lately found how to give cane sugar the flavor of maple sugar, so that, should the maple forests give out, the supply of that sweet morsel can still be maintained.

Among the many problems that still await solution, but that lie along the line we have been considering, is the synthetic production of such valuable substances as India rubber, cotton, silk, and wool. The possibilities of organic chemistry are numberless, and many of them may never be realized; but we have already the sweet consciousness of having mastered more than enough to pay for the disappointment of our alchemical predecessors who hoped to be able to convert iron into gold. But their dream, wild as it really was at that time, may yet become an established fact. No chemist would to-day risk his professional reputation by asserting it an impossible feat. Let some reliable man of good repute in this department of science assert that he had made such a discovery, and it would doubtlessly raise considerable skepticism, but that would be all. No one knowing the present status of the science would use the word "impossible." Reasoning *a priori* on the subject, we would expect that the cost of production would always exceed the value of the product. This is poor encouragement for this line of investigation. In the fields hitherto invaded and conquered the reverse has been true. Substances worth less than nothing—actually having a negative value because of being incumbrances that it cost cash to remove—have been and are being made into goods worth many millions of dollars. The actual facts, when stated in simple language, are more wonderful than the tales of the Arabian Nights. "Yes!" some one answers, "and the names found in the story are perhaps quite as remarkable as any in that volume." This is very true. To read of a substance that has been christened methyl-ethyl-hydroxyl-tetra-hydro-pyridine-tropate sounds anything but musical to the ears of non-chemists, especially when they learn that it is the dangerous medical poison atropine. Every syllable of this name has a meaning, and the whole tells just how the molecule is constructed. To say that rheumatic pains can be relieved by oil of wintergreen is a plain statement to ordinary mortals. Tell him such relief can be had by the use of methyl-ortho-mono-hydroxyl-benzoate, and you puzzle him sorely, though the things are the same.—*Dr. Robert G. Eccles.*

Useful Information

The "Holy Coat" of Treves.

On August 18th, of the year 1844, there was exhibited in the cathedral of the ancient city of Treves in Prussia, the most famous of all sacred relics—the "Holy Coat," a garment said to have been worn by Christ throughout His Passion, His trial before Pontius Pilate, and his agonizing journey to the spot where his crucifixion was carried out. Between the date mentioned and the sixth day of October, when the relic was again withdrawn from public gaze, over a million people, bishops, priests, and laity, visited the cathedral of St. Pierre and feasted their eyes on the sacred robe, for the most part with wonderment and veneration. On the 20th of August after an interval of exactly forty-seven years, the "Holy Coat" will again be exposed to the view of all comers, no matter what their creed, and by virtue of an edict issued by the Church through Bishop Felix, of the local diocese, remain so for a like space of time. The event, it is needless to say, has been for weeks and months awaited with the greatest interest by all true Catholics, not only of Germany, but of the whole Old World. During this period the influx of pilgrims and vistors into the old cathedral city has been daily increasing, until, from the latest accounts, their carriage and lodgement has become a serious question to the railroad authorities and the worthy burghers of Treves. No small proportion of these travelers consists of the sick and maimed, in whose minds is firmly riveted the idea that to touch or even look upon the sacred garment will insure a complete and instantaneous cure.

The history of this venerated relic—to the minds at least of those whose religion bids them venerate it—is plain and sufficiently well authenticated. It was obtained by the Empress Helena, mother of Constantine the Great, during her sojourn in the Holy Land, and presented by her on her return to Treves, then the capital of Belgic Gaul and residence of the Roman Emperors, to the cathedral of the city. This was during the episcopate of Agritius, and some time between the years 314 and 334. That the Empress did make some such gift is proved by an ancient ivory, for centuries in the possession of the cathedral, which represents her seated at the church door awaiting the arrival of a procession closed by a chariot in which two ecclesiastics are standing on guard before a chest containing some precious gift. The ivory was carefully examined and its legend substantiated by the Archæological Society of Frankfort in the year 1846.

At the close of the twelfth century the Holy Coat was translated from the choir—its first resting-place—to the high altar of the cathedral, and, after an interval of three hundred years, was exhibited "for the veneration of the faithful" in 1512. During the wars and stormy times of the seventeenth and eighteenth centuries it was deposited for security first at the castle of Ehrenbreitstein, and later at Augsburg. From this latter hiding place it was removed in the year 1810 by special permission of the first Napoleon, and restored with great ceremony, to the cathedral of Treves then, and until the treaty of 1815, a French possession. In spite of the chaotic troubles through which all Europe was then passing, over 227,000 pilgrims journeyed to the city to celebrate the restoration of the relic.

The exhibition of the Holy Coat in 1844 left a mark, and almost an indelible one, upon the history of the Roman Catholic Church. The excitement caused by the pilgrimage of a million souls to one small Prussian town was as nothing compared with subsequent events which arose solely from the action of the Church in allowing the relic to be displayed and worshipped. Certain members of the Church, stigmatized then and now as rationalists, took offense at the proceedings, and argued in writing not only against the authenticity of the Holy Coat, but against the advisability of thus working upon the feelings and credulity of such vast numbers of their fellow-religionists.—*A. C. Townsend, in Harper's Weekly.*

How Much a Knot is.

How much is a knot? This question is asked, we believe, in every sea passage by some passenger or other, and never meets with a clear reply. Sailors themselves do not describe it distinctly, and books of reference differ as to its dimensions.

A knot is one-sixtieth of a mean degree of the earth's meridian. This definition requires explanation and also numerical computation. The earth's meridian is commonly described as any circle whose center is the center of the earth and whose circumference passes through the poles. This is not exact, because the meridan is not a true circle.

Evidently, it would be a true circle if the earth were a true sphere, but the earth is not a true sphere—it is a spheroid, its diameter measured on the axis being less than its diameter at the equator. Hence the circumference of a section of the earth by a plane passing through its center and the poles, which circumference is a meridian, is not a true circle, but an oval. Bearing this in mind, it will be easy to understand the meaning of a mean degree of the earth's meridian.

If 360 separate degrees be set off from the center of a perfect circle it is evident that the circular measure of each degree measured on the circumference of the circle will be the same. But if they be set off from the center of the oval the measurements on the circumference of an oval will not all be the same. That this is the case any one may demonstrate for himself by drawing an oval and its minor axis, and then, from the center of the oval, with radius equal to its semi-minor axis, inscribing a circle in the oval. If, now, degrees, or rather, for convenience, equi-multiples of a degree, be set off from the common center the geometry of the figure will show at once the variation in the circular measurements on the circumference of the oval.

Now, a mean degree of the earth's meridian is the average length of these 360 unequal measurements, and it is obtained by dividing the length of the meridian by 360. Astronomers have measured the earth's meridian and found it to be 131,259,287 English feet.

Dividing this by 360 we get 364,609·13 feet as the length of a mean degree of the meridian. One-sixtieth of this, then, is a knot, and thus by division a knot is found to be 6,076·818 feet, or 2,025·6 yards, or 1 mile 265·6 yards.

It will now be convenient to notice that a knot being 6,076·818 feet, and a mile being 5,280 feet, the proportion of a knot to a mile is very nearly as 6,076 is to 5,280, or dividing by 4 as 1,519 is to 1,320, which is very nearly as 15 to 13. So that for ordinary purposes knots may be converted into miles by taking thirteen knots as equal to fifteen miles, and *vice versa.*—*Chamber's Journal.*

Money Getting.

Some people think that it is necessary to be mean and miserly in order to become wealthy. There never was a greater mistake. Any man of common intelligence may be prosperous if he chooses to labor diligently and faithfully in a calling which he thoroughly understands. Of course, prudence is indispensable to success—*prudence* mind, not *niggard meanness.*

The man who, commencing with little or nothing, has resolved to rise, must also resolve to sacrifice nothing to appearance. He cannot gain one true friend, nor obtain any popularity that will be really useful to him in his efforts to achieve independence, by endeavoring to *seem to have* that which he has not. The world is shrewder than pretension supposes it to be. It is a curious world—looks sharply into people's private affairs, and if an individual makes a show beyond his means, soon discovers and distrusts him.

No one who has a fortune to make, or who desires to receive even a moderate competence, can afford to incur the world's distrust. Therefore if you are at the foot of the ladder and want to mount, go up in your work-day guise and don't affect purple and fine linen.

Climate and Morals.

The world is tolerably well mapped out as to diseases. The colored charts show us where we may most probably dwell with malaria, with consumption, or with general debility. We study also the adaptability of plants to different climatic conditions. But our knowledge of the relation of man to climate is still far from scientific—that is to say, of the influence of climate upon character and conduct. To come to a detail, what, for instance, do we know of the effect of climate upon veracity? There are portions of the earth's surface where the inhabitants regard truth as a luxury seldom to be indulged in; in others the mind seems rather inclined to truthfulness. Whether the difference is owing to race or climate our observations do not yet enable us to determine. There is a popular notion that the habit of prevarication goes along with warmth, or with a debilitating atmosphere, and that cold is a tonic, a sort of stimulant for truthfulness. We indeed have in the phrase: "the cold truth," a recognition of this. "We say that the northern latitudes nurse the rugged virtue of veracity. It never occurs to us to expect veracity in Egypt, nor in any part of Africa. We should never think of saying that an inhabitant of Malta was untruthful; we should simply say that he was a Maltese. The name Levantine carries with it the same idea. The Levantine, the African, the Oriental habit of indirection is sometimes explained by the amiability of the people, their desire to say that which will be agreeable. Whereas the Englishman prides himself on his blunt honesty, and on speaking the truth, especially if it is disagreeable. But plant the Englishman, or any man whose moral fiber is hardened by a frigid climate, in Egypt, and how long will he continue to speak the truth? How is it about the northern travelers in Africa, who never argue with each other about anything, and habitually accuse each other of misrepresentation? Is this due to climate, or to the contagion of a bad moral example in an atmosphere of duplicity?—*Charles Dudley Warner, in the Editor's Drawer, in Harper's Magazine for July.*

The Arrangement of the Cellar.

When the housekeeper has bought, built, or hired her house, after due consideration of the family needs and tastes, and after careful examination of the locality and construction of the chosen home, her earliest attention should be directed to the cellar, as that part of the home which is most often neglected, and where order and convenience combined add no small amout to the comfort and healthfulness of all parts of the house.

The arrangement of the cellar takes time and attention rather than any great outlay of money. The windows should first be seen to. A stuffy, unventilated cellar, full of dead air, is an abomination. The windows should be so hung that they can be removed from the inside, and during all but the extreme winter months should be taken out, and even in mild days they should be opened in the middle of the day. The outside of the windows should be protected by galvanized wire window-netting, costing two and a half cents the square foot. A heavier, coarser-meshed quality can be used instead, if great strength is desired. This quality costs six cents the square foot. The hatchways of the city houses are troublesome in cold weather. Both the rear and front hatchways admit a great deal of wind during the winter, in spite of the wooden covers that are fitted to them, and make the kitchen and dining-room floors draughty and cold. This can be remedied by covering the iron grating over each hatchway with several folds of old carpeting or furniture sacking, and then fitting the cover down tightly. The hatchway on the sunny side of the house must be frequently opened for air. The cellar ceiling and walls should be thoroughly whitewashed, two heavy coats being enough.

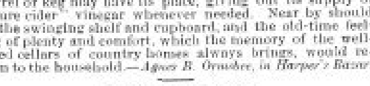
All city cellars, and many in the country towns and villages are cemented, which under most conditions is the safest and cleanest flooring. But in the country, where the ground is not poisoned from leakages of sewers or the foul gases of cesspools, and where yet farther, the ground is dry and sandy, a cellar bottom of well-beaten earth is not unwholesome, and has a mysterious capacity for keeping fruits and vegetables beyond that of cemented cellars. Such a cellar should have boards for walks to bins, barrels, and cupboard, to keep the house-mother from fretting over the dirt "tracked up." If these boards are occasionally turned over when swept, there will be no trouble from dampness or "saw bugs." Raising them up slightly from the ground by inch cleats nailed to the under side of the boards is another and better method.

In a cellar where there is a furnace it is a great help to household management to have a portion of the cellar divided from the furnace portion by a tight board partition, with a padlock door opening into it. The boards used may be rough and cheap, costing two cents a foot; but the partition must be tight, so as not to admit the warm air from the furnace. Under ordinary circumstances the expense need not be over ten dollars, and in many cases even less.

In this cold cellar the vegetables and apples, butter and preserves, may be kept, and even in the city, the uncomfortable habit of living from hand to mouth might be changed to a great degree. Here the time-honored vinegar barrel or keg may have its place, giving out its supply of "pure cider" vinegar whenever needed. Near by should be the swinging shelf and cupboard, and the old-time feeling of plenty and comfort, which the memory of the well-filled cellars of country homes always brings, would return to the household.—*Agnes B. Ormsbee, in Harper's Bazar.*

Scientific Paradoxes.

The water which drowns us—a fluent stream—can be walked upon as ice. The bullet which, when fired from a musket, carries death will be harmless, if ground to dust before being fired. The crystallized part of the oil of roses, so grateful in its fragrance, a solid at ordinary temperature, though really a volatile, is a compound substance containing exactly the same elements, and in exactly the same proportions, as the gas with which we light our streets. The tea which we daily drink with benefit and pleasure, produces palpitations, nervous troubles and even paralysis, if taken in excess; yet the peculiar organic agent theine, to which tea owes its qualities, may be taken by itself—as theine, not tea—without any appreciable affect.—*The Age of Steel.*



Electricity in Mining Operations in England.

Several years have passed away since electricity was first used in connection with coal mining in the United Kingdom, that occasion being, if we remember rightly, the erection of an underground electric pump in the Forest of Dean. Since then, this particular application has been slightly extended, and electric lighting, electric haulage, and electric coal-cutting machines have been introduced. The extent to which electricity has been adopted for these various purposes has, however, been very restricted and has not answered the expectations of either those who wish prosperity to the industry generally, or of those firms which undertake the supply of electric mining plants. At the present time, the number of installations or applications of electricity to different mining purposes in the United Kingdom is probably not more than fifty. Out of these, no less than twenty-eight are electric light installations in mines located in the South Wales district. In these twenty-eight instances, 1,171 fixed incandescent lamps are in use, and the greatest distance lighted is 365 yards from the bottom of the shaft.

What a contrast the great mining districts in the United States present! There electricity has come into very extensive use for: (1) drilling in rock and ironstone; (2) in under-cutting coal, the system of using a series of rotating drills being looked upon with most approval; (3) locomotives hauling underground; (4) pumping water from dip working to the shaft; (5) raising coal in cages of ordinary capacity, or by smaller machines in kibbles; (6) lighting the mines, etc. Remarkable, indeed, is the enormous development which has taken place in the use of electricity for these purposes, and the substitution of electrical for steam, compressed air plant, which process is going on continually, shows conclusively that the American mine owners have learned that electricity is not only more economical, but that it can be adapted to perform work in those parts of a mine where any other agency would be inadmissible. Why has not a similar development taken place in the United Kingdom, and are there any theories which can be advanced to explain the cause of the slow rate of progress made in this country? The answer is in the affirmative.

The first reason is the natural aversion of mine owners to adopt anything new; and the second is that they do not generally feel disposed to incur expense in making experiments with small plants; and the third—which is the most important—is that they object or rather many of them do, to the use of electricity as being unreliable. We will take it for granted that the first two reasons will be generally admitted, but the third may be considered as a bare statement, without any foundation in fact. Let us see whether such is the case.

If reference be made to the proceedings of the various societies of which the mine owners, managers, and engineers are members, it will be found, when the subject of electricity is brought forward, that the majority of the speakers express the opinion that that agency is unreliable and no matter whatever an electrical engineer may say, in order to endeavor to prove that such is not the case, the impression that electricity cannot be depended upon still remains in their minds. Take, for instance, the recent meeting of the Federated Institution of Mining Engineers, and the discussion which followed the reading of the paper descriptive of an electrical safety apparatus for cages. One of the speakers, in order to try to show the unreliability of electricity, stated that he had a telegraphic apparatus which got out of order every week, whilst another said that batteries were always "going wrong," and so forth. After these damaging statements had been made, the efforts of the author of the paper to remove them seemed to be of no avail. Now, the Federated Institution, although a young society, consists of many gentlemen who have been engaged in coal mining for over thirty years, and it is becoming, if it is not so already, the most important mining institute in the kingdom. Consequently, the opinion of the members may be taken as fairly representative of the feeling throughout mining circles in the country.

It is this wrong impression—this impression as to the unreliability of electricity in mining operations—that electrical engineers interested in mining plant must endeavor to remove, and until such an effort is energetically made, the adoption of electricity in the future will proceed but slowly, as in the past. What would doubtless have a good effect on mine owners, would be the collection of data regarding each application that has been made in this country, data giving the cost of installation and of working, comparisons with previous methods employed, and general results of working. Figures dealing with these points, and coming from those mines where electricity has already been adopted, would be more convincing than all the arguments in the world; they would not only remove the "unreliability" objection, but would doubtless greatly increase the trade in this branch of the electrical industry.—*London Electrical Review.*

Electricity in the Orient.

The dreamy and slow-going populations of the Orient, in sympathy with their Western brethren, are beginning to utilize the wizard-like power of electricity in the world of industry and the sphere of private and public illumination. Its practical utility for power purposes is being demonstrated by frequent experiments of societies formed for that purpose, and the reports of their investigations are being received with much favor by many who hitherto have been arrayed against the introduction of the new improvements and practices developed by our more progressive civilization.

The city of Tokio, Japan, now has a telephone exchange, in charge of the government, which has 329 subscribers, and is in a very prosperous condition, and Yokohama also has a similar institution liberally patronized and daily increasing in the popular favor of the people.

The empire of Japan has made rapid strides in the march of progress in the past few years and the traveler from America finds himself quite at home among the rising generation, which seems to have caught the modern fever for rapid transit in no slight degree.

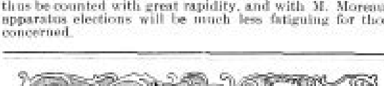
There is a tower in Tokio in which the tourist is carried skyward on an electric elevator, the current being furnished by the Tokio Electric Light Company, and the motor used is of the Sprague type, 10-horse power capacity.

At two or three different places in the Empire experimental works are in operation for refining copper by electricity, and the results thus far are said to be highly satisfactory.

On the whole it is plain that our Oriental kinsmen are no longer in the rear of the parade and their supplies of electrical appliances will no doubt be drawn in a very large measure from the United States.—*Industrial World.*

A New Electric Voting Apparatus.

We have inspected, says the *Independance Belge*, at the Brasserie Flamande, the voting machine invented by M. Moreau, of La Louviere. This machine presents precisely the appearance of a small piano or harmonium. As keyboard there is a series of buttons on which the elector must press to record his vote. The names of the candidates are classified by list. To each name a button corresponds. M. Moreau proposes to place the candidates' photographs opposite their names, so that the illiterate would know for whom they were voting. Under the keyboard is a cupboard, the case of the machine, in which is enclosed a tell-tale. Each button has its tell-tale, which registers the votes in units, tens, hundreds, and thousands. The electric batteries are placed under the case in place of the pedals. To approach the instrument the elector must get on a small rostrum, which suffices to establish the electric current, and he can then vote. The essential of this invention consists in the distribution of electricity. M. Moreau has succeeded in regulating the machine according to the number of votes to be recorded by the elector. If the complete list of candidates is five, the instrument is regulated in such a manner that each voter cannot record more than five votes. It is equally impossible for him to press twice on the button. To do that he must descend and get up again after the lapse of a few seconds. The rostrum, however, is to be made very large, and the presiding officer will see the elector the moment he gets up and also when he descends. No fraud is possible in this direction. We have omitted to say that the machine is naturally protected by a partition. The apparatus permits of the lists being supplied in different colors. There is a button on which the elector must press to obtain a white paper. This button produces the same ringing as the others. Secret voting is thus absolutely ensured; moreover, a number of electricians and skeptics have already been to see the machine, and all, or nearly all, have recognized its practical use. For our part, concludes our contemporary, we have questioned the inventor on a number of points, and all doubts vanished before the precise answers and conclusive experiments. The tell-tale cupboard will be naturally closed at the commencement of operations. When the election is finished it will be opened and the presiding officer will have nothing to do but to take down the figures given by the tell-tales. An election will thus be counted with great rapidity, and with M. Moreau's apparatus elections will be much less fatiguing for those concerned.



The Habit of Washing.

No practice, however long established, has ever been allowed a permanent right to respect. Sooner or later its turn will come to be weighed in the critic's balance, and its quality will have to be proved. Let us quote as a recent illustration, the habit of daily bathing, the utility of which has of late, though not for the first time, been seriously questioned.

The reasonableness of doubt in such a matter, and under ordinary circumstances, does not, we confess, commend itself to our judgment. Whether the opponents of ablution fear the shock of cold immersion, or whether they dread the cleansing stimulation thus applied to the excreting skin surface, their objection must appear to most persons possessed of ordinary health and vigor to threaten impairment of both by fostering uncleanliness. If, on the other hand, it is the too free application of heat by Turkish and other warm baths which appear objectionable, we do not deny that there is here a possible ground for complaint. Let it not be supposed that we ignore the curative influence or the cleansing property of this method when used with judgment. It is true, however, that experience has often proved the mischievous effect of its misuse—in cases, for example, of cardiac weakness or general exhaustion. Cold bathing in like manner is not without its occasional risks. It is not suitable for persons enfeebled from any organic cause, though mere nervous languor is often braced and benefited by it. It has no proper places among the habits of those who are subject to chronic visceral congestions. As regards one advantage derived from bathing—*i. e.*, its cleansing property—there is no reasonable ground for difference of opinion. Less practiced by one people than another though it may be, there still is commonly recognizable a constant habit of ablution, and this fact in itself attests at least an almost universal belief in the necessity of insuring cleanliness by means of washing. Nor can we find reason to doubt the general soundness of this belief. In bathing temperature is of course a chief consideration. For the robust, cold immersion followed by rapid friction is a valuable tonic of nerve, skin, and heart function. For less vigorous constitutions—those, for example, which have been tried by disease, and those of young children—the addition of heat up to temperate point is only judicious. With some persons a warm bath is a daily luxury. Notwithstanding its efficacy as a means of cleanliness, however, this custom is or ought to be discredited by its inevitable action as a nervous depressant, which places it in an unfavorable position compared with the more bracing practice of cold affusion. The benefit derived from bathing, therefore, is likely to assert itself in spite of all adverse criticism, and its mismanagement, which is only too common, should not be suffered to condemn it in the eyes of any judicious and cleanly person.—*Lancet.*

To Make Good Coffee.

"It is quite astonishing that so few persons really know how to make a good cup of coffee," said the master of the house, making a wry face over the thick, muddy fluid which the new cook had served for breakfast. "And it is so simple," he continued, "any one could make it. When I was a bachelor and lived in rooms, I always made my own coffee, and I never failed. Here is my formula, if you like to have it for your new cook, who, I must say needs a hint or two. It is better, of course, to grind your own coffee, as then you are sure of having it good, but I never cared to take the trouble or the time myself. Put the ground coffee in the coffee pot, the quantity being regulated according to the number of persons; a family of six would require about a teacupful. Add half a pint of cold water and one raw egg, but do not put in the shells, as many ignorant cooks do, considering that the broken bits have a peculiarly clarifying power. Stir all well together, add one quart boiling water and let the whole boil for fifteen minutes. While still boiling pour in half a cup of cold water, and put the coffee pot on one side of the stove where it will not boil, and let it stand for several minutes. Coffee made in this manner will be found clear, strong, and free from 'grounds'."—*New York Tribune.*

Apples as Medicine.

Chemically the apple is composed of vegetable fiber, albumen, sugar, gum, chlorophyll, malic acid, gallic acid, lime, and much water. Furthermore, the German analysts says that the apple contains a larger percentage of phosphorous than any other fruit or vegetable. This phosphorous is admirably adapted for renewing the essential nervous matter, lethicin, of the brain and spinal cord. It is, perhaps, for the same reason, rudely understood, that old Scandinavian traditions represent the apple as the food of the gods, who, when they felt themselves to be growing feeble and infirm, resorted to this fruit for renewing their powers of mind and body.

Also, the acids of the apple are of signal use for men of sedentary habits whose livers are sluggish in action; these acids serving to eliminate from the body noxious matters, which, if retained, would make the brain heavy and dull, or bring about jaundice, or skin eruptions and other allied troubles. Some such an experience must have led to our custom of eating apple-sauce with roast pork, rich goose, and like dishes. The malic acid of ripe apples, either raw or cooked, will neutralize any excess of chalky matter engenerated by eating too much meat. It is also the fact that such fresh fruits as the apple, the pear, and the plum, when taken ripe and without sugar, diminish the acidity in the stomach rather than provoke it. Their vegetable salts and juices are converted into alkaline carbonates, which tend to counteract acidity. A good ripe raw apple is one of the easiest of vegetable substances for the stomach to deal with, the whole process of its digestion being completed in 85 minutes.

Gerard found that the "pulpe of roasted apples mixed in a wine quart of faire water, and labored together until it comes to be as apples and ale—which we call lambswool—never faileth in certain diseases of the raines, which myself hath often proved, and gained thereby both crownes and credit. The paring of an apple, cut somewhat thick, the inside whereof is laid to hot, burning, or running eyes at night, when the party goes to bed; and is tied, or bound to the same, doth help the trouble very speedily; and contrary to expectation—an excellent secret."

A poultice made of rotten apples is of very common use in Lincolnshire for the cure of weak or rheumatic eyes. Likewise, in the Hotel des Invalides, at Paris, an apple poultice is used commonly for inflamed eyes, the apple being roasted and its pulp applied over the eyes without an intervening substance. A modern maxim teaches that—To eat an apple going to bed, the doctor then will beg his bread.—*London Hospital.*

What is Education?

In order to be successful in active life a man must have a working knowledge of three things:

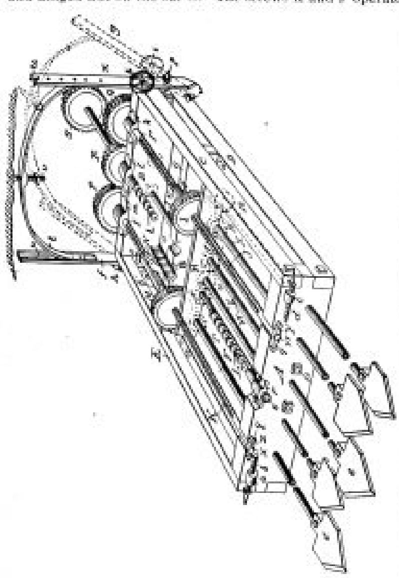
1. Human nature.
2. The practices in vogue among his neighbors.
3. Logic.

Whatever study or mental exercise or discipline teaches him the most regarding these matters is the best practical education. This practical education must be supplemented by special training in the prerequisites of that particular vocation in life which he is to follow.

Other things being equal, a large school or college affords a better education than a small one, for the reason that it gives to each student a larger opportunity to observe human nature and the customs of his neighbors. The mere information obtained by studying text-books is in itself ordinarily of very little value compared with the whetting which it gives to the mind, and when the mind is once sharpened it should be so turned as to learn from the world of to-day, if the student wishes to be in the world and of the world. Should he show a fondness for studying politics and a wish to enter public life, a comprehension of American democracy is of more value to him than a knowledge of Athenian democracy. Should he decide to enter business, knowledge of human nature and business practices is of equal consequence with logical nicety of calculation—an important result of studying the classics—however valuable this last may be. This fact explains why it is that those valedictorians who do not join in the general life of their college class and who devote themselves entirely to the text-books, are frequently outstripped in public life, law, and business by classmates who stood a grade or two lower in scholarship. These latter give a portion of time to observing their environment, while valedictorians of the kind mentioned take all their views from books, and are consequently less self-reliant.

MINING MACHINE.

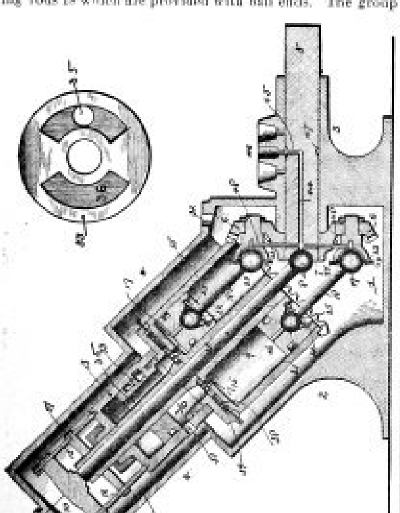
No. 451,988. Isaac Wantling and James T. Johnson, Peoria, Ill. *Patented May 12, 1891.* A gang of rotary cutters *e e* are set so close that the cut of one overlaps that of the next. These cutters are fastened to suitable shafts which are turned by spur pinions (shown by dotted circles) carried in the sliding-head H G. The pinions are driven by gears M I, which are carried on long screws K and J. Both screws have a keyway cut from end to end, and the gears K and J are turned by feathers running in these grooves. The screws work through nuts which are divided and hinged on the bar G. A course pitched screw L (shown broken away in the middle) also passes through a divided and hinged nut on the bar G. The screws K and J operate



as feed-screws to drive forward the head G H with the boring bits *e e*, and at the same time convey the power to rotate the cutters. The screw L operates only as as a return feed. When the machine is boring and the head G H is feeding forward the nut on L is thrown open, as shown. When running back the nut on L is closed, and those on K and J are opened. The sliding head is guided in slots in the side frames. Spur points *a e o p* are provided at the corners of the frame, and an adjustable brace *f t z* serves to firmly anchor the machine when at work. Small truck wheels are attached to the brace to help in moving the machine from place to place. By turning the frame up on edge, vertical cuts are readily made.

ENGINE.

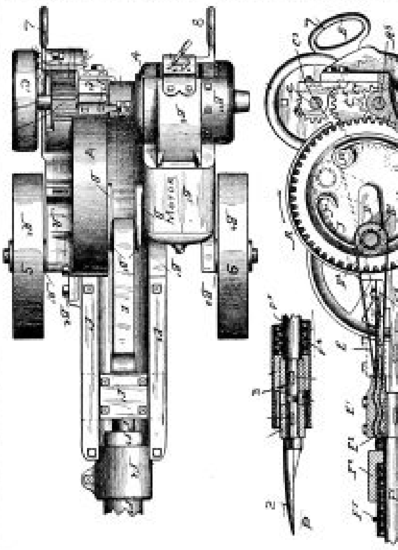
No. 453,862. Robert C. Berry, Lafayette, Indiana. *Patented June 9, 1891.* A number of single-acting steam cylinders are grouped around a central shaft 9, and the several pistons are connected to the crank disc 6, by connecting rods 18 which are provided with ball ends. The group



of cylinders revolve with the shaft 9, in unison with the crank disc, the two being connected by bevel gearing, as shown. The pistons are driven outward by the steam or compressed air during the downward half of the revolution, and during the upward half the crank drives them back to the inner end of their cylinders. A stationary circular valve 33 located within the stationary steam chest 13, bears against the cylinder head, and controls the admission of steam through the port 35, and the exhaust through the ports 36 and 31. Between the end of each separate cylinder and the head 30 is a small "grid-iron" slide-valve. These valves are forced toward the center shaft by coiled springs 38, whose tension can be adjusted by the set screws shown. As the cylinders revolve, these valves are thrown outward by centrifugal force, and throttle the opening into the cylinders, thus operating as governors. All the working parts are enclosed in the casing shown, and the internal friction of the engine appears to be unusually small. There are no dead centers, and it runs equally well in either direction. The movement can be reversed by turning the valve 33.

MINING MACHINE.

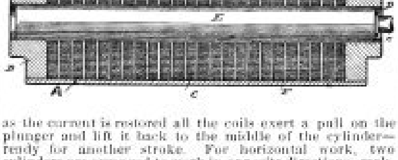
No. 454,500. Elmer A. Sperry, Chicago, Ill. *Patented June 23, 1891.* This machine employs a reciprocating pick 2, which is keyed into a collar 3, which is keyed to the sliding bar F^3 and slides inside the guide tube F^6. The bar and pick are thrown forward against the coal by a heavy coiled spring F^4 coiled within the guide tube and bearing against the collar 3. The pick is drawn back and the spring compressed by means of a strap pitman E which is attached to the cross-head E^1 and E^2. The pitman is provided with a bushing D^1 filled with balls or rollers where it bears on the crank pin of the crank D. This crank is double, and



the crank shaft consists merely of short trunnions which bear loosely in sockets in the center of the spur-wheel C^8 and in the field magnet B^2 of the electric motor which drives the machine. The armature 4 of the motor is attached to the shaft C^5, and the speed is reduced, and the power is conveyed to the driving-wheel C^8 by the spur-gearing shown. The driving wheel carries a strong curved spring J which is hooked at J^1 in such a way that it catches the crank pin (which extends through one side of the crank) as the wheel revolves, and carries the crank around with it, in the direction shown by the arrow. Soon after the crank passes the back center, or approaches the position shown in dotted lines, the spring F^4 throws forward the bar F^3 and pick 2 and causes the crank to jump to the position shown, where it stands until again picked up by the hook J^1 on the revolving driving-wheel C^8. The machine is mounted on two loose wheels 5 and 6, and is pushed into the cut and held up to its work by means of the handles 7 and 8, which are grasped by the operator. The fly-wheel C^1 and spur gear C^9 are attached to their shafts by spring couplings, which are intended to ease off the shocks caused by the violent motions of the pick and bar. A rubber collar F^7 is also placed between the crosshead E^2 and the front end F^2 of the machine frame for the same purpose.

ELECTRO-MAGNETIC RECIPROCATING ENGINE.

No. 450,543. Charles J. Van Depoele, Lynn, Mass. *Patented April 14, 1891.* This is a new arrangement of the coils composing the "cylinder" of reciprocating apparatus suitable for rock-drills, etc. The outer casing is a heavy tube of A iron closed at the ends by iron heads B. The coils C of insulated copper wire (shown in cross-section) are separated by iron discs F which act as inward extensions of the magnetic casing A, when an exciting current is run through the coils. By this means the magnetic pull of the coils tending to draw the iron plunger E to the center of the cylinder (the position shown) is greatly increased. When the current is interrupted, the plunger E which carries the drill rod, will fall by gravity, and as soon



as the current is restored all the coils exert a pull on the plunger and lift it back to the middle of the cylinder—ready for another stroke. For horizontal work, two cylinders are arranged to work in opposite directions, making the plunger double-acting. The plunger E is of such length that it can close the magnetic circuit between the heads of the machine, and in this position the plunger is capable of sustaining a great weight with a very small amount of current passing through the motor-coils. The main feature of the present invention consists, as before stated, in employing the magnetic extensions between the iron envelope of the machine and the moving piston, and this may be availed of in a very great many ways.

LIQUIDS FOR SEPARATING METALS FROM GANGUE.

No. 454,116. Joseph S. Lurie, Kansas City, Mo. *Patented June 16, 1891.* After the quartz has been passed through the stamping mill or crusher it is passed into a vessel containing water and a liquid which is insoluble in water, which is of greater specific gravity than water, and which is also of greater specific gravity than the quartz, but of less specific gravity than the metals mixed with the quartz. It will be seen that the quartz will float with the water on the surface of the liquid, which is of greater specific gravity than the quartz and water, and that the metal that has been held by the quartz until the same has been crushed will be precipitated through said liquid. Any desired number of troughs and screens may be used to grade the materials. Four liquids are made, called No. 1, No. 2, No. 3, and No. 4. The inventor thus describes his processes: "Liquid No. 1 is obtained in the following way: By the action of bromine on alcohol I get a fluid which by distilling at a temperature of 280° Fahrenheit is decomposed into two parts, one of which remains in the retort and the second is distilled over into the receiver. The fluid which remains in the retort is taken out and decomposed by a caustic alkali, forming a bromide of the alkali and a heavy fluid at the bottom. The last named fluid, being carefully washed and of a specific gravity of nearly 4, constitutes my liquid No. 1. For the liquid No. 2 I use the tetrabromethane ($C_2H_2Br_4$) mentioned in any extensive chemistry; but I take care that if the liquid is prepared with acetylene the acetylene should be obtained in a perfectly pure state. Liquid No. 3 is made as follows: In preparing liquid No. 1 I receive a part which is distilled over into the receiver. This liquid is separated from the water which is on top of it, and combined with pure acetylene is changed into a liquid of a specific gravity of about 2, thus forming my liquid No. 3. Any methyl-propyl-benzene or cymene being dissolved in alcohol gives my liquid No. 4. These four liquids can be combined by two, three, or all together in the proper proportions to give a mixture of a specific gravity greater than any quartz or gangue but of less specific gravity than the metals therein contained.

"It is obvious that in treating the quartz the proportions of the various liquids must be regulated according to the specific gravity of the quartz being treated. Consequently I do not confine myself to any specific proportions of the same. The following proportions which I have used in the treatment of the following ores will enable any one skilled in the art to perform the same.

"In treating carbonate ore of 1·8 specific gravity I use one-half part of liquid No. 1, two parts of liquid No. 2, one part of liquid No. 3, and one-half part of liquid No. 4. In treating white quartz ore of 2 specific gravity I use one part of liquid No. 1, two parts of liquid No. 2 and one part of liquid No. 4."

It will be seen that the liquid employed is a non-metallic and a non-mixing one—that is to say, it will not unite with the metals to be operated upon.

ROCK DRILL.

No. 454,228. Edward A. Rix, San Francisco, Cal. *Patented June 16, 1891.* The front cylinder-head I is made in halves and is clamped together by bolts J. The back head R is held in place by a stout spiral spring S which is confined by a yoke P. This yoke is connected by long bolts M to the front cylinder-head I, so that the spring acts to keep both heads in their places. If the main piston E strikes either head they are free to yield and thus avoid breakage. The spirally grooved rod H and the ratchet *s* are very similar to those commonly used for turning rock

Fig. 2

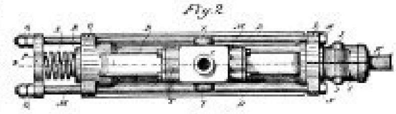


Fig. 1

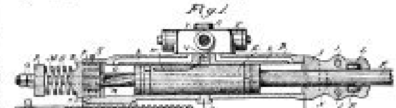

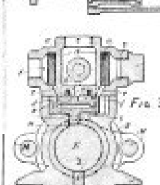

Fig. 3

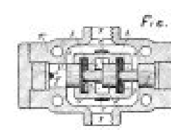
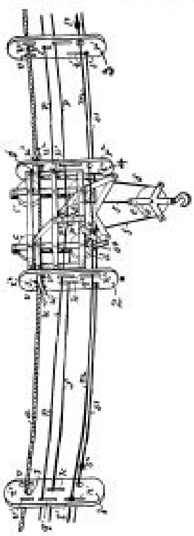
Fig. 4



drills. The point of the set-screw *g* works in a groove in the loose cylinder-head R and keeps it from turning. The main valve U is a piston valve which is clearly shown in Fig. 4, which is a section through the steam ports Y. Small ports *y* extend to a small supplementary valve V, shown in Fig. 3, which moves crossways of the main cylinder and controls the movement of the main valve. The small valve V is moved by a lug which projects into the main cylinder and enters the long cam groove W in the main piston. The body of the piston is kept from turning by a feather 3. The cylinder B slides on the frame A in the usual manner.

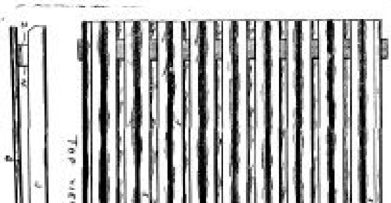
LIFTING AND CARRYING APPARATUS.

No. 447,892. THOMAS S. MILLER, NEW YORK, N. Y. *Patented March 10, 1891.* The trolley runs on the stationary cable *a* which is stretched between two towers or masts. The rope *f*, is the fall rope, one end is secured to the block *e*, and it passes over sheave d^1, then to the block sheave c^1, then over sheave *d*, to the left-hand tower where it is operated by any approved windlass. The trolley is held in its place along the cable *a*, by the rope *p*, which is fastened to the trolley at p^1 and runs to the right-hand tower, where it passes around a proper sheave, and returns to the left-hand tower where it is operated by a second windlass located in the same frame as that which controls the fall rope *f*. Hoisting is performed by locking the drum holding rope *p*, and then hauling on rope *f*. The load is carried to the left by hauling on rope *f* and simultaneously paying out rope *p* an equal amount, and movement to the right is effected by paying out *f* and hauling on rope *p*. The operating ropes *f* and *p*, are prevented from undue sagging by wooden hangers 1, 2, 3, 4, etc., which are strung on the main cable *a*. These hangers are spaced by ropes s^1 and *m*, which are provided with stop balls of varying sizes. The holes in the hangers for the passage of ropes s^1 and *m*, are also of varying sizes, and each stop ball will engage only that hanger which it cannot pass. The hangers are prevented from sliding upon and chafing the main cable, by means of horns *n*, n^1, and n^2, n^3 on the trolley, which pick up the hangers, lifting them clear of the cable, and carry them until they are pulled off by the stops on the stop ropes s^1 and *m*.



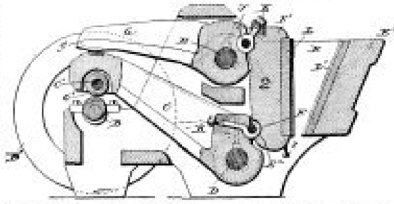
SLATE PICKER.

No. 454,393. EDMUND A. BARTL AND JACOB C. BOWMAN, SCRANTON, PA. *Patented June 16, 1891.* This picker is composed of a series of angle-iron bars 3, placed with the angle upward as shown in the end view. Each bar is attached by a post or pin 4 to cross bars 1 and 2 at each end. A set of round bars 6 are placed below the spaces between the angle bars; these round bars drop away from the angle bars toward the lower end of the picker which is set on an incline, so that flat pieces of slate passing through the spaces between the angle bars will not stick and clog the apparatus. The beveled sides of the angle bars give the flat pieces of slate a strong tendency to separate from the coal, and drop through the slots shown, while the coal passes onward over the bars to other screening or sizing apparatus.



STONE CRUSHER.

No. 452,615. JOHN O'NEIL, JR., KEESEVILLE, N. Y. *Patented May 19, 1891.* The moving head 2 is operated by two levers C and G, which rock on shafts D and H. The lever C has a roller C^1 at its rear end, which bears on the eccentric on the driving shaft B and is moved up and down by it as the shaft turns. The lever G bears on top of the lever C as shown and receives motion from it. Both levers are connected to the moving head 2 by hinge pins J and F. These pins lay in half round grooves made across the back of the moving head, and across the face of the levers, and transmit the motion of the levers to the head. They are held in place and the joints are completed by the hook bolts K. By the arrangement of the levers shown the head

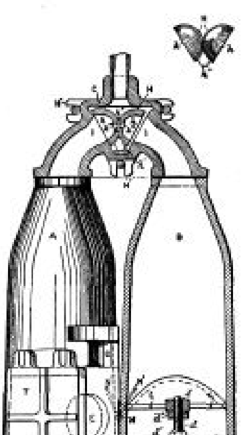


is moved forward and slightly downward, both ends alike. The fly-wheel B^1 is held on the shaft by the friction clamps, which are adjusted to just such a degree, that in case anything gets into the hopper that will not crush, the fly-wheel will slip on the shaft instead of twisting it off, or breaking the levers.

PULSOMETER.

No. 452,400. WILLIAM P. THEERMAN, SALFORD, ENGLAND. *Patented May 19, 1891.* One working chamber is shown in section, also the steam chest and valve. The two working chambers A and B are of any ordinary form, preferably circular in cross-section and tapering toward the top, and are connected together at the top in the usual way by means of a valve chamber or chest C, and are fitted at the base with water-valves D and E for suction and delivery, one opening into an inlet-chamber F and the other into the discharge-chamber G. The steam-valve H, which is placed in the valve-chamber C and controls the admission of steam to working chambers A and B, is formed of two hemispheres or half-balls *h*, joined together at their back or convex surfaces. Each of the semi-spherical parts *h* of the valve may be concave, as shown, or may be solid with a flat face. The concave or flat face of the valve H finds a seating over the ports I in the upper end of each of the working chambers A and B. On the under side of the steam-valve H midway between the two parts *h* projects a rib or lugs *h'*, upon which it rests and oscillates between the valve-seats over the ports I, opening and closing them alternately.

This form of valve offers less obstruction or resistance to the steam and allows the valve to change from one side to the other, quicker than a ball. The impact of the incoming current of steam acts to assist the change of the valve from one seating to the other. When intended to be used with exhaust-steam, or steam at a very low pressure, the valve is formed with a vertical passage *h''*, extending from the top of the valve between the two semi-spherical parts *h* down to

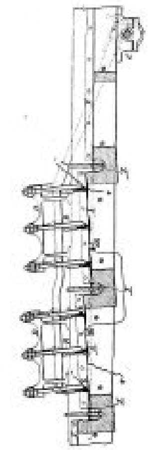


meet a horizontal cross-passage *h'''*, leading from the interior cavity of the one part into that of the other part. The cross-passage *h'''* is of double V-shape, or of V-shape at each opening, to allow for rapid expansion of steam as it is passed through. Through these passages a small quantity of the exhaust or low-pressure steam is admitted into the working chamber after the valve H has closed the admission of steam to that chamber. By this means a sufficient vacuum is produced to insure the complete filling of the chamber with water. The inlet and discharge-valves D and E have each a conical seat K, which fits loosely in a conical bearing, cast in the body of the pump and chilled. The valve is of rubber, and covers the joint between the seat K and its bearing. The seat is held down by a stud *d* which passes through a boss on the edge of an inclined shelf L, which extends part way across the chamber. The space under this shelf forms a kind of pocket, the use of which is explained further on. At this level there is also formed a passage or port N, leading from the discharge-chamber into and joining a passage or port N' from one working chamber to the other. When the water has been forced down in one of the working chambers below the shelf L, a certain amount of water that has been held up by the pressure of the steam under the shelf L falls and meets the steam, thus forming a partial vacuum, relieving the pressure, and thus causing the valve H to close. A jet of water is then projected either from one chamber into the other through the passage N^1, or from the discharge-chamber by the passage N, or from both, and by these means the condensation of the steam in the working chamber is almost instantaneously effected.

ELECTRICAL AMALGAMATING APPARATUS.

No. 455,164. GEORGE BUTTON AND WILLIAM E. WYETH, GRIQUALAND WEST, SOUTH AFRICA. *Patented June 30 1891.* The table is constructed with transverse shallow channels or corrugations A, in each of which is contained a body of mercury, and the finely-crushed ore to be treated is made to flow, together with water, along the table, passing across these channels A. Above each channel is mounted on a framing D a brush B, composed of any desired bristles ordinarily employed in making brushes, said brush extending the whole width of the table and its bristles of such lengths as to dip into the water and nearly touch the surface of the mercury. Against one side of each brush is fixed a conducting-bar *b* adjustable in height. The brushes all receive from a crank or eccentric C a reciprocating motion so as to sweep to and fro over the surface of the mercury.

The table, which is by preference formed of corrugated copper plates, is connected to the negative electrode of a dynamo-machine or other source of electricity, while the conducting-bars *b*, bearing against the brushes, are connected to the positive electrode. Thus as the ore and



water flow continuously along the table, passing from channel to channel, an electric current is transmitted by the bars to the brushes and through the ore-bearing liquid and the mercury to the table, and the electrolytic action combined with the stirring action of the brushes causes the gold or silver to be effectually taken up by the mercury and amalgamated with it.

The corrugated plates are preferably coated with gold burned into the copper, so as to prevent any action upon the latter.

The ore and water are made to flow over flat plates E, both before and after passing over the corrugated table, and these plates are also preferably coated with gold burned in. It is also of advantage to have dams F containing mercury.

ORE CRUSHER.

No. 450,890. WILLIAM L. MORRIS, CLEVELAND, OHIO. *Patented April 21, 1891.* Fig. 1 is a cross-section of the machine on the line *xx* in Fig. 2. Fig. 2 is a vertical section lengthways of the hopper. As shown, the hopper B is inverted and is nearly semi circular in cross-section. It is provided with three removable die blocks C, 1, and 2. The middle one serves as a key to retain the other two, and it is

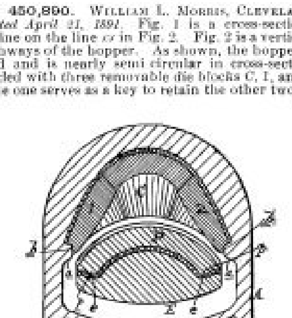


FIG. 1.

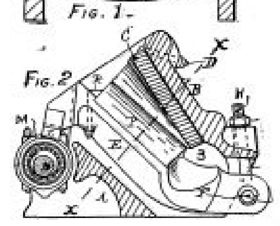
FIG. 2



fastened in place by a hook bolt D. The movable jaw E is also faced with a removable die P, which is secured by a hook bolt R. The moving jaw is hung by trunnions F and a jaw bolt H, by which it is adjusted. The hopper has a large side opening 3, on each side, by which the crushed material escapes. The jaw is worked by an eccentric N and strap M. The jaw is provided with a wearing block L, where it bears on the eccentric strap. As the edges of the movable die P are clear of the hopper on both sides and end, it follows that the crushed material can escape far more readily than in other forms of crushers, where escape is possible only at the throat of the hopper; consequently the power is used wholly for crushing, and none is wasted in merely pressing material already ground fine enough, but unable to escape.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

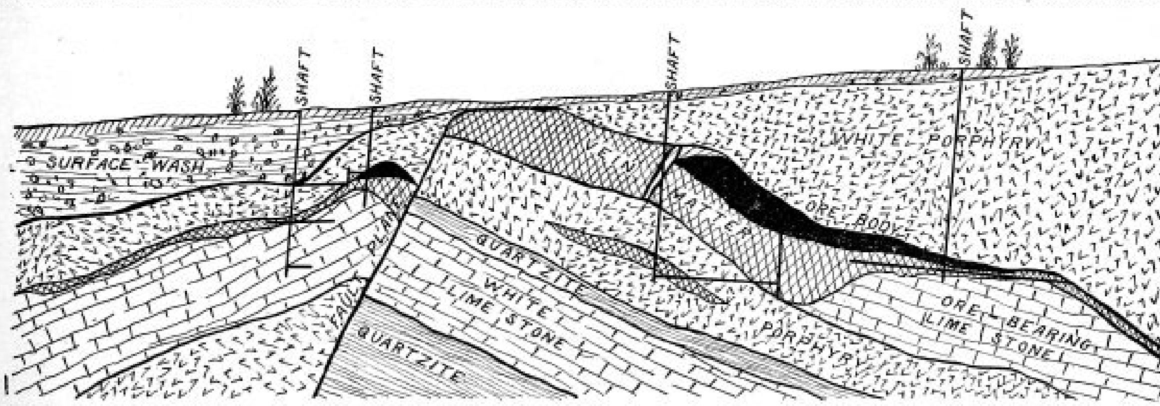
VOL. XII.—NO. 4. SCRANTON, PA., NOVEMBER, 1891. WITH WHICH IS COMBINED THE MINING HERALD.

THE ECONOMIC GEOLOGY OF SILVER.

The Mineralogy, Mode of Occurrence, and Production of Silver.

BY H. A. WHEELER, E. M., OF ST. LOUIS.

A district which created great excitement in 1878 is Leadville, Colo., where numerous profitable miners usually extract their ore along the contacts of an overlying trachyte and an underlying limestone, or else in the limestone only. Some very rich horn-silver ore has been found in some of the Leadville mines that sold for $1,000 to $10,000 per ton, but the great bulk of the ore is either lead carbonates in the upper parts of the mines, assaying 20 to 200 ounces per ton, or galena from the lower workings that assays 10 to 100 ounces per ton. The veins usually lie quite flat, or with dips of 5 to 25°, and are quite badly faulted. While the ore bodies are not continuous and much money is often spent in searching for them, the Leadville mines, on the whole, have been exceptionally profitable, and few camps can show such a magnificent record as this does for its moderate length of life and large number of dividend-paying mines. The sketch shown is through Carbonate Hill, back of Leadville, after Emmons. The Aspen district, which is but a short distance west of Leadville, is a young mining camp that has thus far done very well and threatens to finally eclipse Leadville's handsome record, from a group of mines that very much resemble those of the latter place.



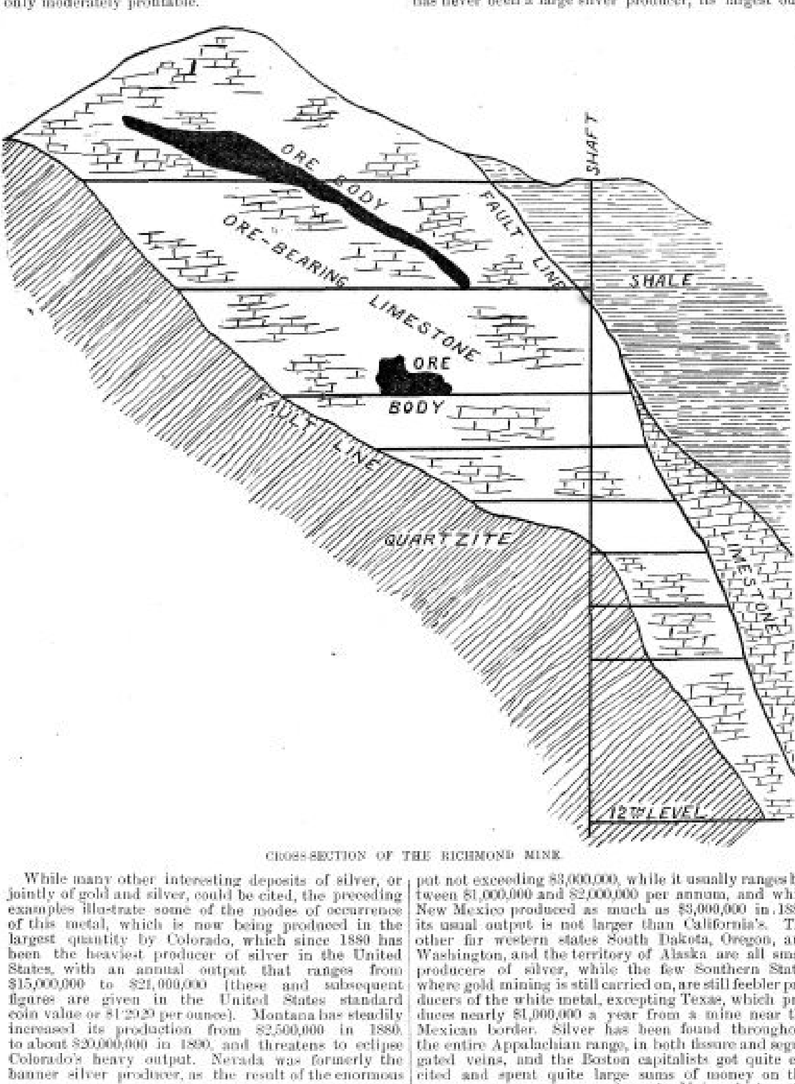
CROSS-SECTION OF A LEADVILLE ORE BODY.

A series of chamber deposits of silver-lead ore that have been the cause of famous litigation occur in the Richmond-Eureka belt of lime-tone at Eureka, Nevada. The Richmond and Eureka-Consolidated are adjoining mines that work a series of chambers of gold and silver-bearing carbonate of lead that occur in a narrow belt of limestone. The chambers are very irregular in their size and occurrence, and are not always entirely filled with ore, quite large caverns being of common occurrence. The ore assays from $40 to $70 in gold and silver and 15 to 30% in lead, and usually occurs in such large bodies as to be very profitable, the Richmond Co. having declared $4,332,887 in dividends, and the Eureka $4,892,500. The limestone in which the chambers occur varies greatly in width, or from a few feet to 450, having an average width of about 250, being underlaid by quartzite that dips about 45° to the north, and overlaid by shale, and the attempt was made in the big law suit in which the above two companies were involved to prove that the ore-bearing limestone belt, which is dolomatized or magnesian limestone, was a lode or vein. The sketch shown is through the Richmond vertical shaft, taken across the formation, after Curtis.

As a type of the stockwerk class of ore-deposits may be cited the Silver King Mine, in Pinal Co., Arizona, which seems to consist of a central mass or chimney of quartz about 200 feet in diameter, carrying innumerable radiating veinlets bearing a great variety of rich silver ores, the whole occurring in a dike of porphyry. The ore has been very rich, milling as high as $200 per ton, but is not holding out in depth, the mine having produced but little below the 500 foot level, and at a depth of 900 feet the outlook thus far is very discouraging; it has paid dividends that aggregate $1,950,000.

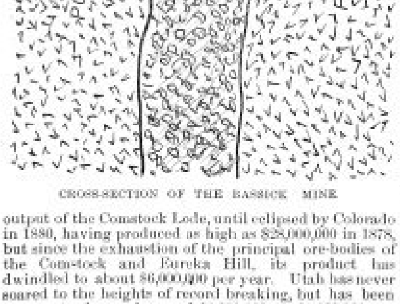
An odd type of ore occurrences is the Bassick Mine, at Rosita, Colorado, which seems to occupy the vent or channel of an old hot spring. The ore occurs as thin films and incrustations on boulders and pebbles that fill a funnel-shaped, nearly vertical opening or conduit of 20 to 100 feet in diameter in volcanic rock (trachyte). These boulders seem to have fallen in and choked up the outlet of this old hot spring during its expiring efforts, and the ore-bearing solutions have afterwards deposited gold and silver with quartz in the interstices between the boulders. The ore is very rich, it partly occurring as tellurides, and though shipments have been made assaying from $200 to $5,000 per ton, the financial history of this company is not a bright one, as no large quantities of this rich ore have been found, and the low grade ore, as the boulders are found to be more or less permeated by the precious metals, has not thus far built up a big dividend record.

An interesting occurrence of disseminated deposits is found at Silver Reef, in Southern Utah, where triassic sandstone is found impregnated with horn-silver that assays from $5 to $30 per ton. The horn-silver is often quite invisible, while again it is found replacing stems and leaves. Though there is no trace of vein formation, the silver follows certain channels and seems to be intimately connected with neighboring dikes of intrusive rock, and was probably brought up from below by mineral-bearing solutions that readily permeated the porous sandstone from small fissures or dislocations that followed the outburst of the volcanic rocks. The silver changes to the sulphide condition below the water level, and as the average value of the ore has always been low, no very heavy dividends have been paid by any of the mines of this camp, as the best of them have been only moderately profitable.



CROSS-SECTION OF THE RICHMOND MINE.

While many other interesting deposits of silver, or jointly of gold and silver, could be cited, the preceding examples illustrate some of the modes of occurrence of this metal, which is now being produced in the largest quantity by Colorado, which since 1880 has been the heaviest producer of silver in the United States, with an annual output that ranges from $15,000,000 to $21,000,000 (these and subsequent figures are given in the United States standard coin value or $1·2929 per ounce). Montana has steadily increased its production from $2,500,000 in 1880, to about $20,000,000 in 1890, and threatens to eclipse Colorado's heavy output. Nevada was formerly the banner silver producer, as the result of the enormous



CROSS-SECTION OF THE BASSICK MINE.

output of the Comstock Lode, until eclipsed by Colorado in 1880, having produced as high as $28,000,000 in 1878, but since the exhaustion of the principal ore-bodies of the Comstock and Eureka Hill, its product has dwindled to about $6,000,000 per year. Utah has never soared to the heights of record breaking, but has been a very steady producer of $6,000,000 to $9,000,000 per year for the past twelve years. Arizona has produced as much as $7,500,000 in 1882, when the Tombstone mines were in bonanza, but since they have reached the water level, together with the exhaustion of the Silver King Mine, in Pinal Co., its annual product has fallen to about $2,000,000 in 1889. Idaho has come up from a product of about $500,000 in 1880, to about $4,500,000 in 1889, and promises to at least continue to do as well as the last figure for some time. California has never been a large silver producer, its largest output not exceeding $3,000,000, while it usually ranges between $1,000,000 and $2,000,000 per annum, and while New Mexico produced as much as $3,000,000 in 1884, its usual output is not larger than California's. The other far western states South Dakota, Oregon, and Washington, and the territory of Alaska are all small producers of silver, while the few Southern States where gold mining is still carried on, are still feebler producers of the white metal, excepting Texas, which produces nearly $1,000,000 a year from a mine near the Mexican border. Silver has been found throughout the entire Appalachian range, in both fissure and segregated veins, and the Boston capitalists got quite excited and spent quite large sums of money on the numerous prospects opened up in Maine during the mining fever of 1880 and later, but no profitable mines have resulted from the explorations thus far conducted. Missouri, and Arkansas, in the Mississippi Valley, can also show quite an expenditure of money in prospecting silver-bearing veins that as yet have given no encouragement for profitable returns.

The total silver production of the United States has grown from $2,000,000 in 1861, when we first really entered the world's market as a producer, to about $65,000,000 in 1889, and it has exceeded $50,000,000 since 1885.

The United States stands well in the lead as the world's heaviest silver producer, and the only other country which approaches us in the output of this metal is Mexico, which turned out the unusually large amount of $55,500,000 in 1889, its usual quota being between $30,000,000 and $40,000,000. Following Mexico in importance comes Bolivia, which produced about $9,500,000, in 1889, while Chili turned out about $8,000,000. The Australasias produced $6,000,000 in 1889, which was largely the output of one mine, the famous Broken Hill's Mine, in New South Wales. Spain and Austro-Hungary each produced about $2,000,000 in 1889, which completes the important outputs of the world's silver producers for that year (1889), the total amounting to $161,287,927, which on account of the product of Mexico and ourselves being unusually large, is decidedly above the usual amount, or from $120,000,000 to $140,000,000 per annum.

H. Ward Leonard & Company now have on exhibition at their offices in the Electrical Exchange Building, 136 Liberty St., New York, a Crocker-Wheeler motor operating under Mr. Leonard's new principle for controlling the speed, torque, and direction of motors. The motor is made to perform various work in such a manner as to clearly show the principle used and the facility with which either the speed or torque is controlled. The exhibition is extremely interesting.

An Appeal to the Public for Aid for the Miners' Hospital, at Ashland.

The Board of Trustees of this State Hospital desire to place before the public certain information regarding it, in order to draw attention to its needs, and if possible, secure contributions to aid them in carrying on its work of healing the wounds and saving the lives of the unfortunate men entrusted to their care.

The Hospital was built in 1883 under an act of the Legislature of the Commonwealth, by Trustees appointed by the Governor, in accordance with its provisions. It was handed over to the Trustees, our predecessors, appointed to administer the charity, in an unfinished condition. Nor have the Trustees to this time been able to secure the means necessary for the finishing and furnishing of the buildings and the proper enclosing and grading of the grounds.

The number of patients treated in this Hospital last year was 1,414, and since its opening, 4,831 inside patients, and 3,876 outside patients have received treatment.

Being located in the Anthracite mining region, and under the act of the Legislature required to give preference, first, to persons employed in and about the mines, second, to persons employed on or about railroads, third, to persons employed on or about workshops, and having its sphere limited to the treatment of injured persons, its patients are often persons suffering from injuries of the most serious character, fractures of the skull, ribs, spine, and limbs, and severe burns of the whole body from explosions of gas in the mines. During the past year 567 operations were performed, many of them of the most delicate and difficult character, and with wonderful success.

The Hospital was built to accommodate 56 patients. It has now crowded into it 90 beds, always full, and at times during the past year has had as high as 110 in-patients, besides out-patients, treated in the Hospital.

For various reasons the appropriations asked for the proper support and continuance of the work of the Hospital were cut down by the recent Legislature and the Executive to the mere maintenance and treatment of patients. Appropriations asked, for a ward for the separate treatment of patients burned by explosions of gas in the mines, who on account of the offensiveness of their wounds, and their ravings in delirium often lasting for days and weeks, should be kept separate, for the erection of a vestibule shed at the Hospital entrance under which patients might be taken from the ambulance and carried on a level into the operating room without exposing them when in a weakened condition to rain and winter storms, for a large, better lighted and equipped operating room, for repairs to the buildings, for finishing the buildings, and for enclosing and grading the grounds, were wholly cut off.

Under this condition of affairs the Trustees find themselves confronted with the fact that additional funds are needed to preserve the property from decay, and keep it in condition to enable them to properly care for the unfortunate patients who are committed to their charge.

A supplement to the Act creating the Hospital was passed by the Legislature on the 19th of May, 1887, under which the Trustees are empowered to receive contributions or donations from any person, firm, or corporation to aid in the support and maintenance, and for improving the property of the Hospital.

The Trustees present this statement of the needs of the Hospital, and refer to the act of the Legislature authorizing them to receive contributions from individuals, firms, or corporations by will, deed, gift, or otherwise, for the information of the public, and earnestly call upon persons, firms, or corporations whose employes are taken care of by it, and upon other charitably disposed persons to come forward and contribute for its support.

They would be glad to have persons contemplating a gift, or others interested in this great charity to visit the Hospital, to see the work done by it, and ascertain its needs by their own personal observation.

William Lilly,
President of the Board of Trustees.

E. C. Wagner, Secretary.

An Enterprising Company.

The Star Drilling Machine Company, of Akron, Ohio, has just increased its capital stock from $50,000 to $100,000. Its business has increased so rapidly during the past two years that this step was necessary.

They have just purchased the entire plant of the Norwalk Foundry and Machine Company, of Norwalk, Ohio, and will move it to Akron, and connect it with their present works as soon as suitable buildings can be erected. The Norwalk Company has been manufacturing for the past six years the famous "Standard" governors, horizontal engines, stone planing machines, and has been doing a general business in brass founding. The stone planer referred to is the only machine for the purpose which has ever been designed and built in the world. It is a wonder in its way, and planes gigantic stones of all sizes and dimensions so that after the stone is removed from the planer it has a surface as smooth as the floor. To give an idea of the magnitude of this machine, Berea stone 16 feet long, eight feet wide, and one foot in thickness, are planed to a smooth surface, and are being shipped to Chicago, for a walk on what is known as the boulevard on Michigan Avenue. The consolidated companies will continue to manufacture the "Star" drilling machine, horizontal and "Star" upright engines, "Standard" governors, stone planing machines, hoisting engines, Dowell pin machines, drilling tools, and will also make a specialty of building anything in the line of machinery from drawings which can be produced in any machine shop in the country.

AN APPARATUS FOR TESTING THE SENSITIVENESS OF SAFETY-LAMPS.

BY FRANK CLOWES, D. SC.,

Professor of Chemistry, University College, Nottingham, England.

[Proceedings of Royal Society, London, June 18, 1891.]

It is generally acknowledged that the Davy safety-lamp cannot with certainty detect less than 3% of fire-damp in the air of the mine. Gas indicators of much greater sensitiveness have been invented; among these the electrical apparatus of Liveing and the spirit safety-lamp of Pieler take first rank. The objection to these special forms is, however, a serious one. They do not serve for illuminating purposes, and, therefore, it becomes necessary to carry an ordinary safety-lamp together with the testing apparatus. Many attempts have been made to obviate this inconvenience by producing a safety-lamp which will serve the double purpose of illumination and of detecting minute percentages of fire-damp. The invention of such a lamp would be of great value to the miner, in view of the fact that very low percentages of fire-damp have been proved to be dangerous in the presence of coal dust.

The following apparatus has been devised to render easy the process of testing the sensitiveness of different forms of safety-lamps when used for detecting fire-damp. To enable satisfactory tests to be made in the laboratory, it was necessary to insure (1) the easy and rapid production of mixtures of fire-damp and air in known proportions; (2) to insure economy of the artificially prepared methane, which represented fire-damp; and (3) to examine the flame of the lamp under conditions similar to those existing in the mine.

A wooden cubical box of about 100 litres capacity was constructed so as to be as nearly gas-tight as possible. It was then made absolutely gas-tight by painting it over with melted paraffin wax, which was afterward caused to penetrate more perfectly by passing an ordinary hot flat-iron over the surface. This testing chamber was furnished with a small inlet tube at the top, and with a similar outlet tube below. It had a plate-glass window in front for observing the lamp in the interior, and a flanged opening below for introducing the safety-lamp. This opening was closed by a water-seal consisting of a small zinc tray supported by buttons, and containing about 2 inches depth of water, into which the flange dipped. A mixer was arranged, which consisted of a light flat board, nearly equal in dimensions to the section of the chamber and suspended by an axis from the upper corner of the chamber. The mixer was moved rapidly backward and forward from the side to the top of the interior of the chamber by grasping a handle projecting through the front of the chamber.

When a mixture of air with a certain definite percentage of fire-damp was required, the methane prepared and purified by ordinary chemical methods, was introduced into the chamber in the requisite quantity by the top inlet. It displaced an equal volume of air which escaped through the lower outlet, the exit end of which was sealed by being immersed just beneath a water surface. A vigorous use of the mixer secured a uniform mixture of gas and air throughout the interior of the chamber in the course of a few seconds. The lamp was then introduced into the chamber, and placed in position behind the glass window. The simplicity of arrangement of the water-seal rendered the necessary opening of the chamber very brief, and the introduction and removal of the lamp many times in succession were not found to produce any appreciable effect upon the composition of the atmosphere inside the chamber. The appearance and dimensions of the "cap" over the flame were noted as soon as the cap underwent no further change. A lamp was left burning in the chamber for a considerable length of time, and its indications underwent no change owing to the large capacity of the chamber and the very limited amount of air required to support the combustion of the small flame always used in gas-testing. The whole interior of the chamber and mixer were painted dead black, so as to render visible pale and small caps against a black ground.

The methane was introduced from an ordinary gasholder. A volume of water, equal to that of the methane to be displaced, was poured into the top of the gasholder. The gas tap of the holder was then momentarily opened so as to produce equilibrium of pressure between the methane and the atmosphere. The gas tap having then been placed in connection with the upper inlet of the chamber, the water-tap was opened and the measured volume of water was allowed to flow down and drive the methane into the chamber. As soon as bubbles of air ceased to appear through the water at the outlet, the chamber was closed; the mixer was then vigorously worked for a few seconds, and the mixture of gas and air was ready for the introduction of the lamp. Before introducing the methane for a fresh mixture, the atmosphere of the chamber was replaced by fresh air by removing the water-tray from beneath the opening at the bottom of the chamber, and blowing in a powerful stream of air from a bellows to the top of the chamber.

The chamber was supported on legs, which were arranged so as to place it at a convenient height for observations through the window, and also for the introduction and removal of the safety-lamp.

The accuracy of this method was tested by introducing the Pieler lamp into the chamber, which was charged successively with a series of mixtures containing proportions of methane varying from 0·5% to 4%. The height and appearance of the cap over the flame absolutely corresponded with a series of standard tests already published, and made by a different method in which fire-damp was used instead of methane.

The observations were usually made in a darkened room, but the flame caps were easily seen in a lighted room, provided direct light falling on the eye or chamber was avoided.

The capacity of the chamber was 95,220 c. c.; accordingly the following volumes of methane were introduced: for ½% mixture 476 c. c., for 1% 952 c. c., for 2% 1904 c. c., for 3% 2856 c. c., for 4% 3808 c. c., and for 5% 4760 c. c. It will be seen that a series of tests, in which the above mentioned percentage mixtures are employed, involves an expenditure of only 15 litres of methane, a quantity far smaller than that required by any other method of testing as yet described.

Of many forms of safety-lamp tested in the above apparatus, the one which most satisfactorily fulfilled the two purposes of efficient illumination and delicacy in gas testing was Ashworth's Improved Hepple-white-Gray lamp. This lamp is of special construction, burns benzoline from a sponge reservoir and its flame is surrounded with a glass cylinder, which is ground rough at the hinder part; this latter device prevents the numerous reflected images of the flame, and the generally diffused reflections which are seen from a smooth glass surface, and which render the observation of a small pale flame cap very difficult, if not impossible.

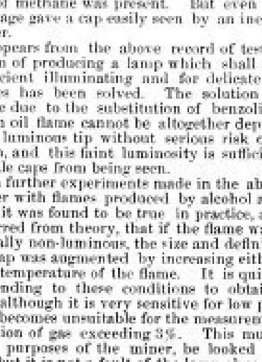
The wick of this lamp, when at a normal height, furnishes a flame of great illuminating power. When lowered by a fine screw adjustment the flame becomes blue and non-luminous, and does not interfere therefore with the easy observation of a pale cap. The following heights of flame cap were observed, which fully bear out the unusual sensitiveness of this flame. With 0·5% of methane 7 m. m.; with 1% 10 m. m.; with 2% 14 m. m.; with 3% 20 m. m.; with 4% 25 m. m.; and with 5% 30 m. m. The cap, which with the lower proportions was somewhat ill-defined, became remarkably sharp and definite when 3% and upwards of methane was present. But even the lowest percentage gave a cap easily seen by an inexperienced observer.

It appears from the above record of tests that the problem of producing a lamp which shall serve both for efficient illuminating and for delicate gas-testing purposes has been solved. The solution is in some measure due to the substitution of benzoline for oil, since an oil flame cannot be altogether deprived of its yellow luminous tip without serious risk of total extinction, and this faint luminosity is sufficient to prevent pale caps from being seen.

From further experiments made in the above testing chamber with flames produced by alcohol and by hydrogen it was found to be true in practice, as it might be inferred from theory, that if the flame was pale and practically non-luminous, the size and definition of the flame cap was augmented by increasing either the size or the temperature of the flame. It is quite possible by attending to these conditions to obtain a flame which, although it is very sensitive for low percentages of gas, becomes unsuitable for the measurement of any proportion of gas exceeding 3%. This must, for the general purposes of the miner, be looked upon as a defect, but it is not a fault of the lamp already referred to. It is of interest to note that with the Pieler spirit lamp a flame cap an inch in height was seen in air containing only 0·5% of methane.

A Good Grease Cup.

You might as well expect a man to live without food as machinery to run efficiently without grease. Food may be of the best quality, yet not accomplish best results in man if not partaken of properly. It is the same with grease and machinery, to secure best results, grease must be applied properly, and this can only be done by the use of a simple, practical, and efficient cup, such as the Lunkenheimer Plain Brass Grease Cup shown below.



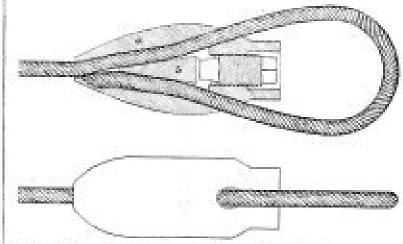
Referring to the illustration, E E is an adjustable leather washer that can be compressed and spread by the ring C C, thereby insuring a tight joint, and preventing the grease from oozing out. This cup is extensively used on mining machinery. It is made of the best materials and has great advantages over iron cups which usually rust and are liable to break, thereby causing great annoyance.

They are fully warranted and can be purchased of any dealer, or from the Lunkenheimer Brass Mfg. Co., of Cincinnati, Ohio, who also manufacture a full line of brass and iron body steam goods; regrinding globe, angle, and check valves; "Handy" gate and lever throttle valves; pop safety-valves; sight feed lubricators; and glass oil and grease cups, all strictly first-class and warranted. A handsome and complete catalogue illustrating and describing the above will be sent free to any address, if requested on a postal card addressed to The Lunkenheimer Brass Mfg. Co., Cincinnati, Ohio.

We have received from Messrs. H. Ward Leonard & Co., of 136 Liberty St., New York, advance pages of a neat little pamphlet entitled "The Value of the Services of a Consulting Electrical Engineer to Persons Investing in Electrical Plants." This little work contains much of value to present or prospective owners, of electrical plants, and we advise them to drop a postal card to Messrs. H. Ward Leonard & Co. for a copy of it.

Strobach's Wire Rope Holder.

An ingenious device, designed for making a loop at the end of a wire rope without the tedious and difficult operation of splicing, is now being introduced by Messrs. Thomson & Co., Westminster, Eng. The holder consists of a cast-iron block *a*, with four holes, the rope being passed through the end of the block and out by one of the holes at the side. The end is then curved round to form the loop and passed through the other hole at the side of the block and out at the end, as shown in the engraving, for which we are indebted to *Engineering*. In this way there is a tapered space between the two portions of the rope in the block. A cast-iron wedge *b*, hollowed at its sides to fit the rope, is passed into this space, and driven home by a screwed plug *d* which passes through the fourth hole in the block as shown.



When this plug is driven home it grips the rope so firmly against the sides of the block that it is impossible to draw it out. In certain instances it is not considered advisable to carry the end of the rope quite through the block, and in such cases a block is used in which the hole in the end is partially blocked, so that the rope can only pass through it once. When properly made the joint is just as secure and its appearance is improved, but the plan of passing the end quite through the block renders it certain that the plug shall wedge the rope properly, whereas in the other case a careless workman may not push the end of the rope sufficiently far into the block for the wedge to properly grip it. To take the wear and preserve the rope a liner of galvanized iron (not shown) is placed inside the loop. This liner can, of course, be replaced when worn through, and the wear of the rope entirely prevented.

Wiring for Mines—An Ingenious Cable that Cannot Spark when it Breaks.

A brief note was recently made in these columns of a safety cable for mining work which does not throw a spark when by any accident the cable is broken. The inventor now makes public the secret of his invention, which consists practically in transferring the breakage of the wire to some place at the top of the mine where its action is not important.

The cable contains an inner core of closely coiled spiral wire insulated by braid, and an outer core which is joined in parallel with the inner. In case the cable parts the inner spiral pulls out to a considerable distance and takes the whole current.

As soon as the exterior main is broken the fuse at the switch-board burns out and releases a switch which cuts out the whole current.

In case the cable should be completely severed as by an ax, thus crushing the two conductors together, a small resistance coil is placed in the circuit, and any contact between the two wires causes the fuse to melt as before.—*Philadelphia Record.*

A Novel System of Coal Hoisting.

The Mt. Pleasant *Journal* says the Southwest Coal and Coke Company will introduce a novel system of coal hoisting when it gets the new air shaft at its Tarr's plant completed, as that work will be done by water. The big fan and part of the machinery are already in place awaiting the erection of the house and the sinking of the shaft which, at this point, will reach the coal at a depth of some twenty-five feet, although it is the basin for a goodly portion of the company's 2,500-acre coal field, and from it the drainage will be pumped. One of the cages will not differ from those in general use, while the other will have built on it a tank. When a wagon of coal for the boilers has been placed on the cage at the bottom, water from a pump discharge pipe will be turned into the tank until it is heavy enough to sink to the bottom, drawing the cage up as it descends. An automatic valve will then let the water run out, when the tank, being lighter than the cage and empty wagon, is in turn drawn to the mouth by them.—*Connellsville Courier.*

THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.*

BY W. S. GRESLEY, M. E.

[Written for the Colliery Engineer]

Figs. 40 and 41. These are cross-sections of workings in a 45 ft. thick coal seam, also in France. The dip or pitch here is 35°. The coal is removed in successive parallel cuts or slices of about 7½' thick each, on same pitch as that of the seam, commencing with the one next to the foot-wall or floor and working across, entry or haulage road, either removed or to be removed. The main road or central gangway-level pillars are got out last. Of course, while one side of the shaft is being exhausted, the other side is being opened out; this in order to regulate and keep up the hoistings. Such work as this makes a very clean job of the saddle coal; every foot of coal is mined with method and plan, and great security of property is obtained by the filling-in business, so essential to a complete exhaustion of the coal bed.

Figs. 45 and 46 are cross-section and plan of mode of working a pitching deposit of coal in France, varying between 47 and 56 feet in thickness. This particular and remarkable bed is at Blanzy. It is divided into two splits or benches by a seam of sandstone (see both Figures) which contain quartz pebbles. The system of working is removing the coal in sections in descending order, about 50 ft. in vertical height being taken out at a time, divided into about seven horizontal cuts or slices, each about 7 feet high (see Fig. 45; 1, 2, 3, 4, 5, 6, 7). The upper end of this Figure shows all gob—gob packed full from top rock to bottom rock; and the lower end of Figure shows the coal all solid at present. The method of work may be briefly as follows: Shafts are sunk outside the coal seam and tunnels put across the measures at suitable vertical intervals to cut the coal. To each section or lift of 50 ft. is a tunnel which intersects it about the middle, as at 1, Fig. 45. Out of this tunnel, levels or gangways are driven in, right and left, on the strike of the seam, in both splits. Inclined planes are also driven, both to the rise and to the dip in each split, that to the rise to serve the cuts or slices, 2, 4, 6, above the central tunnel; and that to dip to serve the three bottom cuts, 3, 5, 7, respectively. These inclined planes are operated by compressed air engines, placed about the center of the district or section. With them the packing material is raised to the upper cuts, and the coal hoisted from the lower ones. Working the coal goes on continuously in both divisions of a district. The middle cut, 1, is first of all exhausted; then 2 off top of gob of 1, and then 3, 4, and 5; 6 and 7 being taken out last. The rooms or working places are laid off square with the levels or gangways and are driven up narrow, about 50 ft. apart, and timbered systematically; they are driven on one side only of each gangway (see plan Fig. 46). When a room strikes the hanging or foot-wall, as the case may be, a skip or rib is worked back towards the gangway, the spaces behind the men being lightly filled in with rock, etc., taken in for the purpose, or, it may be quarried in another part of the mine. Then another skip is worked off, and so on until the block between the rooms is all removed and the entire excavation closely gobbed. The central seam of sandstone is not touched save where the tunnels or airways have to be driven through it.

As one side or district is being exhausted another is being opened up. In this, as well as in other somewhat similar systems of coal mining, steel props and cap pieces, bars, collars, etc., are very widely used, especially in place of heavy timbering. They cost rather more than timber at first, but their greater strength, smaller bulk, lighter weight, greater durability, reliability, and efficiency, facility of fixing and replacing, have induced coal operators in European countries to use them with great economy and in large quantities of late years. The system of conveying the packing material into the working levels by air machines, does away with the objection to and difficulty of keeping open a special incline from a higher lift for the purpose as was, until a short time ago, the practice at Blanzy.

The ventilation is conducted on the diagonal or ascensional system; the air current entering a lift by a tunnel and passing around and across the working levels, etc., ascends by a special airway on the foot-wall at the end of the district, not shown in Figures, to surface. In this mine each room is lighted by "electrics," as are also the cross-cuts or tunnels communicating with shafts. Mechanical haulage is used on these tunnels. The coal or refuse in it, being rather liable to spontaneous combustion, the dimensions of each lift or section (50 feet in height by a few hundred feet in length) are regulated or set out so that the entire body of coal in it may be removed and the district abandoned, within a few months, at a certain speed of working and at a given output per day.

slice after slice, to the hanging wall or roof, or top-rock. Here again the close-packing system is carried on systematically, the rock, etc., for filling, entering by the higher gangway or level, while the coal goes out along the lower one. Fig. 40 shows slices 1 and 2 exhausted, and 3 being worked.

Fig. 42 is a longitudinal section through the workings in a thick coal seam, say 20 to 25 feet thick. The plan of excavating the coal is to consider the seam as three seams lying one on top of the other, and to work away the lowest cut first, the middle one on top of gob (close-packing as before) of first cut, and the upper one on top of gob of middle cut; the faces being stepped or worked forward as shown right and left; then all the seam is worked. If the pitch is heavy, the coal is mined out from one wall to the other across the natural stratification of the seam as in Fig. 39.

Figs. 43 and 44 are cross-section and plan respectively showing a French method of working the saddle or crown of an anticline in a seam some 45 feet thick. The general system is the same as the last few described, viz., removing the coal in slices of not more than 7½ ft. at a time, and systematically stowing rubbish in every working-place as the work goes forward. Thus the horizontal slice No. 1 is removed first, then 2 on the packing of No. 1, and so on upwards to top of the saddle in 6. The plan Fig. 44 shows how the work is opened up in each slice and how the pillars or panels are worked back from the top slate or hanging walls towards the central gangway; the black and white dotted lines represent the cuts, ribs, or skips, between each

THE PREVENTION OF ACCIDENTS IN MINES.

An Essay on Practical Means to Insure Safety in Coal Mines.

(The following is Inspector Thomas K. Adams' paper, which is one of the four essays recommended for publication by the committee of judges in the *Pittsburgh Times'* prize competition contest. Mr. Adams resides at Mercer, Pa., and is Inspector of the Third Bituminous District.)

The object to be attained in presenting suggestions concerning methods in coal mining is to diminish the number of fatal accidents, and to mitigate in the future, if possible, such disasters as occurred at the Dunbar and Mammoth mines. The results due from mine explosions and from mine fires fall upon the people of the State with appalling effect, yet when we consider the aggregate number of lives lost from such disasters, and compare them with the total number of deaths resulting from other causes, such as falls of coal and roof and miscellaneous causes, they almost sink into insignificance, if we consider the results for at least a period of ten years, consequently in dealing with this subject we must not lose sight of the latter class of fatalities.

The present mining act contains some excellent provisions for the protection of the miners which have been the means of producing most beneficial results, as far as giving them healthful places in which to labor, yet such has been the wonderful development in the coal mining industry in the Bituminous region of the State for the last ten years that the dangers to life and limb have increased greatly. The mine regulations that afforded the miners ample protection when the Bituminous mining law was enacted are insufficient to meet the emergencies of to-day.

What additional regulations or precautions other than what are now required by law at mines producing fire-damp, (CH_4), etc., would we suggest to insure the greatest degree of safety to the workman, keeping in consideration the economical operation of said mine.

MINING AND FIRE-BOSSES. Mining bosses and fire-bosses should be sober, steady, and reliable men, and any known case of intemperance by such persons should disqualify them from holding said position. Neither should examining boards grant certificates of competency to persons for the position of mining boss and fire-boss if they had been known to have been under the influence of alcoholic, spirituous, or distilled, or fermented liquor within two years of the date of making application for examination.

If fire-damp exists in any part of a mine the fire boss must examine every working and temporary abandoned place within three hours of each shift going to work, and permanently abandoned places to be securely fenced off and examined as far as practicable.

A fire-boss should only examine 60 rooms within the three hours, provided they are reasonably contiguous, and after having made his report in a properly prepared book, at the surface, he should return to the mine, and it should be his further duty to again examine all pillar workings where squeezes exist, if any, and the narrow work of the mine frequently during the day.

The fire-boss can examine about 60 rooms in three hours thoroughly, but should there be more, his duties will be done in a perfunctory manner, which would not insure safety.

If fire-damp is produced and mine ventilated by a single air current or said current divided in the interior of the works, every person in said mine should work with a locked safety-lamp of the most approved type, such as the Gray, Marsaut, Evan Thomas No. 7, and Bonneted Mueseler. The Davy and Clanny lamps, commonly used in this country, are unsafe, especially in currents of air where the velocity exceeds six feet per second.

Every mine producing fire-damp and employing more than 50 persons should be operated in separate and distinct sections, with not more than 50 persons to work in any one section. Each and every section of mine to be ventilated by a separate current of air, conducted in separate and distinct air passages from a point as near as practicable to the bottom of the inlet shaft, and return air of said section to be conveyed in independent air courses to near outlet. All overcasts used in carrying out the system should be driven in the solid strata. The coal in front of the currents at overcasts, where said currents take their ascensional direction to be left in a solid condition; all permanent "stopping" used to conduct the air to face of works to be built of brick or stone, and doors used in guiding the ventilation should be double, and have an attendant.

By working a mine on this "split" air system, if fire damp is produced in one section all the men working therein would be required to work with locked safety-lamps, but should no fire-damp exist in one of the other sections, the men in it could work with perfect safety without the use of safety-lamps; but the great consideration of this mode of working is the increased safety given to the workingmen. Each division or section of work having, practically speaking, its separate ventilation, should an explosion take place in one section the probability would be that little damage would be done to the other sections of the mine, resulting in a saving of lives and property.

SAFETY-LAMPS AND THEIR USE. The safety-lamps used in the mines should be cleaned and thoroughly tested by a competent person, employed in whole or in part to perform that duty, every day before they are placed in the hands of the workman.

No person should be employed to work in any mine producing fire-damp who cannot detect the same, and who is not familiar with the use of the safety-lamp, and in no case should any persons be engaged who do not understand the instructions given by the mining boss or fire-boss, or who can not communicate their knowledge, if they have any, on such matters to said officials.

To employ any person who does not possess the above

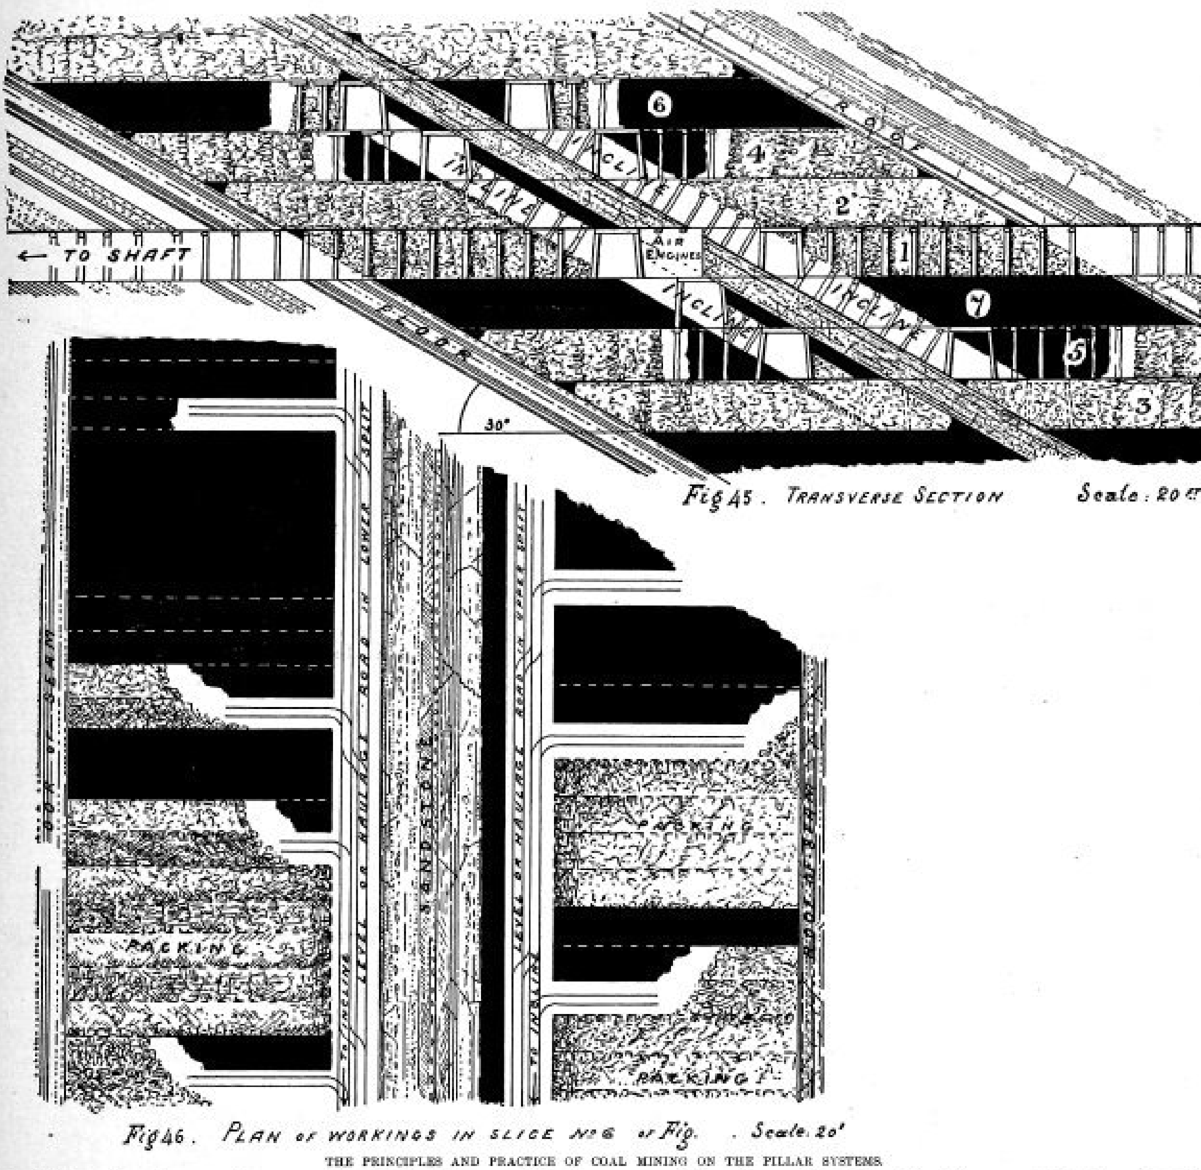

Fig 45. TRANSVERSE SECTION Scale: 20 FT.

Fig 46. PLAN OF WORKINGS IN SLICE No 6 of Fig. . Scale. 20'

THE PRINCIPLES AND PRACTICE OF COAL MINING ON THE PILLAR SYSTEMS.

knowledge or requirements would be simply putting the other employes' lives in jeopardy.

All shots or blasts to be fired in a gaseous mine should be done by a skillful miner at the end of each shift, when the miners have retired from the said mine; under no circumstances should shots be fired in any section of a mine where fire-damp exists, until such place, where the blast is to be fired, and contiguous places have been thoroughly inspected by the mining boss or fire-boss. Shot-firing has been proven to be a very fruitful source of causing mine explosions.

The fine coal-dust in fire-damp mines should be dampened by sprinkling it with water as far as practicable.

When the air of a mine is laden with fine dust or a cloud of it is raised by a "blown out" shot, if from one to two per cent. of fire-damp be present and ignition takes place, a violent explosion may occur. An explosion happening under these conditions might be more deadly in its effect than if there had been ten per cent. of fire-damp present with said mixture being free of dust, so as one to two per cent. of fire-damp in the air can hardly be detected with any safety-lamps when working with them under ordinary conditions it therefore becomes imperative that the dampening of the dust in mines should be a lawful regulation.

PRECAUTIONS AGAINST CLAY VEINS.

In all narrow work (headings, entries or air courses) that is being driven in solid or new territory, when clay veins or other disturbances are encountered in the coal seam, the clay veins should be penetrated by drilling two or three bore-holes through and into the solid coal beyond them.

Sometimes, in meeting with those disturbances in the coal bed, fire-damp is produced copiously in the shape of strong "blowers," or in such quantities as to very suddenly "flood" that portion of the mine; but, were those clay veins to be tested by bore-holes, if much gas were found, it could be safely controlled and dangerous consequences avoided. The inflow of gas could be regulated and sufficiently diluted with air, so as to render that portion of the mine safe.

The minimum volume of air should be 200 cubic feet per minute per person employed, and from 500 to 600 feet per mule employed. The ventilating power of fire-damp mines should be a fan, the casing and housing to be built of iron, placed at a short distance off the top of shaft, and have a secondary engine in place to be used in case of accident to the other.

Large volumes of air should be constantly provided for fire damp mines, conducted through double headings, or through a single heading with a parallel airway, the circulating currents of air to be conducted into the working places (rooms) by means of "check doors" (canvas cloth), hung about every 200 yards apart on the headings.

The above mode of ventilation will be a safe, healthful, and advantageous system for diluting all kinds of gases, whether they are explosive or non-explosive, in all mines.

All entrance to slope or drift mines producing fire-damp should be provided with doors or gates and kept locked until mine has been examined by the fire-boss and his report made that the mine is safe.

In all slope mines which are driven down in the coal seam and have men working on both sides of the same, the employes working on the side not provided with a separate and continuous traveling way to the surface should be provided with a suitable and convenient escape-way (size not less than 5 x 5 feet) at convenient distances, made as the sinking of the slope progresses, said means of escape to consist of safe passage-ways from the interior works to the overcasts, said overcasts to be driven in the solid strata over the top of slope to main manway.

Had such means of escape been provided for the men at the unfortunate Dunbar mine no such number of lives would have been lost.

All bore-holes that have been drilled from the surface to the coal, if persons are working to approach them, should be tapped by boring holes of a small diameter to them when they are near the location of the holes. Such work, and work advancing to old and abandoned works, containing explosive gas or water, should be done at night when the other men are not at work.

STORAGE OF EXPLOSIVES.

The storage of powder and other explosives, kerosene and other illuminating oils, straw, hay, or other material saturated with oil in mule stables in mines should be prohibited, and all brattice-cloth used in mines should be incombustible. Miners or other persons delegated to fire flashes, after such has been done should return to the places to examine them, and if fire exists to see that it is put out before leaving said place. Lodgements for the accumulation of water should be provided in each entry or heading, so that water could be had in case of fire in any of the working places. In very fiery mines a three or four-inch diameter pipe should be connected with the main pumping system or machinery, and conveyed to main portions of the works, so that water could be forced to fires with necessary connections.

A miner should be furnished with at least five sprags of at least eight inches in diameter and of suitable lengths, and required to be set to the undercut coal not more than five feet apart, and the point of the opened cut of coal must be made secure by a sprag or by leaving the coal solid.

The inspector of mines should be furnished with a copy of all mine maps by mine operators, and all extensions to be added thereto, as the law now directs.

Owing to so many accidents happening through incorrect maps, the inspector should have a copy of all such, so as he could thoroughly examine them and thereby familiarize himself with the workings of each mine, which would enable him to make a more thorough examination or inspection of it.

When a second opening has been made (as now considered by law) a traveling way leading therefrom of at least five feet high and five feet wide should be extended into the body of the workings and to the boundary lines of every mine, and when said traveling way is being driven in the coal seam or other strata it should be separated from the hauling ways by a solid pillar of coal or other strata of at least 25 feet in width, but said traveling way may be used as a haulage road if allowed by the mine inspector. No miner or other employe should be allowed to work in any place in any mine beyond any point therein, unless there are two separate passage-ways by which he can travel to and from his working place. Such traveling ways must be kept free from stagnant water, so as not to accumulate on bed of roads, free from debris and in a safe condition.

Locomotives driven by steam should be excluded from the mines when they enter near to the workings thereof; steam boiler, steam lines, and fires in "baskets" or fires on unprotected grate-bars should be prohibited.

The law should require all mines to be ventilated by artificial means (a fan or properly constructed furnace); they should be erected immediately after the opening of said mines; no person to be allowed to work ahead of an air current more than a distance of 30 yards or less if so ordered by the inspector, and miners should be prohibited from turning rooms of an entry beyond the air current; every door placed upon an entry or heading used in directing the air currents and every furnace for producing the same should have an attendant.

The mine inspector should be given the power to temporarily close down any part of a mine if he thinks there is immediate danger to any of the workmen, or if their health is likely to be injured by working in an impure atmosphere. He should be given police powers.

An inspector having such powers, whenever he observed any willful violation of the law, could prosecute the offenders upon sight, instead of having to give all such five days notice as now required by law, which has proven to be a very convenient means for evading the law.

The mining boss should have exclusive charge of all the inside workings of the mine; provide the ventilating power and all necessary supplies (at the expense of the company) for the safe and economical operation of said mine, and he should not be interfered with directly or indirectly in the performance of his lawful duties by any person whatever. Neither should any agent or superintendent direct a mining boss in matters pertaining to the safe and healthful operation of the mine, unless such agent or superintendent has proven his competency to give instructions by having passed an examination before a lawful board of examiners, and holds a certificate of competency.

CONCERNING FINES FOR DISCIPLINE.

The penal clause or section of the Mining act should provide for a graded fine and Justices of the Peace be given jurisdiction of trifling offences.

I consider the above a very important requirement to insure proper discipline at the mines. Unless discipline is maintained at the mines they cannot be operated with a favorable degree of security, and the best way to maintain it is by imposing a fine commensurate with the nature of the offence upon all mine officials and other workmen for the violations of the provisions of the laws. The minimum fine now, whether or not the offence is of a trifling or of an important nature, is $200, consequently, owing to the severity of the fine, offences are condoned; but were the fines to be graded, say from $5 and upward, and the law compelling the mining boss to prosecute all employes who in any way violate the rules and regulations of the mine, and the justice of the peace to have jurisdiction of such cases so that summary punishment could be had, the discipline would soon improve at the mines, and lives be saved.

The question might be asked why not suggest the introduction in all fire-damp mines of the use of electric lights or the use of the Shaw signal and gas detecting machine? With the knowledge we have of those appliances as to their practical utility, we would not be warranted in advising their introduction into the mines by legislative action. Arc lights can be successfully used at top of mines at night, and also the glow lights may be successfully applied in pit bottom or on haulage ways leading from the bottom for short distances; but such stationary lights cannot be successfully or practically used in the working places of the mine. It would be an impossibility to keep the large number of small insulated wires connecting with lights and main conductors in proper condition, and the fact of their being stationary is a very serious defect and have been proven, beyond doubt, to be very inefficient. There has been patented, however, by J. Wilson Swan, of England, and manufactured by the Edison-Swan Electric Company, a self-contained lamp with a glow light or a portable secondary battery sweep which in the near future may become of great practical benefit to the mining public. Owing to their weight (7 pounds) and first cost (about twice the price of the very best safety manufactured), it will be some time before they are generally used in mines. However, there are three large companies in England using them in their mines exclusively.

The Shaw machine is only in its experimental stages of development in a practical sense, and of very doubtful efficiency. The multiplicity of pipes used in its operation in an extensive mine is a serious defect; it is only supposed to give indications of gas from a point at the extreme face of the working place, leaving the old abandoned and other portions of the mine between the surface and innermost point of working place without any means of inspection and detection for gas. The pipes are one fourth of an inch in diameter and in an extensive mine will be from 3,000 to 4,000 feet long, and might be double that length in some cases. So an expert miner can judge of the effect such a pipe hung up in a chamber would have on a body of fire-damp being produced a few yards away from the mouth of the pipe. If a sudden inflow of gas should take place and a miner working with an open light the machine would not afford any protection. The pipes would be constantly out of repair by roof falling upon them and holes would wear in them by the action of the mine water. The machine would create a false idea of security among the workmen and mine officials, thereby creating gross carelessness among them. It would by the introduction of such an appliance impose a heavy tax upon the coal mining industry of the State without insuring greater safety to the miners; therefore, the State should not legally require mine operators to provide expensive precautions where there are so many doubts existing as to their efficiency.

GENERAL RULES.

In order that any mine rules may have lawful effect, they must be passed by the Legislature and become a part of the act itself, and as we have none such regulating the working of Bituminous mines, I offer the following amended general rules, to become part of the act, which have been culled from rules now in existence:

A majority of the persons employed in a mine may from time to time appoint two of their number who are practical working miners to inspect the mine at their own cost, and the persons so appointed shall be allowed once in every month, accompanied, if the owner, agent, superintendent, or mining boss of the mine thinks fit, by any one or all of them to go to every part of the mine and to inspect the shafts, headings, traveling ways, planes, working places, ventilating apparatus, airways, old works, and machinery. Every facility shall be afforded by the owner, agent, superintendent, or mining boss, and all persons in the mine for the purpose of inspection and the person appointed shall forthwith make a true report of the result of the inspection and that report shall be recorded in a book to be kept at the mine for the purpose, and shall be signed by the persons who make the inspection, and if the report states the existence, or apprehended existence of any serious danger, the owner, agent, superintendent, or mining boss shall forthwith cause a true copy of the report to be sent to the mine inspector.

The following general rules shall be observed in every mine to which this act applies:

Rule 1. The owner, operator, or superintendent of a mine or colliery shall place the underground workings thereof and all that is related to the same under the charge and daily supervision of a competent person who shall be called "mining boss."

2. Whenever a mining boss cannot personally carry out the provisions of this act so far as they pertain to him, the owner, operator, or superintendent, shall authorize him to employ a sufficient number of competent persons to act as his assistants, who shall be subject to his orders.

3. The mining boss shall have charge of all matters relating to ventilation, and the speed of the ventilators shall be particularly under his charge and direction.

4. All accessible parts of an abandoned portion of a mine in which explosive gases have been found shall be carefully examined by the mine foreman or his assistant at least once every week, and all danger found existing therein shall be immediately removed. A report of said examination shall be recorded in a book kept at the colliery for that purpose and signed by the person making the same.

5. In mines generating explosive gases the fire-boss shall make a careful examination every morning of all working places and traveling roads before the workmen shall enter the mine, and such examination shall be made with a safety-lamp within three hours at most before time for commencing work, and a workman shall not enter the mine or his working place until the said mine and part thereof and working place are reported to be safe. Every report shall be recorded without delay in a book which shall be kept at the colliery for the purpose, and shall be signed by the person making the examination.

6. The person who makes said examination shall establish proof of the same by marking plainly the date thereof at the face of each working place.

7. A station or stations shall be established by mining boss at the entrance to each mine or different parts of each mine, as the case may require, and a workman shall not pass beyond any such station until the mine or part of the mine beyond the same has been inspected and reported to be safe.

8. If at any time it is found by the person for the time being in charge of the mine or any part thereof, that by reason of noxious gases prevailing in such mine or such part thereof, or of any cause whatever, the mine or the said part is dangerous, every workman, except such persons as may be required to remove the danger, shall be withdrawn from the mine or such part thereof as is so found dangerous until the said mine or said part thereof is examined by a competent person and reported by him to be safe.

9. In every working approaching any place where there is likely to be an accumulation of explosive gases or in any working in which danger is imminent from explosive gases no light or fire other than a locked safety-lamp shall be allowed or used. Whenever safety-lamps are required in any mine they shall be the property of the owner of said mine, and a competent person shall be appointed for the purpose, shall examine every safety-lamp immediately before it is taken into the workings for use and ascertain it to be clean, safe, and securely locked, and safety-lamps shall not be used until they have been so examined and found safe, clean, and securely locked, unless permission be first given by the mine foreman to have the lamps used unlocked.

10. No one except a duly authorized person shall have in his possession a key or any other contrivance for the purpose of unlocking any safety-lamp in any mine where locked safety-lamps are used. No lucifer matches or any other apparatus striking a light shall be taken into said mine or parts thereof.

11. No blast or shot to be fired in any mine where locked safety-lamps are used, except by permission of

the mining boss, or his assistants, and before a shot is fired the person in charge must examine the place and adjoining places and satisfy himself that it is safe to fire such shot or blast before such permission is given.

12. The mining boss, or some other competent person or persons to be designated by him, shall examine at least once every day all slopes, shafts, main roads, traveling ways, signals, pulleys, and timbering, and see that they are in safe and efficient working condition.

13. The mining boss shall cause a blackboard of suitable form and size to be hung in some conspicuous place, near the entrance of the mine, whereon a copy of the mining law and general rules shall be placed.

14. The mining boss shall also cause to be constructed a blackboard or slate large enough, and shall have it placed in some building, near the entrance of the mine, upon which shall be the numbers used by miners, and space sufficient to each number, so that the miners can write plainly the quantity of props, their length and size, number of caps and other timbers they require, with the time and date of the order, etc.

15. The miner when in want of props, caps, or other timbers shall give his order at least twenty-four (24) hours before needing them, and in no case shall he allow himself to run out of props and caps before ordering a new supply.

16. It shall be the duty of the mining boss to direct and supervise the whole of the inside work of the mine; to instruct all workmen and boys in their several duties, and to every employe employed by himself or superintendent he shall read to such employe the general rules of this act as far as they pertain to him.

17. The quantity of air in circulation in the mine shall be measured or ascertained by the mining boss with an anemometer.

18. Whenever a place is likely to contain a dangerous accumulation of water or explosive gases, the working approaching such place shall not exceed eight feet in width, and there shall be constantly kept at a distance of not less than 12 feet in advance at least one bore-hole, near the center of the working place, and at least one flank bore-hole on each side.

19. Not more than 10 persons shall be hoisted or lowered at one time in any shaft, whenever five persons shall arrive at the bottom of any shaft (if it is not within one hour of the time set apart when the shift shall expire or stop hoisting coal, or if any one person should be sick or have received bodily injuries), in which persons are regularly hoisted or lowered, they or he shall be furnished with an empty cage and be hoisted.

20. An engineer placed in charge of an engine whereby persons are hoisted or lowered in any mine, shall be a sober and competent person not less than 21 years of age.

21. An engineer who has charge of the hoisting machinery by which persons are lowered or hoisted in a mine shall be in constant attendance for that purpose during the whole time any person or persons are below ground, and he shall not allow any person or persons, except such as may be deputed by the owner, operator, or superintendent, to handle or meddle with the engine under his charge or any part of its machinery.

22. When any person is about to descend or ascend a shaft or slope, the headman, or footman, as the case may be, shall inform the engineer by signal or otherwise of the fact, and the engineer shall return a signal before moving or starting the engine. In the absence of a headman or footman the person or persons about to descend or ascend shall give and receive the signals in the same manner.

23. Any miner or other workman who shall discover anything wrong with the ventilating current or with the condition of the roof, sides, timber, or roadway or with any other part of the mine in general, such as would lead him to suspect danger to himself or to his fellow workmen or to the property of his employer shall immediately report the same to the mine foreman or other person for the time being in charge of that portion of the mine.

24. Any person or persons who shall knowingly or willfully damage or without proper authority remove or render useless any fencing, means of signaling, apparatus, instrument, or machine, or shall throw open or obstruct any airway or open a ventilating door and not have the same closed or enter a place in or about a mine against caution, or carry fire, open lights, or matches in places where safety-lamps are used, or handle without authority or disturb any machinery or cars, or do any other act or thing whereby the lives or health of persons or the security of the property in or about a mine or colliery are endangered shall be guilty of an offence against this act.

25. No person shall be employed to blast coal or rock unless the mine foreman is satisfied that such person is qualified by experience and judgment to perform the work with ordinary safety.

26. A person who is not a practical miner shall not charge or fire a blast in the absence of an experienced miner, unless he has given satisfactory evidence of his ability to do so with safety, and has obtained permission from the mine foreman or person in charge.

27. An accumulation of gas in mines shall not be removed by brushing where it is practicable to remove it by brattice.

28. When gas is ignited by blast or otherwise, the person igniting the same shall immediately extinguish it if possible and notify the mine foreman or his assistant of the fact, and workmen must see that no gas blowers are left burning upon leaving their working places.

29. Every fireman in charge of a boiler or boilers for the generation of steam shall keep a constant watch of the same. He shall see that the steam pressure does not at any time exceed the limit allowed by the outside foreman or superintendent. He shall frequently try the safety-valve and shall not increase the weight on the same. He shall maintain the proper depth of water in each boiler, and if anything should happen to prevent this, he shall report the same without delay to the foreman for the time being in charge and take such other action as may under the particular circumstances be necessary for the protection of life and preservation of property.

30. At every shaft or slope in which provision is made in this act for lowering or hoisting persons, a headman and footman shall be designated by the superintendent or foreman, to be at their proper places from the time that persons begin to descend until all the persons who may be at the bottom of said shaft or slope when quitting work shall be hoisted. Such headman and footman shall personally attend to the signals and see that the provisions of this act in respect to lowering and hoisting persons in shafts or slopes shall be complied with.

31. No person except the mule driver shall couple or uncouple loaded or empty mine wagons or cars while the same are in motion.

32. When mine cars or wagons are running on gravity roads by brakes or sprags, the runner shall only ride on the rear end of the last car or wagon, and when said cars are run by sprags a space of not less than two feet from the body of the car shall be made on one or both sides of the track wherever it may be necessary for the runner to pass along the side of the moving car or cars, and said space or passage-ways shall always be kept free from obstructions. The regulations of this rule shall also apply to drivers with mules bringing a trip of cars over any graded road in the mine.

33. Safety-blocks or some other device for the purpose of preventing cars from falling into a shaft or running away on a slope or plane, shall be placed at or near the head of every shaft, slope, or plane, and said safety-blocks or other device must be maintained in good working order.

34. The engineer in charge of any ventilating fan must keep it running at such speed as the mining boss directs, and on no account shall he slacken its speed except by proper instruction from the mining boss, which shall be given in writing. If repairs to the fan or machinery become necessary he must give timely notice to the mining boss and await his instructions before stopping it. He shall also examine, as often as it is necessary, all the fan bearings, stays, and other parts, and see that they are all kept in proper working order.

35. Every miner shall examine his working place every morning and take down all loose and dangerous slate, and otherwise secure the sides and roof by properly timbering the same before commencing to dig or load coal, and he shall at all times be very careful to keep his working place in a safe condition during working hours.

36. Should a miner at any time find his place becoming dangerous, either from gas or roof, or from any unusual condition which may arise, he shall at once cease working and inform the mining boss or his assistant of such danger, and before leaving such place to search for the boss he shall place some plain warning at the entrance thereto to prevent others from entering into the danger.

37. Every miner shall use great caution in the care and handling of his powder, and when making a cartridge, he shall not keep his lamp on his head nor have a lighted pipe or cigar in his mouth, he shall place his lamp at least four feet from him and at a point at which the air would carry a spark away from him.

38. A person when charging a hole for a blast, if his cartridge sticks he must remove it carefully and reduce its size or enlarge the hole so that he may push it in easily; he must not ram or force the cartridge with a drill, and when firing a shot with a patent or other squib, he must not break off or bend the end of the squib, or light it at any part other than the extreme end, or do any other act that would tend to cause the shot to go off before he could reach a place of safety.

39. In driving cross-cuts through pillars, before firing his shot, the miner must give ample warning to the workmen in the room toward which he is driving so that they may find a place of safety.

40. Tamping bars must be tipped with at least six inches of copper or other soft metal when used for tamping a hole for the purpose of blasting coal, rock, or slate, and no iron or steel pricker or needle shall be used.

41. A charge of powder or other explosive which has missed fire shall not be withdrawn or the hole reopened, but, where necessary, a new hole shall be prepared.

42. After a shot has been fired, the miner must exercise great care in examining the roof and coal and securing them safely before resuming work.

43. The miner shall not go into any old or abandoned parts of the mine or into any other place which is not in actual course of working without permission from the mine boss or his assistant, nor shall he, under any circumstances, travel to or from his work, except by the traveling way arranged for that purpose.

44. It shall be the duty of every miner to undermine his coal properly before blasting it down, and to set sufficient sprags under the coal while undermining to secure it from falling, and the said sprags not to be further apart than five feet and the point of all opened ("cut") coal to a secured sprag or solid coal.

45. Any miner or other person who is about to explode a blast or shot by use of a patent or other squibs or matches shall not shorten the match nor saturate it with mineral oil, nor turn it down when placed in the hole, nor ignite it except at its extreme end, nor do anything tending to shorten the time the match will burn.

46. No person is allowed to travel to or from his work on the locomotive roads during working hours, nor shall they travel such roads after the locomotive has ceased running unless they have the permission of the mine boss; but no locomotive using fire shall be allowed in any mine where the miners are at work.

47. The fire-boss shall see that all dangerous places are properly fenced off, all across and danger signal boards so hung on such fencing that they may be plainly seen.

48. No person in a state of intoxication shall be allowed to go into or loiter about the outside of the mine.

49. The fire-boss shall frequently examine the edges and accessible parts of new falls and old gobs and air courses, and should he detect gas of an explosive nature or find any place rendered dangerous, from any cause whatever, he shall fence off all entrances leading to such places, on which he must either place a danger board or write intelligently a warning, and should the men be at work he shall immediately withdraw them from any place rendered dangerous, and have the place fenced off until the danger is removed, and should the danger arise on account of the presence of gas, the same to be removed immediately.

50. Any workman who shall disobey or fail to carry out any order given, or willfully violate any rule whereby his own life or the lives of other persons may be endangered, or any employe or other person who shall willfully deface, pull down, or destroy any notice board, danger signal, general or general rules or mining laws, will be prosecuted as provided for in the section of this act.

Other rules could be added, but the different points are covered by the general suggestions I have made and by the present Bituminous mining act. All matter has been omitted from the suggestions and rules given that is already the law regulating the Bituminous mines of the State. I could have treated on the topic of how to work the coal seam, but I think I have given *The Times* enough of matter of which to construct a good and efficient mining law.

A Fine Haulage Plant.

Messrs. J. & J. B. Milholland, of Pittsburgh, Pa., have just erected for the American Coal Company, at their Jackson Mine, No. 5, in the George's Creek, Maryland region, an excellent haulage plant that is doing good work. The engines are of 200 H. P; the cylinders are 14 inches in diameter, and the stroke is 24 inches. They are strongly built, and are guaranteed to do twice the work at present required of them without strain. They are not reversed at any time, and are connected to two drums with two gear wheels placed in front in the center between the engines. The drums are each five feet in diameter, and work free on the main shaft; they are connected or disconnected by clutches, as may be desired, by the engineer, and a brake is attached to each drum. They are made to carry 4,500 feet of ¾ inch wire rope. Two ropes, made by the Williamsport Wire Rope Works, are used. The tail rope is ⅝ inch in diameter, and 9,000 feet long. The hauling rope is ¾ inch in diameter and 4,500 feet long. The tail rope leads from the right hand drum around a bull wheel placed at the mouth of the mine, and continues along the side of the track, and at the fartherest point passes around another bull wheel. From the mouth of the mine to Station No. 1, the track is perfectly straight, and the grade is with the load. From Station No. 1, there is a 15° curve, and a grade against the load for 2,500 feet. The ropes are guided around this curve by pulleys, and they are wound on the drums from the bottom. An electrical signaling apparatus is used.

The steam plant consists of two return flue tubular boilers, each sixteen feet long in the clear, fifty-four inches in diameter, and are guaranteed to carry a pressure of 150 lbs. Sixty three-inch tubes are in each boiler, and they have all necessary fixtures now attached to high grade boilers. A steam pump furnishes water for both. Both boilers can be used at one time if necessary or disconnected at will.

This plant, on a test trial, hauled a trip of 45 loaded mine cars, weighing 6,200 lbs. each, up a 4% grade with ease. The Messrs. Milholland, who rank among the leading makers of haulage machinery, are naturally proud of this plant. They are now at work placing a similar plant in position at the Koontz mine of the New Central Coal Company in the same region.

Sphincter Grip Steel Armored Hose.

Hose, for water, steam, or compressed air is largely used in all mining operations, and in no other industry does it receive harder usage. To make it more serviceable the Sphincter Grip Armored Hose was introduced. Already over half a million feet of it are in use at British collieries, and its use is rapidly being extended in American mines and industrial establishments. It is so strong that it will stand practically unlimited pressure, and long use and crucial tests have proved its superiority over ordinary hose, both in strength and durability, and as these desirable qualities are guaranteed by the makers, its cost in the end is much less than any other. A peculiarly valuable feature of this hose is, that it cannot be kinked. More hose is destroyed by the sudden concussion through kinking, when a full velocity of water is rushing through it than by actual wear. It is more flexible than unarmored hose, and perfectly protected from abrasion. It can be cut at every wind of the wire without loosening or uncoiling, as the Sphincter grip is self-holding through its entire length. It is especially adapted for use at collieries, coke works, and for steam and compressed air transmission, and is in fact the most serviceable hose made for any use.

Strong evidence of its worth is found in the fact that inferior imitations are being made, and placed on the market.

The Waterbury Rubber Company, 49 Warren Street, New York, are sole owners of the patents, and are the only manufacturers of the genuine Sphincter Grip Armored Hose in America, and they place brass plates under the wire, marking each coil, so that purchasers may readily distinguish the genuine from spurious imitations. They are also manufacturers of plain hose, belting, packing, and mechanical rubber goods of all descriptions. Catalogues and price-lists are sent on application.

Correspondence

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.*

Ventilation.

Editor Colliery Engineer:

SIR:—In answer to "A. B.," of Hanna City, Ill., I submit the following:

(1). An airway 8′ × 8′ × 1000′ is passing 40,000 cu. ft. of air, what diameter should a circular airway 1200′ long be to pass one-half the quantity, the pressure remaining the same?

(2). A mine is ventilated by natural ventilation passing 10,000 cubic feet of air per minute with a pressure of 5·5 pounds, the temperature in the downcast being 42°. The air current is reversed by erecting a furnace at bottom of the downcast producing 14,000 cubic feet of air per minute, what is the effect on the pressure and temperature?

In neither of the questions does there seem to be sufficient data given, and I do not think the first can be worked out correctly unless by chance; I may be mistaken, however, if so, I would be pleased to see "A. B.," or any one else solve it in the columns of THE COLLIERY ENGINEER for the benefit of your readers.

To the second question we will supply sufficient data, viz., depth of shafts, as it is necessary to have the depth of upcast, and as both shafts are upcasts in turn it is necessary to have the depth of both, we will assume the depth to be 600′, then the 5·5 lbs. pressure will have to be neutralized by a counter pressure in what was the upcast shaft by raising the temperature and making the air lighter to the extent of 5·5 lbs. in the downcast, and then as the pressure varies as the square of the quantity we have

$10^2 : 14^2 :: 5{\cdot}5 : x$, or 10·78 lbs., = the pressure shown on the other side or leg of the water-gauge.

Then,

$$10{\cdot}78 + 5{\cdot}5 = 16{\cdot}28 \text{ lbs.},$$

= total pressure to be maintained, which would require a motive column equal to

$$\frac{p}{w},$$

where p = pressure and w = weight of a cubic foot of air at 42°, the temperature of the air in motive column

$$w = \frac{1{\cdot}3253 \times 30}{459 + 42^\circ} = {\cdot}07936, \text{ then}$$

$$\frac{16{\cdot}28}{{\cdot}07936} = 205{\cdot}14 = \text{motive column.}$$

Then

$$T = \frac{D\,(459 + t)}{D - m} - 459 =$$

$$\frac{600\,(459 + 42)}{600 - 205{\cdot}14} - 459 = 302{\cdot}28^\circ.$$

Therefore the temperature of the upcast will equal 302·28°, downcast 42°, and the pressure to be maintained 16·28 lbs. The pressure shown on the opposite leg of the water-gauge = 10·78 lbs.

Yours, etc.,
T. S. C.

Gardner, Ill., September 26th.

Ventilation and Mining.

Editor Colliery Engineer:

SIR:—I submit the following in reply to questions by "S. U. P.," of Red Bank, Pa., in your October issue:

(1.) By the formula

$$P = \frac{K\,s\,v^2}{a}$$

the pressure is found thus, substituting their given values we have

$$P = \frac{{\cdot}0000000217 \times 24{,}000 \times 250{,}000}{128} = \frac{12{\cdot}97}{128}$$

= ·101336 + lbs. the pressure required.

In the next case we have the following formula to find the quantity:

$$q = a\sqrt{\frac{P\,a}{K\,s}}$$

by substituting their values and solving we have

$$\frac{{\cdot}101336 \times 64}{{\cdot}0000000217 \times 16{,}000} = \frac{6{\cdot}485504}{{\cdot}0003472} = \sqrt{18682{\cdot}32}$$

$$+ = 136{\cdot}6 \times 64 = 8742{\cdot}4, \text{ and}$$

$$8742{\cdot}4 \times 2 = 17{,}484{\cdot}8 \text{ cu. ft.},$$

the volume required.

(2). If a breakdown should occur caused by the engine or fan, the result would be the same whether it be an exhaust fan or a blower, as the one could not take any air out of the mine, and the other could not send any in. In a gassy mine there should always be two fans, so that in case anything happened to one, the other would be ready to be started up to keep a current passing through the mine.

In case a large fall should occur the greatest danger would arise where an exhaust fan was used, as it would take all the air from the mine and the gas would rush out from the strata, fill up the mine, and, no doubt, cause a loss of life and property. A blower would press more and more weight upon the pent-up gas, and thus more time would be given for the men to escape.

Suddenly removing the obstruction in the first case would leave a mine full of gas to contend with, and the air would have to force it all out before it, or make a path through the gas, as has happened in some cases when the current is not strong enough. In the second case the current would go on as before the fall had happened, as the pressure of the air would keep the gas in the strata and the mine would be free from it.

Yours, etc.,
L. P. H.

Avoca, Pa., October 7th.

Correction.

Editor Colliery Engineer:

SIR:—I made a slight mistake in my answer to "S. U. P.," in your last issue, which was caused by my statement that

$$P\,a \times q = u.$$

It should have been

$$P \times q = u,$$

which would change the h. p. in the 3d and 5th questions to the same as found by "T. S. C.," of Gardner, Ill., in the same issue.

Yours, etc.,
J. K.

Connellsville, Pa., October 5th.

Examination Question.

Editor Colliery Engineer:

SIR:—I notice by your last issue that "J. W. S.," of Westville, N. S., is not satisfied with the replies he received to his question, and solves the problem himself, finding the temperature to be 145°.

Now, as he wishes, I will try to show the error and its source. In the first place he makes a mistake in the data used to find the motive column, when he assumes water to be 833 times heavier than air. A constant cannot be found for weight of H_2O as compared with air, since liquids are not so sensitive to heat as gases, with the exception of CO_2. The specific heat of air is found to be 4·2 times less than H_2O. The co-efficient of expansion of H_2O from 0° C. to 100° C. is ·000466, while the co-efficient of gases is ·00366, or $\frac{1}{273}$ of its volume for every degree C., or $\frac{1}{490}$ for every degree F. Also the expansion of gases is nearly uniform, while H_2O is not, for its maximum density is at 4° C., or 39° F., weighing at that temperature nearly 62·5 lbs. per cubic foot. Now you will observe 40° is the temperature of the downcast or 1° from the maximum density of H_2O. If "J. W. S." would work out the formula

$$\frac{62{\cdot}5}{{\cdot}07966}$$

he would find that a cubic foot of H_2O is 784 times heavier than air at 40° F., which is the temperature of downcast. By using the formula below we find the length of the motive column

$$\frac{784 \times 1}{12} = 65{\cdot}3' \text{ m.},$$

which would alter his answer, as he reckons the *m.* to be 69·5. By multiplying ·07966 the weight of one cu. ft. of downcast by 69·5′, we obtain 5·5 lbs. pressure, but by multiplying it by 65·3′ we obtain 5·2 lbs. (within $\frac{1}{1000}$ part of a lb.) I think "J. W. S." has followed Mauchline too closely. Is it necessary to find the *m.* at all? It may be correct enough, but too long a method. I will assure "J. W. S." that the temperature of upcast is 137·29°; if he will find the *m.* thus

$$\frac{5{\cdot}2}{{\cdot}07966}$$

he will find it to be 65·3′; also if he tries to find the depth of upcast shaft from the temperatures—upcast 145°, and downcast 40°, he will find it to be deeper than the downcast shaft.

Yours, etc.,
J. V.

Punxsutawney, Pa., October 9th.

Correction.

Editor Colliery Engineer:

SIR:—In my answers to "S. U. P.," in last month's issue, I took the wrong area and, in consequence, my quantity was too large, although the principles used were all right. I would refer "S. U. P." to "T. S. C.'s" answers which were correct.

Yours, etc.,
J. V.

Punxsutawney, Pa., October 9th.

Effect of Gas on the Flame of a Safety-Lamp.

Editor Colliery Engineer:

SIR:—In answer to "R. P.," of Greensburgh, Pa., in the October issue, I would say:

(1.) That if a Davy lamp were subjected to a mixture of one part CH_4 to 13 of air, it would cause a blue column to extend from top of flame to crown of gauze tapering outward full width of gauze at top while at bottom it would be slightly wider than the flame.

(2). With one part CH_4 to 5 parts air, the gauze would be filled with a blue flame and continue to burn long enough to bring the gauze to a red heat if it is not withdrawn.

Yours, etc.,
J. K.

Connellsville, Pa., October 5th.

Coal Mining in No. 6 Seam, St. Clair Co., Ill.

Editor Colliery Engineer:

SIR:—Permit me through your columns to thank Mr. Leo Gluck, E. M., for his very practical paper on the above subject in your October issue, p. 53. Would that he or others would contribute articles specifically describing the details of underground coal mining in other sections of the country, where the natural conditions are very similar or dissimilar to those obtaining in the Belleville Seam, Ill.

Mr. Gluck gives figures at the end of his article that are very significant, and in regard to which I feel constrained, with your permission, to make a short comment.

We are told that the quantity of coal that is actually hoisted is only 51·15% of the seam, *a trifle over one-half*, and further, that of this 51·15%, 8·33% is slack, having but little value. An explanation of this startling statement of fact is partly found in Mr. Gluck's remark that 38% of the seam is left as pillars, as shown by the maps of the workings, and further that of this 38% in ribs and pillars one quarter or 25% is mined when these are *robbed*. It does not appear therefore, that the pillars are "drawn" or *cleaned out* entirely, and consequently the loss of coal in them is enormous.

Now, there may be good reasons why these pillars are not taken out, but as none are given in the article, I presume the real reason is because of the *method of working* the coal.

If the full explanation is that, if the pillars were robbed more than 25%, the surface water would come down and cause trouble with the floor to such an extent as to practically close the mine, I have nothing further to say, but, on the other hand, if it would be cheaper to pump the water than to leave nearly half the coal in the pit, would not some other method of working, some *better system of laying out the mine to suit the local conditions*, be worth while adopting?

This looks as if it were a place—a district—where the *Longwall withdrawing* system of working might be practiced with profitable results, and make a far better showing as regards *yield of coal*, together with much easier and cheaper digging, less slack produced, less shooting, with much more compact workings and infinitely better ventilation than is possible in room and pillar mining.

It seems to me that if the operators in this region or their superintendents, would think this Longwall "pulling back" system well over, and give it a trial, as Mr. MacDonald did (see COLLIERY ENGINEER, August 1890), they would no. want to go back to the old system. I don't wish, however, to be understood to say that the way Mr. MacDonald laid off his entries is the best, for his was merely an experimental or trial place more than anything else, but what I do claim is that in *principle* his system is the correct one to work upon if cheap digging, a well ventilated and compact, mine and all the coal worked are objects to be attained.

And let me make myself clearly understood on another point, which is that there is *no necessity* (as some seem to suppose) to drive entries right to the limits of the property before beginning to extract the bulk of the seam. That to do so in the case Mr. Gluck writes about would seem to *be* necessary, but then, look at the extra percentage of coal that would have been available in his case had the method I am anxious to see adopted in these moderately thick seams been in vogue.

The following appears in Mr. Martin's official report on his mine inspection of South Western district of Great Britain for last year. The paragraph has reference to the Llanerch Colliery explosion inquiry. "The system of working was 'pillar and stall,' which is the old-fashioned system of the district. The reason for adopting it when reopening was probably a matter of convenience, and because it always had been the system worked in this mine. The seam being 7½ to 9 ft. thick, and apparently without any important rubbish for stowage purposes, it was said that the *Longwall* system would not suit. This is the old story, but experience has found it wrong in the cases of the Black Vein, at Risca, Abercarn, Celynen, and other places where Longwall has given more satisfactory results than pillar and stall. An attempt has since been made to introduce Longwall work, but the men looking upon it as an innovation, have resisted it. I, however, hope that before long it will be got over, as I am confident the change would be advantageous to all."

I think it is to the Longwall *advancing* (the "gob road" system) that Mr. Martin has reference to here; a system I do not advocate for wet, shallow, thick seams, unless the seam itself carries ample slate, etc., of a suitable kind for "building" material, and the floor were hard.

Considerable space might be occupied in your columns in quoting statements of *fact* as well as of eminent mining men's *opinions* in regard to the relative economy and safety of the Longwall over pillar methods; and your readers will have noticed in last month's COLLIERY ENGINEER that the former system has been put in practice in an Anthracite mine in the Wyoming-Lackawanna coal field, Pa., where the chamber and pillar system would have been unsuited. And, only the other day, the remark was made to me that "Longwall must come before long; it is only a question of a very few years before operators will have to abandon the wasteful system of to-day."

If there is one system of working that suits undercutting machines better than another surely it is a Longwall system and I was pleased a few weeks ago to find a Longwall face in the Bituminous region of Pa. in which the bearing-in was done by machinery.

Those operators who are first in the field to adopt Longwall (where the conditions favor that method) will be first to reap the good results to be had from it.

I should like to see this much-neglected system discussed more and more in your paper, and trust my reference to it will call up correspondence.

Yours, etc.,
W. S. GRESLEY.

Erie, Pa., October 9th.

Examination Question.

Editor Colliery Engineer:

SIR:—"J. W. S.," in your July issue, gives the following problem:

"A furnace at bottom of shaft 400 ft. deep produces 15,000 cu. ft. of air per minute with 5·2 lbs. pressure per sq. ft. Temperature in downcast is 40° F. What is temperature in upcast?"

Various solutions have been published, including those from "H. L. D. W." and "J. W. S.," himself. As the last-named asks "to be corrected if in the wrong," I venture to attempt to point out his error, which lies in the assumption that water is 833 times heavier than air. This assumption is true only for one certain temperature; but the true relation between their weights at the given temperature may be determined easily. From Molesworth 1 cu. ft. distilled water at 39° F. weighs 62·425 lbs. The co-efficient of expansion for water being very small may be neglected in this case and 62·425 lbs. taken as weight of 1 cu. ft. water at 40° F. To determine weight of 1 cu. ft. air at 40° F.,

$$W = \frac{1·3253 \times 30}{459 + 40} = ·0797 \text{ lbs.}$$

Dividing 62·425 by ·0797 we find water to be 783 times heavier than air at the given temperature. If "J. W. S." substitutes this for the figure he used his results will agree closely with those of "T. S. C.," "A. B.," and others.

"H. L. D. W." has not used the given temperature; but if he had, his result would have still differed from the correct one, since he has not used the proper formula for this case.

The term motive column is applied to the length of column *in the downcast* which would be equal in weight to the difference of the weight of air in the two shafts. To find this motive column we use the formula:

$$M = D \times \frac{T - t}{459 + T}$$

The formula employed by "H. L. D. W.,"

$$M = D \times \frac{T - t}{459 + t}$$

gives the length of motive column in feet of air of the temperature *in the upcast*. Now, as "H. L. D. W." calculates his M in the first place on the basis of the *downcast* temperature he cannot rightly substitute the value thus determined in a formula based on the *upcast* temperature.

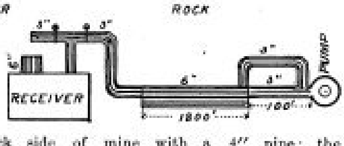
Yours, etc.,
JOHN DOE.

Tennessee, October 9, 1891.

Pumping.

Editor Colliery Engineer:

SIR:—In reply to J. T. Roger's question on page 11, of the August issue, I would say that good results would be obtained by connecting the receiver and 6″ pipe on



the rock side of mine with a 4″ pipe; the valve may then be closed on the present connection of 3″ pipe, and the pipe removed, the T could be plugged, which would leave a 3″ connection for the Sumner independent of the other side. The 4″ pipe on Rock side is in area nearly equal to two 3″ pipes for

$4^2 = 16$, and $(3^2 + 3^2) = 18$;

then the pump could be connected as suggested with a 3″ pipe to the 6″ pipe.

Yours, etc.,
F. B.

Maccan, N. S., Sept. 21st.

Blasting.

Editor Colliery Engineer:

SIR:—In answer to John Kane, in your September issue, I would say that the fire-damp will burn at the outer end of needle-hole as fast as the pressure of the blower can supply it. Fire-damp is not inflammable until mixed with air, and air could not enter the needle-hole against the pressure of the gas-blower.

Yours, etc.,
F. B.

Maccan, N. S., Sept. 21st.

Trigonometry.

Editor Colliery Engineer:

SIR:—I submit the following in reply to question (1.) asked by Richard Lewis, in your July issue:

Sin. = 250′; cos. = 600′;
Cos.² = 360000
Sin.² = 62500
422500, and
$\sqrt{422500} = 650$ = hypothenuse.
250 ÷ 650 = sin. ·384615, and
Sin. 22° 37′ = ·38456.
·000055.

Now as
22° 37′ = ·38456, and 22° 38′ = ·38483,
then ·38483 — ·38456 = ·00027
therefor ·00027 : ·000055 :: 60″ : *x*, or 12″ +,
so the angle is 22° 37′ 12″ +.

Yours, etc.,
W. G. ROGERS.

Wilkes-Barre, Pa., Sept. 28th.

Mensuration.

Editor Colliery Engineer:

SIR:—I would like to send another brief solution to T. W. Hale's question in your May issue, as my answer in the July number is a trifle too large. I find in working it over and carrying the decimal places out farther.

A horse is tied to the corner of a barn 25′ square, by a rope 100′ long. How many square feet of surface can the horse graze over?

$200^2 \times ·7854 \times \frac{3}{4} = 23,562$ square ft.

$$\frac{\sqrt{(25^2 + 25^2)}}{2} = A\ N = 17·8868993,$$

and

$$\frac{17·8868993}{75} = ·23570226 = \sin.$$

13° 37′ 58 $\frac{2510''}{2827}$ therefore the angle of

sector = 58° 37′ 58 $\frac{2510''}{2827}$; area of sector equals

$$\frac{(150^2 \times ·7854) \times (58°\ 37'\ 58\ \frac{2510''}{2827})}{360°} =$$

2878·124001638. Area of triangle =
$75^2 - 17·6776695^2$, or $\sqrt{75^2 - 312·5}$ =
(72·8868993 × 17·6776695) — 312·5 =

975·97051670518135 area of triangle,
2878·133366787988 area of sector,
2878·133366787988 area of sector,
23562· area of ¾ circle

described with radius = 100′. 30,294·23725028115735 = area.

Yours, etc.,
F. B.

Maccan, N. S., Sept. 21st.

Sustaining Life Under Pressure of Air.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to "Rescuer," of Jeanesville, Pa., who asked the following questions in your June issue:

(1.) There is a slope 624 feet long having a perpendicular depth of 160 feet and it is filled with water. Breasts are driven up 416 feet in length and 100 feet perpendicular height from a gangway which is level from bottom of slope. The compressed air holds the water back 80 feet from face of breast.

How many cubic feet of air is in one of the breasts which is 4 feet high and 30 feet wide, and what would be the volume of this air if the pressure of water were removed? Allow the temperature to be 62° Fahr., the weight of a cubic foot of air to be ·0763122 lbs., and of water 62·355 lbs.

(2.) How long would the amount of air contained in a breast, as above described, maintain the lives of four men? I gave a similar question which was published in the *Mining Herald* five years ago, taking figures and conditions from an accident in Wales where the shaft workings broke into a creek and some of the miners were enclosed for ten days. By cutting through a pillar 40 yards thick from an adjoining colliery all were rescued alive, but one of the rescuing party was killed by the pressure of the air driving him against the side of the opening as they broke through.

(3.) When the water is taken out of above workings, and exploration is being made, if lamps refuse to burn, what is the probable cause?

The above questions arose in connection with the Jeanesville disaster, and upon their solution depended the lives of several men.

First

416′ — 80′ = 336′ of water in the breast.

Then

416′ : 336′ :: 100′ : *x*, or 80·793′ = vertical head of water in breast.

160′ = head of water in slope,

then

160′ — 80·793′ = 79·207′ vertical head of water in slope above water line in breast.

79·207′ × ·434 = 34·3758 pressure per sq. in. exerted by head of water;

34·3758 + 14·7 = 49·075838 lbs. total pressure on air confined in breast.

14·7 : 49·075838 :: 80 : 267 feet, length of breast which would be occupied by air if pressure were reduced to one atmosphere;

(267 × 30 × 4) = 32,040 cu. ft. of air.

According to Kirk's Physiology a healthy man from young to middle age, at rest, requires under ordinary circumstances 686000 cubic inches of air in 24 hours, and will exhale 32,304 cubic inches of carbonic acid gas in the same time. Now, if we assume ten per cent. of carbonic acid gas to render air unfit for sustaining life we have

$$323040 + 686000 = (1009040 \times 4) = \left(\frac{4036160}{1728}\right) = 2335·74 \text{ cu. ft. of air required}$$

per day for 4 men, then

$$\frac{32040}{2335·74} = 13 \text{ days, } 17 \text{ hours, } 13 \text{ minutes.}$$

I may say that if the water were pure as from a lake, or river, some of the carbonic acid gas would be taken up by the water which would slightly extend the time but if from an old mine would likely be so charged by acids and gases that it could not take up any more. In such cases it is best for the men to place themselves at the highest points to escape the exhaled carbonic acid gas which would settle in the lower section of the place also to escape drowning when an opening is made and the pressure decreased, however there should be all the pressure possible maintained. This could be best accomplished by driving a small place to tap and have two strong air-tight stoppings with small tight fitting doors, then let all the men be taken between the stoppings, the inner door securely closed before proceeding out.

Yours, etc.,
F. B.

Maccan, N. S., Sept. 21st.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in reference to ventilation in your Correspondence Department:

For the safety of mines and those employed therein, I would say that in a large and extensive mine giving off much explosive gas, that the return current of air should be conducted to the upcast shaft without coming into contact with any open or naked lights. In the past we have read of some very heavy explosions and large losses of life supposed to have been caused by the highly charged return current of air igniting at the furnace. As a safeguard in such cases the dummy drift was brought into use, so that the return current could be passed through it into the upcast shaft without coming into contact with the furnace. The furnace being supplied with enough fresh air from the downcast shaft or intake airway.

No person should be allowed to enter into the main return airways of any extensive or large mine except the fire-boss or some other official whose duty it should be to travel the return airways, at least once a week, to see that there were no falls or anything to impede the free flow of the return air current. Also, he should use no other light except the safety-lamp.

Mr. Austin King says, in his essay, that he would make the hoisting shaft the upcast shaft, so as to keep it free and clear of ice. It is my opinion that it would be better to try and devise some other means of keeping the ice out of the hoisting shaft aside from making it the upcast, since if there were any open light in use it would probably be at the bottom of the hoisting shaft, and the return air current being charged with gas to an explosive point it would ignite from a small lamp blaze as readily as from a furnace, and serious consequences would follow.

Yours, etc.,
ROBERT ROCHESTER.

Robbins Station, Pa., Sept. 28th.

Mechanics.

Editor Colliery Engineer:

SIR:—Please insert the following question in THE COLLIERY ENGINEER:

Two compressors, 20″ in diameter, are each light in boiler power, what advantage is to be gained by condensing one or both. Also, what size pump is required for one or both?

Yours, etc.,
A. RITCHIE.

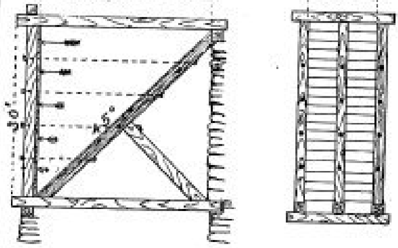
Lebanon, Ill., Oct. 9th.

Mensuration.

Editor Colliery Engineer:

SIR:—I submit the following in reply to question by "J. C. B.," in your May issue:

Ore weighs 116 lbs. per cubic ft. Please give me



the formula for determining the pressure on face of bin as shown in sketch.

The angle which line of rupture makes with vertical is half of angle which line of natural slope, or angle of repose makes with same vertical line. When material is level on top its pressure may be ascertained by considering it as a fluid, weight of a cubic foot of which is equal to weight of a cubic foot of the material multiplied by square of tangent of half the angle included between natural slope and vertical.

When co-efficient of friction is known it may be used instead of square of tangent of half angle included between natural slope and vertical. Morin gives the co-efficient of iron on wood at ·62 which I think is proper to use in this case.

Rule for finding pressure on face of wall: Multiply together the area in square feet of the surface pressed; the vertical depth in feet of its center of gravity below the surface; the weight of material, and co-efficient of friction.

It follows from foregoing rule that the amount of pressure of material against any surface is entirely independent of the quantity so long as the area pressed and the vertical depth of the center of gravity below the surface remains unchanged. The wall 30 feet high by 12 feet wide, would sustain as great a pressure from a layer only one inch thick behind it as if the material had extended back for miles.

The tabulated results are given below, giving the pressure for each space beginning from the top of "J. C. B.'s" sketch:

Division.	Area Pressed.	Depth of center of gravity.	Weight of a cu. ft. of material.	Co-efficient of friction.	Result.
First	6 x 12	3	116	·62	15534·72
Second	6 x 12	9	116	·62	46604·16
Third	6 x 12	15	116	·62	77673·60
Fourth	6 x 12	21	116	·62	108743·04
Fifth	6 x 12	27	116	·62	139812·48

Exact solutions of problems of this nature must be in a great measure experimental, and even then the results given might be called in question, unless more than ordinary care is exercised by the most competent in determining the co-efficient of friction.

Theee remarks are open for criticism and it will give me satisfaction and more knowledge on the subject if some more able than I will treat the question.

Yours, etc.,
H. L. D. W.

Lethbridge, Alta., N. W. T., Canada, Sept. 21st.

Miscellaneous Questions.

Editor Colliery Engineer:

SIR:—Will you kindly insert the following questions in the next issue of THE COLLIERY ENGINEER?

(1.) How is a water-gauge affected when the air course is suddenly contracted or enlarged?

(2.) By what means is density increased and diminished?

(3.) It is proposed to increase the quantity of air circulating in a mine, 10,000 cubic feet per minute, by building a chimney on to the upcast shaft; the original volume is 60,000 cubic feet, and the upcast shaft is 400′ in depth, what must be the height of the chimney?

(4.) There is a cistern 20′ square, and 10′ deep placed on the top of a tower 60′ high, what power is required to fill this cistern in 30 minutes; and what will be the diameter of pump, when the length of stroke is 2′, and making 40 strokes per minute?

Yours, etc.,
S. W.

Irondale, Jeff. Co., Ohio, Oct. 16th.

Fans.

Editor Colliery Engineer:

SIR:—Please publish the following questions in your valuable journal, which I hope will be answered fully by some of your able correspondents:

(1.) Is there any difference between the "Initial" and "Theoretical" head due to a fan?

(2.) How is E. O. of a mine found?

(3.) How is E. O. of a fan found, and what is the difference between them?

(4.) If the size and number of revolutions and the water-gauge is given, can the different heads and orifices be found?

(5.) How many different "heads" are there used in connection with the fan?

Yours, etc.,
T. S. C.

Gardner, Ills., Oct. 10th.

NOTE.—Considerable correspondence is unavoidably left out of this issue on account of lack of space. It will all be inserted in our December number.

Those who have noticed by comment in our paper the results which Mr. H. Ward Leonard is able to accomplish by his new method of operating electric motors, will be interested to learn that Mr. Leonard announces that he has now perfected his method to such an extent that, by a slight modification in a central station plant, which will not in any way affect the operation of existing devices, he will be able to control any motor upon the circuit so that it will operate in either direction and automatically at any desired speed and torque and with perfect efficiency under all conditions.

Mr. Leonard's first development of this method made it necessary, when using his motor from a central station circuit, to use the equivalent of a transformer of the energy. In his latest development no transforming of the energy is required; consequently, the first cost will be no higher than for shunt motors in use today, and yet all the advantages will be secured of the perfect control obtained by his method. No change in the generators, conductors, or translating devices of the present stations will be required in order to accomplish this result.

BARRIER PILLARS.

An Important and Well Arranged Plan for the Establishment of Barrier Pillars.

To avoid all trouble and complications likely to arise in the adjustment of barrier pillars, the engineers of several of the larger companies, in conjunction with Inspector Williams, of the former Third, but now Fourth Inspection District, arranged the following agreement and table, which have been mutually agreed to. For the benefit of readers in other districts we publish both in full.

TABLE OF BARRIER PILLARS TO BE LEFT BETWEEN ADJOINING PROPERTIES.

DEPTH BELOW WATER LEVEL—ALL DIMENSIONS IN FEET.

FORMULA: Thickness of workings × 1% of depth below drainage level + thickness of workings × 5 = width of barrier pillar.

Each adjoining owner is to leave one-half of the pillar thickness required.

AGREEMENT.

In compliance with the requirements of Section 10, Article III, of the Act June 2, 1891, entitled "An Act to provide for the health and safety of persons employed in and about the Anthracite Coal Mines of Pennsylvania, and for the protection and preservation of property connected therewith," it is hereby agreed between the Engineers of the..and of..and the Inspector of Mines of the................ Anthracite District of Pennsylvania, that the barrier pillars to be left, one-half (½) by each owner, between the workings ....on their adjoining properties, are to be, as nearly as practicable, of the thickness to be determined as follows:

First. That after this date the width of barrier pillar between the workings of adjacent properties is to be five times the thickness of seam mined out from floor to roof at the water drainage level; and that at all points below such level its width shall be equal to the thickness mined out at that point multiplied by one per cent. of the depth below drainage level added to five times the said thickness mined out. Thus: Thickness of workings × 1% of depth below drainage level + thickness of workings × 5 = width of barrier pillar. And as further illustrated by the attached table of pillars to be left between adjoining mines of different thicknesses of workings at different depths.

Second. That the water drainage level shall be understood to mean the level at which water would drain off from any abandoned workings, and that where the level is higher in one mine than in an adjoining one the higher level shall be taken, and where there is but one mine opened it shall determine its drainage level, and if the drainage level of a mine subsequently opened upon adjoining lands is higher, the additional thickness required shall be left by the owner of said mines.

Third. That these thicknesses shall be subject to such modifications as may be deemed advisable under varying conditions of the strata and seams due to proximity of other seams, faulty nature of seam or strata or other conditions shown by the development of the workings.

Fourth. That on notice of either party that any modifications of this agreement are desirable, a meeting shall be forthwith held to decide the same.

Fifth. That copies of this agreement and modifications thereof shall be furnished the Mining Superintendents for the instruction and guidance of those in charge of the workings. And there shall be marked on the map used at the mines the formula and such portion of the table as is applicable to the workings.

And It Is Further Agreed that the duplicate surveys and certified map to be furnished the Inspector shall consist of independent maps of surveys made by the Engineers of the adjoining properties, each map showing the land line and the workings, stations, monuments, etc., on both properties in the vicinity of division land lines.

In Witness Whereof, the said parties have hereunto set their hands this..........................day of..........................A. D. 189...

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since our Last Issue.

Suwanee Phosphate Co.,	Anthony, Marion Co., Fla.
El Sueno Gold and Silver Mining Co.,	Oakland, Cal.
The Colorado Mining Drill Co.,	Denver, Colorado.
The Washington Mining and Milling Co.,	Denver, Colo.
The Electric Mining and Milling Co.,	Denver, Colo.
The Exodus Mining Co.,	East Liverpool, Ohio.
Wall Street Mining Co.,	Helena, Mont.
Bunker Hill & Sullivan Mining and Concentrating Co.,	Portland, Oregon.
Margerum Mining Co.,	Webb City, Mo.
The FredoniaConsolidated Mining Co.,	Buena Vista, Colo.
Cyanide Process Gold and Silver Extraction and Mining Company for Baker County, Oregon,	Jersey City, N. J.
Palatacha Kaolin Company,	Riverside, Fla.
The Texas Coal and Coke Mining Co.,	San Antonio, Texas.
Santiago Canyon Silver Mining Co.,	Los Angeles, Cal.
The Sutton Mining and Milling Co.,	Denver, Colorado.
Pandora Mining and Milling Co.,	Butte, Mont.
Argenion Mining Co.,	Missoula, Mont.
Gold Group Gravel and Quartz Mining Co.,	Salt Lake City, Utah.
Butte Mining and Milling Co.,	Butte, Mont.
The Cumberland Consolidated Mining and Milling Co.,	Aspen, Colo.
Wilderness Gold Mining Company of Oakland, Cal.,	Oakland, Cal.
Tepeonta Copper Mining Co.,	San Francisco, Cal.
Virginia Block Marble Co.,	Fincastle, Va.
Burkeville Granite Company,	Roanoke, Va.
The Fall River and Colorado Mining and Milling Co.,	Fall River, Mass.
The Wainwright Coal Company,	Wellston, Ohio.
The Cleveland Coal Company,	Cleveland, Ohio.
The Anaconda Mining and Milling Co.,	Denver, Colo.
The Red Raven Consolidated Mining Company,	Romley, Colo.
The Salem Coal Company,	Salem, Ill.
Blaine Mining Company,	Helena, Mont.
Shasta Gold Extraction Co.,	San Francisco, Cal.
Southern California Mining Co.,	Los Angeles, Cal.
Gold Thread Mining Company,	Los Angeles, Cal.
North Clinton Gold Mining Co.,	San Francisco, Cal.
The Golden Hope Mining and Milling Company,	Chicago, Ill.
Western Mineral Company,	East St. Louis, Ill.
The Lick Creek Natural Gas, Minerals and Mineral Water Co.,	Indianapolis, Indiana.
The Colorado and Utah Mining and Investment Company,	Denver, Colo.
The Silver Chord Mining Co.,	Chicago, Ill.
Jefferson Gold Quartz Mining Co.,	Marysville, Cal.
Los Angeles and Utah Mining and Improvement Company,	Los Angeles, Cal.
The Bonaventure Industrial Co.,	Silver City, New Mexico.
The Golden Eagle Mining Co.,	Leadville, Colo.
Alba Company,	Saco, Me.
The Comstock Gold-Silver Mining and Milling Company,	Denver, Colo.
Richland Coal Company,	Altoona, Pa.
Frazier Mining Company,	Los Angeles, Cal.
The Lime City Co.,	Lime City, Ohio.
Eastern Oil Company,	Buffalo, N. Y.
The Silver Brick Mining Co.,	Wheeling, West Va.
The Ella Coal Company,	McKeesport, Pa.
Basin Mining and Concentrating Co.,	Helena, Mont.
Boulder Smelting Company,	Helena, Mont.
The Stonewall & Greenwood Mineral Company,	Denison, Texas.
Dunbar Phosphate Company,	Citra, Marion Co., Florida.
The Boulder County Lode Mining and Milling Co.,	Boulder, Colo.
The Mine Owners' Trust, Limited, (English),	Ouray, Colo.
The Red Mountain Silver Mines, Limited, (English),	Ouray, Colo.
Clear Creek Co-Operative Coal Co.,	Springfield, Ill.
Consolidated Morning Star Mining Company,	Butte, Monta.
Marshall County Oil and Gas Co.,	Moundsville, West Va.
Juneau Mining Company,	San Francisco, Cal.
Pahrump Mining Company,	San Francisco, Cal.
Mexican Importing Company,	San Francisco, Cal.
The Lemhi Placer Gold Mining Co.,	Denver, Colo.
Sheridan Consolidated Mining Co.,	Chicago, Ill.
The Chariton Coal and Mining Co.,	Kansas City, Mo.
Coaldale Mining & Manufacturing Co.,	Coaldale, West Virginia.
The Hope Splint Coal Co.,	Ferguson, West Virginia.
The West Virginia & Ohio Gold and Silver Mining Company,	Parkersburg, West Va.
The Pinon Mining Co.,	Santa Fe, New Mexico.
The Pitkins Mining Company,	Gunnison, Colorado.
The Eurydice Mining Company,	Denver, Colorado.
The Jicarilla Placer Mining Co.,	La Vegas, New Mexico.
Iron City Sand Company,	Pittsburgh, Pa.
The Blanche Coal Company,	Collins, West Virginia.
The Zieger Coal Company,	Chicago, Ill.
King Solomon's Mining Co.,	Grass Valley, Cal.
Land and Mining Investment Co.,	San Francisco, California.
Glenwood Heights Company,	Charleston, West Va.
Henry Coal & Coke Company,	Piedmont, West Va.

The Scandinavia Mining Co.,	Marble, Gunnison Co., Colo.
Montgomery Tunnel & Mining Co.,	Roseburg, Oregon.
Victor Mining Company,	Chicago, Ill.
The Little Eagle Gas Company,	Cornel, Hamilton Co., Ind.
The Beaver Valley Stone and Clay Co.,	New Brighton, Pa.
The Edgar Union Mining Co.,	Denver, Colorado.
Thompson Hill Mining Co.,	Clinton, Indiana.
The Butternut Land Co.,	Butternut, Wisconsin.
Pacific Mining & Milling Co.,	Great Falls, Mont.
Claney Creek Mining Company,	St. Paul, Minn.
Eureka Mining and Lumber Co.,	Grass Valley, Cal.
Cleveland & Aurora Mineral Land Co.,	East St. Louis, Ill.
Palisade Mining Company,	Minneapolis, Minn.
The Queen's Gulch Mining Co.,	Aspen, Colo.
The Miami Company,	Xenia, Ohio.
The Riverton Coal Company,	Wellston, Ohio.
Claremont Land Association,	Claremont, Va.
Savernake Steel & Tin Plate Co.,	Savernake, Va.
Challenger Mining Company,	Cumberland, Me.

MR. WILLIAM COULSON has resigned his position as General Mine Foreman for the Davis Coal and Coke Co., at Coketon, West Virginia, and has accepted a similar position for the H. G. Davis Coal Co., at Thomas, Tucker Co., West Virginia, where they have two mines.

MR. MATTHEW TAYLOR was appointed manager of the vast coal, iron, and railway interests of the late W. L. Scott, of Erie, Pa., by the latter's will. The estate is estimated at from $20,000,000 to $25,000,000.

THE LATE HON. WM. L. SCOTT.

Wm. L. Scott was a brilliant example of the highest type of self-made Americans. Left an orphan without means, early in life, he successfully fought his way upwards until he ranked among the wealthiest men of America, and had gained an enviable reputation as a clear-sighted and far-seeing business man. He was genial in his manners and enjoyed the respect and admiration of all his subordinates in his numerous business enterprises. He was a man of positive views, but he always satisfied himself that his views were right before he expressed them. He was charitable, and his charity knew no race or sect. He was patriotic, and in the dark days of rebellion, he not only raised and equipped an artillery company for the defense of the Union, but subscribed for Government bonds to half the extent of his fortune.

He was a man of great mental ability as is evidenced by the great fortune of $25,000,000 left by him, and the fact that the immense interests which this sum represents, whether in coal, iron, or railroads, were all thoroughly understood by him, and he held them all under his personal supervision. The portrait we publish with this article, is an excellent likeness, and no student of physiognomy will take it for the face of any but a shrewd, careful, and kindly man. In politics he was a Democrat, and was justly regarded as one of the ablest leaders of that great political party. He was the personal friend of Tilden, Cleveland, and other eminent Democratic statesmen. His social friendships were not confined to prominent men in his own party. His public life and services threw him in personal contact with many of the eminent Republican leaders, and they justly esteemed and enjoyed his personal friendship.

He was born in the city of Washington, on July 2d, 1828, of Virginian parentage. His father, Major Robt. Scott, was a graduate of West Point Military Academy in the class of 1812. His grandfather, Hon. Gustavus Scott, was a delegate from Maryland to the Continental Congress, and by appointment of President Washington, he was the first commissioner of public buildings in the City of Washington. Gustavus Scott was one of the three men who endorsed the Government bond, guaranteeing the payment of a loan of $300,000 borrowed from the State of Maryland, which was used to complete the National Capitol at Washington. This cancelled bond was one of William L. Scott's most highly prized historical papers.

Mr. Scott's parents both died while he was a mere boy, and as they were in poor circumstances he was thrown on his own resources. Early in his teens, he secured a position as page in the House of Representatives, and by his obliging and polite manners he made many friends among the congressmen. Gen. Charles M. Reed, who then represented the Erie district, was particularly interested in the bright young page, and at the close of the session took him to Erie, where he installed him as shipping clerk on his wharves. Gen. Reed at the time was one of the principal owners of shipping on the great lakes. For three years he worked as a clerk, fish merchant, and at any employment he could find, and in 1851, in connection with Mr. John Hearn, he established the firm that is now known as W. L. Scott & Co., but which was then known as Hearn & Scott. This firm was eminently successful and is now the largest coal producing and shipping firm in the world, owning thousands of acres of both Pennsylvania Anthracite and Bituminous coal lands, as well as thousands of acres of coal lands in Illinois, Iowa, and Missouri. The output of the mines owned by this firm aggregate about 10,000 tons per day.

At the time of his death Mr. Scott was the principal owner of the Youghiogheny Coal Co., and the Union Coal Co., of Pennsylvania, and the Spring Valley Coal Co., of Illinois, and he was a large owner in the Northwestern Fuel Co.; the Missouri Iron and Coal Co.; the Sligo Furnace Co., of Missouri, and the What Cheer Coal Co., of Iowa. He also recently purchased 2,000 acres of first-class iron ore land in Algona, Province of Ontario, Canada.

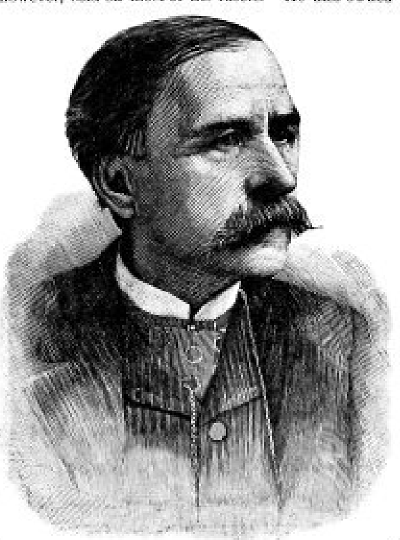
On Sept. 19, 1853, Mr. Scott was married to Miss Mary M. Tracy, a daughter of the late John A. Tracy. By the marriage Mr. Scott was placed in control of considerable property, and shortly afterwards secured an introduction to the New York Stock Exchange. There he became acquainted with the late Commodore Vanderbilt, and Hon. Samuel J. Tilden. These great financiers were quick to recognize his ability as a financier and manager, and from this time his progress towards great wealth and influence was rapid. He became interested in the construction and operation of railroads as well as in the mining of coal and the manufacture of iron, and at the time of his death, either as a director or president, he controlled more miles of railroad than any man in America, with the possible exception of Jay Gould.

Mr. Scott commenced his railroad career with the construction of the Erie and Pittsburgh Railroad in 1861-'64. In 1862 he built the extension of the Chicago, Rock Island and Pacific Railroad from Grinnell, Iowa, to the Missouri. This was the first railroad that had ever been built to the Missouri River. He was largely interested in the establishment of the Elevated Railroad in New York City. He was also one of the most prominent men in the construction of the New York, Philadelphia and Norfolk Railroad in 1884, and was its first president. At the time of his death he was the oldest and only living original director in the board of the Lake Shore and Michigan Southern Railroad. He was a director and member of the executive committee of the Chicago and Northwestern Railway, and a director in the following corporations: The New York, Philadelphia and Norfolk Railway; the Pittsburg, Cincinnati, Chicago and St. Louis Railway; the New Castle and Beaver Valley Railroad; the Michigan Central Railroad, and the Albermarle and Chesapeake Canal Co.

Mr. Scott was elected Mayor of Erie in 1866, and again in 1871. In 1884 he was elected to Congress, overcoming a large Republican majority, and made a record on the Chinese question.

His home life was particularly pleasant. The family mansion in Erie being very plain outwardly, but furnished inside in a luxurious and tasteful manner. He was a great reader, and his library is a particularly fine one. In religion he was an Episcopalian, but of very broad views, and the charitable organizations of Erie, of all denominations, had a warm friend in Mr. Scott.

He took great interest in farming and raising fine stock. His race horses, chief of which was Rayon d'Or, imported from Normandy at a cost of $33,000, were his special pride, and many of the best racers in the country were bred at his stock farm. He recently, however, sold off most of his racers. He also owned



HON. W. L. SCOTT.

a fine herd of blooded cattle, which were successfully exhibited at fairs in Northwestern Pennsylvania.

Mr. Scott is survived by his widow and two daughters, the elder of whom, Mary S., is the wife of Mr. Richard D. Townsend, a wealthy banker and broker, of Philadelphia, and the younger, Anna W., is the wife of Mr. Chas. H. Strong, president of the Union Coal Co.

In his character there was nothing false or superficial. He was plain in his tastes and outspoken in his language. In fact, "he was a man."

DIESCHER PATENT COAL WASHER.

For many years past the comparative scarcity of first-class coal has occasioned the frequent use of washing jigs and other apparatus for the purpose of utilizing inferior coals by removing the slate, pyrites, and other impurities they contain. The have been especially useful in improving the quality of coke for blast-furnaces and other purposes. All of these machines operate on the principle that if the coal, by crushing or otherwise, is reduced to parts of approximately one size, and with the impurities detached from the coal, the latter can be separated from the former by agitating the mass in water, and allowing the different parts to arrange themselves according to their specific gravities. Iron pyrites will form the lowest stratum, slate will come next, and the coal will rise to the top, whence it can be carried to its place of storage.

A well known type of washing machine used in Europe, and frequently copied in this country, is a jig consisting essentially of a box containing a screen on which the raw coal is placed; a reservoir for water under the screen, and a compartment back of the latter containing a piston or plunger with a reciprocating motion, which communicates its oscillations to the water, and thence through the screen to the coal. One great defect of this type of jig has been long felt, but never as yet fully remedied, notwithstanding numerous devices for the purpose; viz.: the imperfect and unequal action of the water at different parts of the screen, due to the location of the plunger at the back of the screen, thus reducing the effectiveness of the separation, and the quantity and quality of the washed product.

The Diescher Patent Washer effectually overcomes this defect by placing the plunger or piston immediately below the fixed screen, and making it equal in size to the latter. This arrangement renders the machine not only more effective, but much stronger, more compact, of simpler construction, greater washing capacity, and increased durability. The accompanying engraving represents two Diescher boxes or washers operated by one shaft on which the eccentrics are so arranged that the plungers balance each other. Each box consists of heavy and rigid cast-iron standards and cross-pieces to which are bolted 4'' planks, planed, tongued, and grooved so as to form a water-tight compartment. At the top of this compartment is a screen 4 feet square, while within it and below the screen is the iron plunger mentioned above. This plunger is of strong and simple construction, and is connected with the eccentric straps by two stout suspension rods having bronze bearings at the upper end. The straps receive their motion from two eccentrics keyed to the main shaft, which is driven by the pulley shown on the left.

The stroke of the plungers varies with the size and specific gravity of the coal to be washed, the larger the coal the greater the stroke required. For washing slack in Western Pennsylvania, they usually have a stroke of 1½ inch, while the eccentric shaft makes 60 to 80 revolutions per minute.

In the center of the front edge of the screen is seen a small cast-iron box called the slate valve. It has two rectangular openings parallel to the sides of the washer and closed more or less by slides operated by a hand-wheel and screw. All impurities in the coal pass through these openings into the triangular compartment seen in front of the washer. From time to time as the compartment becomes filled, the slide-valve at the bottom is raised by the lever, so as to allow the escape of the slate and other impurities. When there is no suitable place for these below the level of the washer, the latter is so arranged that the impurities are continuously discharged into an elevator which carries them either to a bin or a car. Below the water reservoir is a long casting carrying a valve which serves to allow the escape of water when the washer is emptied, or of fine heavy impurities which pass the screen and plunger.

One of the principal parts of a washer is the screen. In the Diescher jig it is made effective and durable consisting of a strong wrought-iron frame carrying a series of hardened brass wires placed parallel and very close to each other, and held by small copper wires protected by solder. This arrangement allows the easy passage of water through, and of coal along the screen, while preventing very nearly all solid material from passing through it.

The feed-water enters through a three-inch pipe at the back of the washer and between the screen and the plunger. This arrangement helps to keep the water in the box from excessive agitation—an object also aided by the equilibrium chamber between the two boxes, and by the alternating motion of the two plungers where two or more boxes are connected. In the case of a single box there is a larger equilibrium chamber at one side, and the driving pulley is weighted to balance the weight of the plunger. This machine is so rigid and self-contained that it can be set on almost any kind of foundation, although there are advantages obtained by having solid supports.

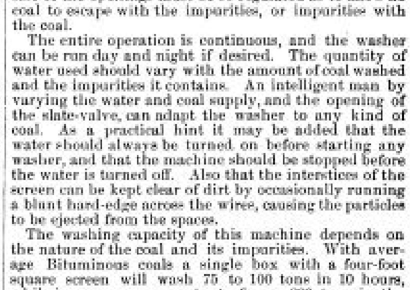
The operation of washing coal is as follows:

The coal is occasionally crushed and classified before washing. It is then carried from a bin or elevator to the back of the washer where it falls on the screen, over which it is at once spread by the oscillating water. The pure coal rises to the top as it advances along the screen, and on reaching the front of the washer, passes through the discharge spout to a receiving elevator or bin. Sometimes a close mesh screen, similar to that of the washer, is placed in front of the spout to drain off the water from the washed coal.

The slate, pyrites, and other impurities sink down to the screen under the action of the water and gravity, and when they reach the front of the screen, they are discharged through the side openings of the slate-valve into the compartment in front of the washer. The size of the openings must be so regulated as to allow no coal to escape with the impurities, or impurities with the coal.

The entire operation is continuous, and the washer can be run day and night if desired. The quantity of water used should vary with the amount of coal washed and the impurities it contains. An intelligent man by varying the water and coal supply, and the opening of the slate-valve, can adapt the washer to any kind of coal. As a practical hint it may be added that the water should always be turned on before starting any washer, and that the machine should be stopped before the water is turned off. Also that the interstices of the screen can be kept clear of dirt by occasionally running a blunt hard-edge across the wires, causing the particles to be ejected from the spaces.

The washing capacity of this machine depends on the nature of the coal and its impurities. With average Bituminous coals a single box with a four-foot square screen will wash 75 to 100 tons in 10 hours, while in some cases an output of over 200 tons in the same time has been attained. The cost of washing will also vary according to circumstances, but in every case



it will be greatly inferior to the benefits derived from the increased value of the coal or coke and the saving of freight on the eliminated impurities. An engineer, superintendent, and one assistant can operate a washing plant of 800 to 1,000 tons capacity in ten hours, while the cost of maintenance and repairs is very slight where the plant is properly constructed.

The Diescher Washer is manufactured by the Scaife Foundry and Machine Co., Ltd., of Pittsburgh, Pa. It has been in successful operation for ten years, and at the present time is to be found not only in all sections of this country, but in Mexico, British Columbia, and Australia, where, owing to its simplicity, it has been erected and operated by men who had previously never seen a coal-washer.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED 1881. INCORPORATED 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.

THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed

STEAM PLANT AND ENGINES AT COLLIERIES.

AT the recent meeting of the American Institute of Mining Engineers, Hon. Eckley B. Coxe made a statement that is worthy the consideration of every colliery owner and colliery manager, when he said that the engines and steam plant used at coal mines were wasteful and tended to greatly increase the the cost of coal production. That every cent or fraction of a cent added to the cost of production means a corresponding decrease in the narrow margin of profits is evident to every man, and the fact that colliery managers have for years gone on erecting wasteful steam plants and engines, does not tend to increase their reputations for progressiveness gained in other lines.

The probable reason for this, lies in the fact that the excessive amount of fuel consumed is not purchased direct, but is produced on the ground. Nevertheless its cost of production, and the cost of handling an excessive amount of coal and of disposing of an excessive amount of ashes must be considered. Coal is coal, whether it is in the shape of lump coal, or culm, or slack. It has a money value because it cost money to produce, and it brings money in the market. Every ton of salable coal burned costs the operator just as much as he would get for it if he sold it, for he not only loses the cost of its production but the small margin of profit he would make on it, if he sold it, as well.

Besides, as stated before, he pays an excessive amount for labor in burning it, and in removing the ashes. If he does not burn salable coal, these items of expense still obtain.

Notwithstanding the great improvements that have been made by the skill and ingenuity of inventors and machinists, the average colliery steam plant is almost as primitive as were those of thirty or forty years ago, and very few approach anywhere near the possibilities in efficiency and economy. It is doubtful if there is any other portion of a colliery plant in which so little attention has been paid to improvements. The consequent inefficiency of steam plants cannot rightfully be blamed on the fireman at all times, for it is oftener due to a want of proper information and of good judgment in the general construction of the plant.

Mr. William Harrison Bailey, in his excellent little work entitled "Making and Using Steam," says:

"In order to obtain the greatest success in constructing a steam plant, a man must not only possess mechanical ability and intelligence to understand the requirements of the case, but he must have a large and varied experience in testing and observing the practical operation of all the different types and designs of the several parts that go to make up a complete plant; also, good judgment and experience to enable him to properly proportion and connect them for the service to be required. All this cannot be learned from books and drawings in an office, but must be acquired by visiting and making tests at many different plants, running under different conditions, with different kinds of fuel and water, and varying draughts. A special investigation by such an expert, together with the guarantees of makers, properly written to contain discounts or forfeitures, in case of failures to fulfill stipulations, can hardly fail to secure the best and most economical apparatus for any purpose, and save to those who pay the bills an amount of money and annoyance little imagined by the uninitiated. It is not so much what a man knows, as what he thinks of at the right time, that makes him valuable; and, in order to think of the right thing at the right time, he must be in constant practice and familiar with the details of his business or profession."

The boiler is the fundamental apparatus of every steam plant, and requires the most careful consideration in purchasing, and the most intelligence, experience, and skill in its management.

The three essentials in a good boiler are safety, durability, and economy. The first of these is more generally observed, we are glad to say, than either of the others, but they are entitled to consideration also, and they are features that should be secured in every colliery steam plant. The old-time cylindrical boiler and primitive furnace that is at present generally used is wasteful and must make way for the more effective and more economical tubular boilers with improved grates and furnaces. But, even if the cylindrical boiler, under certain conditions that may exist, is the cheaper and more economical, there is no reason why the furnace arrrangements should not be improved on.

There are numerous patented grates, furnaces, and smokeless settings for boilers, which are far superior to the old-time arrangements, but boiler makers do not care to recommend them for fear they will be required to furnish them, and be held responsible for their performance, without any extra compensation.

Some of the devices are really valuable for their simple and scientific methods of regulating the admission of air in correct proportion to secure good combustion, and are worthy of careful investigation.

This is especially true of mechanical stokers, which admit of the profitable use of coal and coke dust screenings, and other cheap fuels.

Quoting again from Mr. Bailey's excellent little work, we have the following advice, which is well worthy of attention:

"Fires should never be regulated entirely by the amount of air admitted beneath the grate, nor by the amount of coal shoveled into the furnace, but by air ducts, terminating on top of the fuel, and above all a damper in the smoke flue, regulated automatically by the pressure of steam carried in the boiler. Any good damper regulator will repay its cost many times in the saving of fuel and repairs to the furnaces. Excellent ones can be purchased for $75 or $100, and it is money well expended.

"The construction of a furnace, including the style of grates, should, of course, be adapted to the kind of fuel to be burned, although to some extent, openings for the admission of air may be made adjustable, so that, by careful observation and experimenting, a fireman may burn several different kinds of fuel in the same furnace economically."

The traveler through the Anthracite region cannot help noticing, after dark, the beautiful blue flames playing around the tops of the boiler stacks, and rapidly destroying them. These blue flames are evidence that coal is being shamefully wasted, and that the carbonic oxide, which by intelligent firing and the use of proper appliances could be utilized, is allowed to waste. In the Bituminous fields the combustible gases are allowed to escape in the same way, but they cannot be so plainly seen on account of the dense smoke.

We have mentioned but a few of the many wasteful methods employed, but they are enough to convince any intelligent man that there is room for improvement, and abundant room. Some few operators have realized this and they are arranging their steam plants so as to secure the best results with the least cost, and we hope many more will follow their example.

The average engines used at collieries are but little better, as far as economy is concerned, than are the boilers. They require an excessive amount of steam to perform their work and this means excessively large steam plants with all the corresponding increase in cost of erection, maintenance, and operation. In conversation with a prominent builder of high grade engines of great merit for efficiency and economy, a representative of this journal asked him why he did not try to introduce his engines for colliery use. His reply was, "My experience with colliery owners has been that they are satisfied with any old rattle-trap, no matter if its cost of maintenance and operation per year is excessively high, and they will not pay a small increase in the initial cost due to better workmanship and economical devices."

This experience had led the engine builder to believe that the colliery owners were either making tremendous profits, or they were very poor business managers, and it is hard to blame him for this belief, notwithstanding we know the profits to be small and the colliery owners to be men of superior business ability.

We were recently told of one European colliery where the coal burned under the boilers was charged to the colliery at the *market price* and the result was, that within a year things were so changed that a decided saving was affected, and this saving was so apparent that a number of neighboring collieries adopted the same plan. If this was a good plan in Europe with cheap labor, and lower prices for machinery and materials, it ought to be a better plan in America.

THE SCHOOL OF MINES.

THE announcement of The Colliery Engineer School of Mines has been received with great favor by persons interested in the advancement of education among miners in all parts of the country. Already a large number of students are enrolled, and every mail brings new enrollments and inquiries.

Inquiries have been sent in regarding the standard of the diploma to be given those who finish the course, and to meet such inquiries we would state that the diploma will not be granted until the student is capable of passing any examination, required by the various State governments.

Each student will be kept on in the several departments till he thoroughly understands the branches taught, no matter how long a time it takes. If he can get through in three months, it will be all the better, but if it takes him three years, owing to lack of time, and of earlier advantages, we can assure him that he will not be given the diploma till he proves his fitness for it. Therefore, it is within the power of every man who really desires educational advancement to obtain it.

The first papers will be ready and will be sent out on the first of November. Students can begin at any time, and all inquiries will be promptly answered.

EDITORIAL NOTES.

MR. C. C. Woodson, State Mine Inspector of Missouri, in a report to the Commissioner of Labor concerning a violent explosion in Mine No. 7, of the Keith and Perry Coal Co., at Rich Hill, on the 7th ult., states that the mine was well equipped both outside and inside, and that ventilation was produced by a ten-foot fan designed to run up to a speed of 150 revolutions per minute, and to furnish about 40,000 cu. ft. of air.

The explosion occurred after the miners had quit work, and there were but two shot-firers in the mine, one of whom was killed, and the other seriously injured. The eight mules in the mine were all killed. If all the miners had been in the mine at the time of the explosion, it is probable that 60 or more men would have been killed.

Mr. Woodson found from personal examination, and an interview with the injured shot-firer, that all the shots on the South side of the hoisting shaft, and those in six rooms on the two West entries on the North side had been fired. Three of the latter were located on the back entry and three on the front entry. He is of the opinion that one or more of the shots in the back entry were "blown out" or "cyclone" shots, the fire from which ignited a keg of powder in a box near by.

The explosion of the powder contained in this box, added to the flame from the shot, carried the fire to two or three boxes containing powder which were distant probably 200 to 250 feet and located in a small entry turned off near the north end of the mule stable. This, in turn, caused the explosion of the powder contained in five or six boxes, located in a passage-way connecting the mule stable with the first east entry on south side of shaft. Doubtless the explosion of the powder in the last-named boxes brought about the greatest damage and killed the mules. It would be well to state just here, that this mine is very dry and dusty, and Mr. Woodson had no doubt but that the coal-dust suspended in the air, which had been set in motion by previous shots, played quite an important part in the disaster by adding fuel to the flames.

The evidence taken before the coroner's jury goes to show that the mine was in good condition prior to the explosion, and that there was no explosive gas in the mine, and that the company employed a fire boss to examine each working place every morning before any one was permitted to enter. Mr. Woodson considers that entirely too much powder was used in the mine in proportion to its production, and severely condemns the practice of careless miners having their powder-boxes within 40 or 50 feet of the faces. He advocates the passage of a law restricting the amount of powder to be taken in by each man to 10 or 12 lbs., and further recommends that a sufficient interval between the firing of shots be given, to allow the dust raised by the previous shot to subside or be carried off in the ventilating current.

JUDGE WHITE, of Allegheny County, recently rendered two important decisions affecting coal mines in oil and gas producing districts.

Inspectors Blick, Louttit, Jenkins, and Duncan, of the First, Second, Fifth, and Seventh Bituminous Districts of Pennsylvania, filed a bill in equity against J. D. Sauters, owner and operator of a coal mine in North Fayette Township, Allegheny County, to compel him to cease operating it on account of the oil wells bored through it and the accompanying danger of escaping gas. While Judge White commended the action of the Inspectors as a very proper one, he did not think, from the evidence, that there was any immediate danger, and refused to interfere at present. However, he allowed the application to stand open for further action of the court, if at any time it was deemed necessary.

J. B. Robbins, owner of another mine in the same county, asked for an injunction against the Wheeling Gas Company, J. M. Guffey, and others, to restrain them from boring oil or gas wells through his coal. Robbins owned the coal under land of which the defendants had leased the oil and gas rights. The plaintiff maintained that the defendants had no right to bore wells through his coal, and that to do so would damage the coal and endanger his property and the lives of his employes by reason of gas escaping into the mines. The defendants asserted there would be no danger, and that they had as much right to bore for oil as the plaintiff had to dig for coal.

In his opinion Judge White said that the owner of the coal must suffer loss if it is allowed. On the other hand, the owner of the land may have mineral wealth below the coal vein of more value than the coal. He was of the opinion that the owner of the land should have a right of way through the coal, but not to an indiscriminate extent. He refused the preliminary injunction asked for as to the wells producing or in process of boring because there was no immediate danger of loss or damage to the plaintiff. They do not interfere with the mining of coal at present and may not for years and probably never. The damage caused by a hole through the coal was merely nominal. If a block of coal must be left around the pipe it could be compensated for. He thought that with proper appliances the wells could be bored with all reasonable safety to the mines and miners, and when abandoned can be securely plugged to prevent danger thereafter. He would not, however, concede the defendants' right to have as many wells as they thought proper. It might work irreparable damage. In consequence he granted an injunction to restrain the defendants from boring new wells or proceeding with any except those now below the Pittsburgh seam of coal. They were also to give a bond in the sum of $10,000 to the plaintiff to secure damages and as security that they would use all possible care, etc., in guarding against damage to the plaintiff.

THE Biennial Reports of the Inspectors of Mines for the State of Iowa, for the two years ending June 30th, 1891, have been submitted to the Governor, and are now in the hands of the printers. They are the most complete reports that have ever been issued by the Inspectors of Iowa, and show that Messrs. Binks, Gildroy, and Thomas have been vigilant and thorough in their work.

A summary of the statistics shows the following interesting figures:

Average No. of Mines in operation	362
Number of tons of coal produced	7,702,483
Average number of miners employed	7,665
Average number of other employes	1,877
Average price paid per ton for mining	63⅝ cts.
Total amount paid for labor	$8,192,294.22
Average selling price per ton at mines	$1·413
No. of fatal accidents	43
No. of non-fatal accidents	180

These figures show that there were 809 tons of coal mined per employe; 179,127·5 tons mined per fatal accident; and 42,791·6 tons mined per non-fatal accident.

THE expenses of the Board of Examiners, who recently examined applicants for the position of Inspectors of Mines for the First and Second Anthracite districts were $910.20. This includes advertising, stationary, and postage. This is not a great cost when it is considered that members of the Board reside at different points in Luzerne County, and that the examination occupied several weeks.

The Anthracite Trade.

The Anthracite trade during the past month was active, and this month opens with the markets in good condition and the demand fully up to the supply for all but the small steam sizes. Most of the coal now being disposed of goes West, and to the line trade. Shipments to tide water are light, and the result will be that Eastern markets will be in excellent shape when navigation on the Lakes closes, which will naturally be the case in a week or two. Circular rates are firmly maintained by the companies, and the increased demand has stiffened the prices of independent operators. The advent of cold weather will still further increase the demand and enhance prices. The output for October has been considerable in excess of the allotment, and at a meeting of the sales agents held in New York on the 28th ult., the output for November was placed at 4,000,000 tons, which practically means no restriction.

The Bituminous Trade.

The Bituminous coal trade is in excellent condition. Prices are firm, even though shipments for the past six months have been largely in excess of those of last year. While transportation facilities have been fairly good they have not been up to the demand. Contract coal, however, has been supplied as fast as called for. The outlook for the trade is good for the entire winter. The only disturbance to the general harmony prevailing, of any account, is the strike of the railroad miners in the Pittsburgh region, and this is on its last legs.

The Coke Trade.

The coke trade continues in fair condition though prices continue the same as they have been for several months past, and a slight restriction in production is adhered to. The Connellsville *Courier*, of the 22d ult., says: "Quite a number of new ovens are nearing completion. It is probable that the new year will see the Connellsville region grown to the magnificent magnitude of 18,000 ovens. Cars are in good supply. The strike at the Pittsburgh district coal mines has thrown a great many coal cars idle, and, in case of shortage, these could be utilized. There is a car famine in the West, but no serious trouble is feared in the coke region. If the coal strike above alluded to continues long, the coke operators may profit by it. Already the latter have received inquiries from dealers in coal. The coke operators do not, as a rule, sell coal, but in the present state of the coke market a coal trade at fair prices won't be despised by any of the coke men. The only drawback is the fact that the Connellsville region is outside the 40-mile radius, and the freight on her coal will be higher."

OBITUARY.

E. W. WESTON.

Mr. E. W. Weston, ex-General Land Agent, and ex-Superintendent of the coal department of the Delaware & Hudson Canal Co., died at his residence on North Main Avenue, Scranton, on the 28th ult., in the 68th year of his age.

Mr. Weston was born in Salem, Wayne Co., Pa., on December 5, 1823. His early years were spent on a farm and in teaching school at Salem. In 1884 he removed to Honesdale, and entered the office of his uncle, John Torrey, who was then the agent for the principal land proprietors, and the most active and prominent land surveyor in Northeastern Pa. In 1857 he removed to Carbondale, and took charge of the land and mine surveys of the Delaware and Hudson Canal Co., and in 1861 his office and residence were removed to this city. In 1874 he succeeded the late Thomas Dickson as Superintendent of the coal department of the company, which at this time was being rapidly developed into its present large proportions. He gave his personal attention to the opening of new collieries, the purchase and development of lands and the erection of breakers. In 1884, the extension and expansion of the business of the company made it necessary to divide into two departments the work which had been under Mr. Weston's control. In the division Mr. Weston retained control of the real estate department as General Land Agent, Mr. A. H. Vandling being made Superintendent of the Land Department. Mr. Weston continued in the position of Genl. Land Agent till February last, when failing health compelled him to withdraw from the active management of the department. In addition to his official connection with the D. & H. Co., Mr. Weston was largely interested in many of the other industries and corporations of Scranton. At the time of his death he was President of the First National Bank; Chairman of the Weston Mill Co.; President of the Northern Coal and Iron Co.; and Vice-President of the Dickson Mfg. Co. He was also connected with a number of lesser mining and manufacturing enterprises, both in and out of Scranton.

He was a man of broad intelligence, keen business sagacity, fertile in resources, and tireless in his industry. He was a prominent member of the Providence Presbyterian Church, and was a large contributor to it. He was married in Honesdale on June 4, 1852, to Miss Susan S. Moore, who with a daughter and son, Miss Caroline S., and Charles S., who succeeded his father as Genl. Land Agt., survive him.

Some Great Coal Hoisting.

The Lehigh & Wilkes-Barre Coal Co. since general superintendent E. H. Lawall has assumed control, with general inside superintendent Morgan R. Morgan as his able assistant, runs along very smoothly, and the condition of the workings is such that they are able to work the extensive collieries to their utmost capacities. There have been no serious accidents to record. Such a record shows that everything in and around the collieries is properly systematized, which can only be accomplished by the selection of competent foremen both in and out of the collieries.

The celebrated Nottingham Colliery, Plymouth, inside foreman William Leckie, and outside foreman George Connor, made another remarkable run yesterday. They hoisted 1,313 cars in nine hours. J. B. Hammond, the driver boss, made things hum below the surface. The engineers who handle the throttle valve and brake, and who have made such remarkable records in hoisting are William Jenkins and Louis Wagner. At No. 11 colliery of the same company, yesterday, in a day of nine hours, 993 cars were hoisted. Such a showing as this must assuredly make the present management feel proud.—*Wilkes-Barre Record.*

The Providence Steam Engine Co., Providence, is changing the drums of the Moore boilers (which were recently set up at the Narragansett Electric Light Co.'s station by the National Water Tube Boiler Co., of New Brunswick, N. J.) to the Babcock & Wilcox system. The Babcock & Wilcox Co., of New York, has the contract for the alterations, which have been delayed until the job of putting in of 1120-horse power of its own boilers was completed.—*Boston Journal of Commerce.*

ANTHRACITE COAL STATISTICS.

Statement of Anthracite coal shipments, for month of Sept., 1891, compared with same period last year. Compiled from returns furnished by the Mine Operators, by John H. Jones, Chief of Bureau of Anthracite Coal Statistics.

	Sept. 1891.	Sept. 1890.	Difference.		For Year 1891.	For Year 1890.	Difference.	
From Wyoming Region, - -	1,741,272·08	1,788,650·14	Dec.	47,378·06	15,020,092·01	13,151,724·07	Inc.	1,868,367·14
From Lehigh Region, - - -	531,507·09	585,488·04	Dec.	53,980·15	4,514,357·11	4,627,318·09	Dec.	112,960·18
From Schuylkill Region, - -	1,060,624·13	1,053,939·02	Inc.	6,685·11	8,701,823·11	7,616,719·15	Inc.	1,085,103·16
Total - - - - - - -	3,333,404·10	3,428,078·00	Dec.	94,673·10	28,236,273·03	25,396,762·11	Inc.	2,840,510·12

The stock of coal on hand at tide-water shipping points, Sept. 30th, 1891, was 568,833 tons; on August 31st, 1891, 648,900 tons; decrease, 80,067 tons.

THE AMERICAN INSTITUTE OF MINING ENGINEERS.

A Successful and Enjoyable Meeting at Glen Summit, Pa.

The sixtieth meeting of the American Institute of Mining Engineers was called to order on Tuesday evening, October 6th, in one of the large parlors of the Glen Summit Hotel, by Hon. Eckley B. Coxe, one of the Vice-Presidents, and Chairman of the Local Committee.

Mr. Coxe welcomed the Institute to the Anthracite Region in a brief address, which was responded to by Mr. John Birkinbine, President of the Institute, who briefly, and in an interesting manner, reviewed the formation of the Institute at Wilkes-Barre in 1871, and referred to the development of the coal fields of America, and quoted statistics from an advance bulletin of the U. S. Census.

On behalf of the *Deutscher Verein Eisenhuttenleute*, Dr. Rossiter W. Raymond, Secretary of the Institute, presented to the Institute a magnificent testimonial of the appreciation the German engineers felt for the hospitality extended them by the Institute during their visit to America last fall. The testimonial was in the form of a massive volume bound in leather and metal. It contained a beautiful title page in which black and white formed a work of art that more resembled a fine steel engraving than pen and ink work. The thanks expressed were engrossed on handsomely illuminated pages of parchment and were in both the English and German languages. Taken as a whole, it is doubtful if a more artistic and beautiful piece of similar work was ever produced, even in the mediaeval days of illuminated text.

At the close of Mr. Raymond's remarks, he read the applications for membership from a large number of engineers, representing almost every state in the Union and seventeen different foreign nations, all of whom were unanimously elected to membership.

The following papers were then read by title only:

"Electricity in Mining as Applied by the Aspen Mining and Smelting Company," by M. B. Holt, Aspen, Colo.; "Electric Locomotives in German Mines," by Karl Eilers, Berlin, Germany; "The Manufacture of Liquid Sulphurous Acid in Upper Silesia," by Karl Eilers; "A Chinese System of Gold Mining," by Henry Louis, Singapore, Straits Settlements; "A Survey of the Planches de Plata Mine, Sonora," by Henry M. Stanley and Henry O. Flipper, Nogales, Arizona; "Co-Ordinate Surveying," by Henry O. Flipper; "Cordwood in the Matting Blast Furnace," by Herbert Lang, Mineral, Idaho; "The Bendigo Gold Field," by T. A. Rickard, Allemont, Isere, France; "Apparatus for the Manipulation of Iron and Steel Plates During the Process of Finishing," by Gram Curtis, Pittsburgh, Pa.; "The Handling of Ingots and Moulds in Bessemer Steel Works," by Gram Curtis; "Tandem Tanks for Hoisting Water from Flooded Slopes," by J. H. Bowden, Wilkes-Barre, Pa.; "The Utilization of Anthracite Waste by Gasification in Producers," by W. H. Blauvelt, Philadelphia, Pa.; "The Mining Resources of Honduras," by W. A. Thacher, Leadville, Colo.; "A New System of Ore Sampling," by H. L. Bridgman, Blue Island, Ill.; "The Iron Ores of Danville, Pa., With a Description of the Longwall Method of Mining Used in Working Them," by H. H. Stock, South Bethlehem, Pa.; "Mining at Guanaguato, Mexico," by W. P. Blake, Shullsburg, Wis.; "The Determination of Nickel in Nickel Steel," by Albert Ladd Colby, Bethlehem, Pa.

Prof. R. H. Richards of the Mass. Inst. of Technology then read a paper entitled

"A HAND TELESCOPE FOR STADIA WORK."

He illustrated it with two telescopes fitted up for the purpose. This is a discovery by Prof. Richards of a device for the measurement of distances by the stadia method, and it possesses an advantage over the old method as it can be applied to a hand telescope, and it is much simpler than the ordinary stadia method.

Over the object glass of the telescope Prof. Richards fixes an achromatic prism so as to cover one-half of the lens, one edge of the prism coinciding with the diameter of the lens. A graduated rod is used. In sighting at this rod two images are seen standing parallel. By rotating the glass the images are made to overlap each other, and the graduations as read off the rod shown by the overlap, gives the distance from the front of the glass to the rod. With a rod specially graduated the distances may be read off the rod; with an ordinary rod it may be determined by multiplying the reading by a constant. By careful tests up to distances of 800 feet, Prof. Richards had found that the maximum error did not exceed 0·1%. In reply to inquiries, Prof. Richards said this system of measurement, as far as the principle was concerned, should be accurate for any distance, and its range was only limited by the visual power of the observer. In commenting on this discovery, Mr. Coxe said that like many other valuable discoveries it was remarkable on account of its simplicity, and it was marvelous that its had not been discovered sooner. Dr. Raymond added that it was not the first unexpected result obtained by the use of the prism. Some years ago when Bunsen announced his great discoveries with the spectroscope, Prof. Richter, of Freiburg, with a small toy telescope and a prism made of five pieces of glass, filled with carbon bi-sulphide, discovered a new element called indium.

Mr. F. H. Newell, of Washington, D. C., then read a most interesting paper on

"STREAM MEASUREMENTS AND RESULTS OBTAINED BY THE U. S. GEOLOGICAL SURVEY."

This paper described in detail the extensive and important measurements now being made by the U. S. Geological Survey to determine the water supply of the country. It was illustrated by a series of charts showing the volume of water flowing in various western rivers each day for the years 1889 and 1890, and some data extending into the present year. Mr. Newell exhibited the instruments used, which were very similar in their principles to anemometers. He described their practical use, and showed an electrical machine that accurately recorded the revolutions of the gauge used in deep waters below the range of vision. In explaining the charts, Mr. Newell spoke of the Yellowstone and Missouri as typical Northern rivers, and took from the charts the following data:

On January 1, 1890, the discharge of the Yellowstone, at a point ten miles below the Yellowstone National Park, was 500 cu. ft. per second; in February it had risen to 600 cu. ft.; on April 5 to 1,000; on May 1 to ,000; on May 31 to 12,000. During the month of June it fluctuated between 12,000 and 10,000 cu. ft. per second. In July it began to fall gradually until December, when the flow was about the same as in January. The plotted lines showing the rise and fall for 1889 showed about the same variations, but the volume of water was at all times less than at the same date in 1890. The Missouri showed proportionately about the same results. Melting snow in the mountains formed the principal source of supply for both these streams.

The Salt River, in Arizona, a tributary of the Gila, was taken as a typical Southern river in which rain forms the principal source of supply, but little water coming from snow, and in consequence it is subject to sudden floods, the maximum volume occurring in winter. Mr. Newell showed by his chart the great flood of some months ago that caused the overflowing of the arid plain and formation of the inland sea which attracted so much public attention at the time. He stated that evaporation was so rapid in this region that the newly formed lake was now almost dried up.

He next described the rise and fall of the Rio Grande, which was measured at three places in Colorado above the big canals in New Mexico, and at El Paso in Texas. Owing to the large amount of water taken out for irrigating purposes, the flow in New Mexico is no larger than in Colorado. At El Paso the river is nearly dry at certain times of the year owing to the use of large amounts of water for irrigating purposes further up the stream.

Dr. Raymond in commenting on this paper, with the iconoclasm natural to scientists, completely knocked the romance out of the Nile, by stating that he visited it while abroad and found it was not the remarkable river we had been taught to regard it. It was remarkable only in the fact that it had no tributary for 1,600 miles of its length, but its rise and fall could not be compared in point of variation with a number of American rivers, and it does not carry in suspension anything like as large an amount of alluvial matter as the Mississippi does. He commended, however, the admirable system of the distribution of the waters of the Nile, and said that during the time of low water, scarcely a drop of the Nile's volume reaches the Mediterranean.

Mr. Coxe stated that the question of water supply was an important one in mining operations, and commended the simple but thorough system as illustrated by Mr. Newell of obtaining the record of volume all the year round. He stated that similar records should be obtained by engineers before the erection of metallurgical works or the opening of mines. Mr. Birkinbine briefly outlined the report of Major Raymond, of the U. S. Engineers, on the recent disastrous floods in the Susquehanna and Juniata Rivers, and endorsed his conclusion that the preservation of timber by the State of Pennsylvania was the only way to prevent their recurrence. Mr. B. E. Fernow indorsed Major Raymond's conclusion also, and cited the action of the recent Irrigation Congress, in Salt Lake City, as evidence that Western men were recognizing this fact.

In reply to questions Mr. Newell stated that observations of the rainfall were being made by volunteers in various parts of the country, under the auspices of the Weather Bureau, but so far the results showed that the amount of rainfall in any one year was not proportional to the volume of water in the rivers.

As the hour of adjournment had arrived, Mr. Birkinbine announced that he would entertain a motion to adjourn and the members and guests left the room unanimously agreeing that the Tuesday evening session was a most interesting and instructive one.

WEDNESDAY MORNING SESSION.

The rain was falling steadily on Wednesday morning, and the outlook for fair weather during the day was not promising, therefore it was agreed to hold three business sessions instead of but two, and to forego the drive to Bear Creek as the guests of Mr. Albert Lewis.

The first paper read was entitled

"THE FLORENCE OIL FIELDS, COLORADO;" BY GEORGE H. ELDRIDGE, U. S. GEOLOGICAL SURVEY.

This paper ably, and in an interesting manner, described an oil field that supplies considerable petroleum, the major portion of which is consumed in Colorado.

It was the first published treatise on the geology of the district, and according to Mr. Eldridge, the oil-bearing zone occurs in the lowest strata of the Montana group of cretaceous rocks, which is here about 4,000 ft. thick, and is known as the Pierre formation. The strata in this field form a synclinal or basin, on one side of which all the productive wells so far opened have been located. The developments have so far been confined to the neighborhood of Florence, and all wells are located within a radius of three miles from the town, and the most productive wells are in the town limits. The field is estimated to be about 14 miles long and 8 miles wide, and as the rocks have been but slightly faulted, if at all, prospecting operations are easy and simple. The oil zone occupies about 1,900 feet in the Pierre formation and the most productive wells are about 1,150 ft. below its top or 2,000 ft. below the surface. Below this there is about 350 ft. of barren ground, and then more oil is found. There is about 350 ft. more of barren ground, and below this, at the bottom of the zone small quantities of oil are found. The wells yield from 5 to 250 barrels per day, and 57½% of all the wells bored have proven productive. During 1890 the average daily yield of the district was about 1,200 barrels per day.

In the discussion of this paper, Mr. Newell stated that the conclusions of scientific men concerning the prospecting of petroleum fields have always been ignored by practical men, and the result has been that by blind prospecting, oil has been found in localities most unpromising, and where according to geological rules it should not have occurred. He further stated that the results obtained by the development of the Florence field were such as to render impossible the deduction of trustworthy conclusions on the subject.

The next topic for discussion was

"THE PRACTICAL USE OF CONCENTRATED IRON ORES."

This discussion was opened by the reading of a paper on "Practical Results of Concentration at the Croton Magnetic Iron Mine," by Mr. Hoffman, followed by Mr. N. M. Langdon's paper on the "Use of Magnetic Concentrates in the Port Henry Blast Furnaces." Mr. Hoffman detailed the methods in vogue at the Croton Mine and stated that the total average cost of mining and concentrating one gross ton of 68% ore from 2·2 tons of 38% ore was but $1 95 per ton. This statement was greeted with loud applause. These concentrates, Mr. Hoffman further stated, have been used in various open hearth and blast-furnaces and have given excellent results.

Mr. Langdon stated that the use of magnetic concentrates at Port Henry had practically demonstrated that there is no difficulty in using at least 80% of high grade concentrate in the blast-furnace, and there is an economy of fuel beyond that which may be due to an increase of iron in the mixture, and this is especially the case when a large percentage of concentrate is used.

The discussion of these papers was opened by Dr. Raymond, who read a communication from Mr. E. K. Landis, who claimed that it was wrong to determine the total iron contents in the tailings from magnetic separators as a basis of judgment on the work of the separating machine. Many of the silicious minerals which go into the tailings, such as hornblende, pyroxene, mica, and apatite, contain iron, but being non-magnetic, it is impossible for the magnets to catch them. Therefore, it is unfair to charge all the iron in the tailings against the machine. There is, however, no satisfactory method of determining the amount of magnetite in these tailings.

Mr. Birkinbine read a letter from Mr. Woodbridge on the same subject, in which the writer stated that he had found, by experience, that all the iron minerals in Old Bed ores were attracted by the magnet when ground fine enough to pass through a 100-mesh, and therefore it was impossible to determine magnetite in this manner, and there was no chemical test that would yield more satisfactory results.

Dr. Raymond stated that Prof. Eggleston had read a paper, some 15 years ago, on a system of mechanical analysis, at a certain stage of which the magnet drew out all the minerals containing iron, and though many chemists doubted this, it had since been proved correct.

Mr. Hoffman stated that he had experimented at the Croton Mine with a view of establishing the proper strength for magnets in the separator, and he had found that the amount of magnetite which escaped those of ordinary strength was very small. The main conditions were that the magnets should be kept clean and a regular feed maintained.

Dr. Dudley suggested that the Thoulet solution might be used advantageously for this purpose; and Mr. Kent thought that a close approximate determination of the amount of tailings might be effected by utilizing the difference in the specific gravity of the minerals. Mr. Firmstone thought that sufficiently accurate results could be obtained by using the Thoulet solution, the specific gravity of which is about 4, provided the ores were not too fine.

In reply to a question Mr. Langdon stated that they used about 2,000 tons of concentrates per month at Port Henry, and the amount of flue dust made, while concentrates were being run through the furnace, did not exceed five tons per month, though it was somewhat richer than the ordinary dust.

THE USE OF MAGNETIC CONCENTRATES IN THE BLAST-FURNACE.

In reply to Dr. Dudley's question, as to whether the use of concentrates had any effect on the regularity of the output of the furnaces, Mr. Langdon said that formerly the Port Henry furnaces had used run of mine ore, and that they were now using concentrates, and the product has been more regular since concentrates had been used. Dr. Dudley stated that the reason he asked the question was that he had once been connected with a furnace which ran very irregularly, and for which no cause could be assigned except that they used a fine ore of a very soft mushy character.

Mr. Moffat stated that the Lackawanna Iron and Steel Co.'s furnaces at Scranton had been run on concentrates for about six years and no irregularity had been noticed. The Lackawanna Co. was the first to extensively use concentrates in the blast-furnace. Concentrates generally formed from ⅓ to 1/10 of the furnace charge and for a very short time 50% had been used. The results have been as a rule satisfactory, and if not so much so as Mr. Langdon's, it was doubtless because a smaller proportion had been used. As for the flue dust, his experience agreed with Mr. Langdon's, it was of very small amount, but he thought it advantageous to moisten the ore, especially if very fine.

Dr. Raymond claimed that magnetic concentrates could only, as a rule, be profitably made from waste dumps. He said that at a former meeting of the Institute he had expressed his opinion that it would not pay to concentrate lean magnetic ore at any American mine, and he was willing to stand by that statement, and would only admit that he was wrong when the Croton mines have been run long enough to furnish regular working figures and not results based on the work of a few months only. He claimed that in Mr. Hoffman's paper no account was taken of royalty on ore or of increase in the cost of mining in the future. He thought the extraordinarily low cost of mining was unusual and by no means represented American mines in general, and the small profits made even there proves how difficult the method is going to be unless everything is in its favor, and therefore magnetic concentration will not likely be profitable, where ordinary conditions prevail. He drew a distinction between the use of concentrates in the shape of fine ore and dust in the blast-furnace and claimed that if dust such as the 60% material from the Ogden mines were used, there would be a great loss in flue dust, and thought that the chief use of magnetic concentrates would be in the open hearth furnace after they had been made into briquettes.

The afternoon session was opened by the reading of a paper entitled

"GOVERNMENT TIMBER TESTS," BY B. E. FERNOW, WASHINGTON, D. C.

Mr. Fernow prefaced his paper by the remark that the present knowledge regarding the properties of our various timbers was not very satisfactory, and that there is not much published information for general use. He gave a general description of the elaborate series of tests which have been undertaken by the Government, and appealed to all men interested in the mining industry to use their influence to secure the proper appropriations for carrying on the important work.

He called attention to the fact that timber of a certain class of trees often varied greatly in strength and other properties, and stated that because one piece of timber of such a class stood certain tests, it was by no means certain that a similar piece of the same kind of timber would do so also. The subject, Mr. Fernow stated, was of the utmost importance to the mining industry and yearly becoming of more importance.

Dr. Raymond commended the thoroughly scientific manner in which Mr. Fernow has started this work, and also spoke of the lack of knowledge concerning the strength of timber.

"TESTS AND REQUIREMENTS OF STRUCTURAL WROUGHT IRON AND STEEL," BY ALFRED E. HUNT.

This paper was devoted to the advocacy of a standard system of tests and methods, and it drew forth the warmest discussion of any paper read at this meeting.

Mr. Hunt stated that the American Society of Civil Engineers, and the American Society of Mechanical Engineers had each appointed committees on "Uniform Methods of Tests of Material Used in Metallic Structures" and "Standard Tests and Methods of Testing," and he suggested that as the iron and steel manufacturers were more largely represented in the American Institute of Mining Engineers than in either of the other bodies, a thorough discussion of the matter would be the best means to lead up to the establishment of a standard system of tests. He spoke of the inconvenience and expense manufacturers were put to by inspections and re-inspections by numerous inspectors and also of the inconveniences inspectors labored under. His idea of what tests should be, he expressed as follows: "Specifications for tests of structural material should furnish all necessary means for excluding all material deemed unsuitable by the engineer. The cost of testing eventually comes from the purchaser, hence the number of tests and the severity of their interpretation should be limited by the engineer as much as possible without sacrificing the idea first stated." Besides the increase of cost by unnecessary tests and too rigid requirements, there is another waste of money through waste of time; rarely, if ever, do the terms of the contract secure to the consumer compensation for the losses by delay caused by the vigilance of his own agent, the inspector. He then offered from the standpoint of an experienced inspector of structural material, some suggestions as to the kind and methods of tests to be adopted, and their interpretation.

Mr. W. H. Morris, of the Pottstown Iron Co., stated that the testing bureaus had worked great injustice to the mills, and criticised Mr. Hunt's paper in several particulars, among others the point that steel should not exceed a certain tensile strength. He also criticised the character of many of the inspectors sent out by the inspection bureaus, and was particularly severe on the young collegian whose swelled head was full of scientific theories, but who had not practical experience enough to apply them. He claimed that no man was qualified to be an inspector unless he has had experience as a manufacturer. He thought the tests made by the manufacturers were full enough, and that those prescribed by the bureaus were too exhaustive. He said that if all inspecting bureaus would agree upon one inspector at each works, it would save time and expense; often there had been as many as five or six in the Pottstown mill at the same time, testing different parts of the same shipment. He suggested that engineers should accept manufacturers' tests where they have been made in the prescribed manner; that surface inspection should be made at the mill; and a standard thickness of test pieces, as well as width, should be agreed upon.

Mr. Kent called attention to the fact that neither Mr. Hunt or Mr. Morris had proposed a standard set of specifications which could be discussed as a basis for a standard code. He thought that the tests, as made at present, might be too severe; the mill men should be heard, and specifications agreed on which would be just to both manufacturers and purchasers.

Mr. Oliver Williams, of Catasaqua, prefaced his remarks by stating that he had heard that Capt. Morris had written an urgent appeal to the Bishop of his diocese, that the Litany be amended so as to contain a new prayer to read "From fresh inspectors—*Good Lord deliver us.*" After the laughter had subsided, he spoke of the greatly improved class of inspectors sent to the mills now, as compared with those of a few years ago. The great difficulty now lay in the fact that we have no settled scale of requirements. Another difficulty was that railroad companies have raised the standard of their requirements and are not willing to pay the increased price. He believed that specifications very nearly like those of standard bridge-makers would meet the manufacturers' views. He agreed with Mr. Morris that present methods were very expensive, and that while the general impression was that the mill pays the bills, the fact is it always eventually comes out of the pocket of the consumer.

Dr. Chas. B. Dudley, of Altoona, stated that the keynote of inspection of any kind is, that the manufacturer knows that he is going to be inspected, and consequently does better work. For this reason he regarded the Pennsylvania R. R. Co.'s testing bureau, with which he is connected, of importance from the mere fact that it existed, if nothing else. Referring to Mr. Williams' remark concerning the increasing requirements of the railroads, he said the Pennsylvania R. R. Co. always had some tangible reason for every requirement in the specifications issued by its testing bureau. He detailed the method in which these specifications were prepared, and referred to a series of boiler sheets that have been in preparation for 16 months and have not yet been issued. In order to get these sheets in proper shape, pieces were taken from 60 worn out locomotive boilers, a record of the life of which had been kept, and tensile and elongation tests of each piece were made, and then a chemical analysis of their constituents was made. From the data thus collected the character of the material was determined, and conclusions regarding the specifications were arrived at but not adopted until the purchasing agents, manufacturers, and master mechanics, had criticised them. These specifications are constantly revised, so as to keep up with increased knowledge gained from practical work and scientific discoveries.

A NEW TEST FOR BOILER IRON.

Continuing, Dr. Dudley stated that in these new boiler specifications an entirely new test, called the homogeneity test, has been introduced. The test is made as follows: The test piece of metal is nicked on one side, put into a vise, and bent until it breaks. The fracture is then examined carefully. If, as is frequently the case, it shows numerous little holes, the piece is rejected. The theory of this test is that it opens out any little gas bubbles there may be in the plate, which have simply been rolled out and not welded. The importance of this test is obvious when it is remembered that these plates are to be used next the fire-box, where the temperature on one side is 350° to 370° and on the other side 3,000°. The heat transmitted through the plate to the water does not pass these rolled out bubbles as easily as it does the homogeneous iron, and consequently those parts of the plate become hotter, and the bubbles expand into blisters, and this is one of the principal causes for taking the affected part out of service.

Dr. Dudley also referred to the reason why steel should not exceed a certain tensile strength, and mentioned the case of the Sherman's Creek Bridge on the Pennsylvania R. R. as an instance.

It was desired to strengthen this bridge, which was a Howe truss, and the iron rods were taken from the first two bays and steel substituted. The steel of these rods was of excellent character; its tensile strength was 96,000 lbs. and its elongation 22%. Yet these rods broke one after another, while the iron rods in the bridge, of far less tensile strength, held as firmly as ever. The fact was, the steel rods were too strong. These rods were held up by nuts, which were not exactly true; that is, the base of the nut did not make exactly an angle of 90° with the side of the rod. As a consequence there was a greater strain on one side of the rod than on the other. The steel being of high tensile strength was very stiff and would not bend, so it had to break. A soft steel of lower tensile strength would not have broken under the same circumstances.

Mr. Coxe agreed with Dr. Dudley that the mere existence of an inspection bureau tended to secure better results from the producer, and stated that formerly, at the collieries of Coxe Bros. & Co., the coal was inspected by the breaker employes, and there were constant complaints from consumers, some of which were made five months after the shipment. Now the inspection is done by the sales department, before the coal leaves the breaker, and every employe from the foreman down, knows that if a lot of coal is rejected, it means more work, to unload the car and prepare the coal properly. Under this system there are no complaints from consumers.

CENTRIFUGAL VENTILATORS, BY R. VAN A. NORRIS, WILKES-BARRE, PA.

This paper was a very long and exhaustive one treating on the efficiency and construction of the various types of centrifugal fans in use for mine ventilation. The paper is too long to be reviewed in the limited space at our disposal, and it together with the supplementary remarks by Mr. A. H. Storrs, of Scranton, will be given more in detail in a subsequent issue.

The figures given in Mr. Norris' table, which embraced a larger number of fans, show a wide divergence in the combined efficiency of the engine and fan. The lowest efficiency given being 23%, and the highest 91·3%, though the latter was marked doubtful. There were eight that showed efficiences ranging between 81%; and 87%; 14 ranging between 70% and 77%; 16 ranging between 60% and 70%; 9 ranging between 50% and 60%; and 20 that ranged from 23% to 50%.

The bulk of the criticism made on Mr. Norris' paper was that the different conditions under which each fan was running and under which measurements were made, rendered it extremely difficult to get results that would give a correct basis for comparison.

The Wednesday evening session was opened with a paper entitled

"NOTES ON A CABLE HOIST AND THE USE OF LOCKED ROPES;" BY E. GYBBON SPILSBURY, TRENTON, N. J.

This paper was a description of a cable tramway across the Susquehanna River at Glen Union, Clinton County Pa., erected by the Trenton Iron Co. for the Glen Union Lumber Co. It was built to convey railway cars loaded with lumber, weighing about twelve tons each, from one side of the river to the other. A tower 70 ft. high was erected on each side of the river, over which were stretched two parallel cables each 2 ins. in diameter. The carriage is suspended from the cables and is large enough to carry one car. The span is 735 ft. The engine used was built by the Lidgerwood Mfg. Co. To reduce the wear on the rope and the wheels of the carriage, Elliot's smooth locked-coil wire rope was adopted, and the desired result was accomplished. Sixty cars of lumber have been transported across the river by this means in a day of ten hours. In reply to questions regarding the use of this locked-coil rope, Mr. Spilsbury stated that it was unquestionably a good rope, and instances that were cited in opposition to this view, were in cases where local conditions were such that made ordinary wire rope more suitable, and the locked-coil rope should not have been put on. The locked-coil rope is largely used in English collieries, and is giving great satisfaction.

"ELECTRIC LOCOMOTIVES IN GERMAN MINES;" BY KARL EILERS, BERLIN, GERMANY.

This paper was read by title, and was not discussed generally, but Mr. H. C. Spaulding, of The Thomson-Van Depoele Electric Mining Co., stated that his company had recently constructed the largest electric mine locomotive as yet produced. It is the same locomotive that was recently illustrated in our columns. It is of 60 H. P., and weighs 21,600 lbs., or about three times the weight of the one described by Mr. Eilers. The dimensions of this locomotive are as follows: 12 ft. 6½ in. long, 3 ft. 6¼ in. wide and 3 ft. 3½ in. high. It is of 3 ft. gauge and has a maximum speed of 10 miles per hour. The armature speed is 1020. Mr. Spaulding exhibited photographs of this locomotive and also of a pair of mine pumps run by electricity. These latter were designed for a 1,500 ft. lift, and under a pressure of 650 lbs. per sq. in. they showed an efficiency of 74%. The pumps were a pair of Knowles pumps and the motor was connected to them by a worm gearing, the pumps being set a little farther apart than usual. The electrical end was specially constructed so as to be water-proof. The statement regarding the efficiency of the pumps was doubted by several members who had made a study of worm gearing. Mr. Spaulding said that at first he and others connected with the company were astounded with the result, but that it had been proven by tests made every fifteen minutes during a period of twenty-four hours.

"THE UTILIZATION OF PUDDLE SLAG FOR PAINT STOCK;" BY AXEL SAHLIN, NEW YORK.

This paper was an interesting description of the manufacture of paint from puddle slag at Boonton, N. J., and the difficulties that were met and overcome before the present excellent results were attained. The slag is ground by means of a Cyclone pulverizer and passed through a simple drum arrangement in which the larger pieces, in themselves very small, are separated from the finer particles conveyed again to the pulverizer and reground. This fine material is then treated with sulphuric acid, calcined and ground a second time to exceeding fineness. It is then mixed with linseed oil and forms the stock of a very permanent paint. Any color except white may be made by the addition of a very small percentage of pigment. The grinding is done for 17 cents per ton.

"THE PREPARATION AND UTILIZATION OF SMALL SIZES OF ANTHRACITE COAL."

This was the subject for a discussion that proved a very interesting one. It was opened by Hon. Eckley B. Coxe, who stated that to secure the best results from Anthracite as a fuel, it was absolutely necessary that it should be well sized. For instance if chestnut, pea, and buckwheat coal was mixed, the smaller sizes would fill the interstices and cut off the draft necessary to support combustion. Anthracite in the fire did not act like Bituminous, and this necessity for air space was an essential feature. He stated that when he first entered in business as a miner of coal, only the larger sizes were shipped to market, and the smaller sizes were utilized for steam purposes at the mines. He spoke of using the major portion of the chestnut production of collieries for steam purposes, but, as the trade learned that it was of value as a fuel, the sales-agents sold the entire product of the collieries and he was compelled to use pea. In course of time Mr. Ely, also sold all they could produce of that, and he had to descend to number one buckwheat. The next year Mr. Ely sold the number one buckwheat and now he was using number two buckwheat. This has in turn been sold and he must now come down to number three buckwheat, and he suppose his next step would be to a smaller size, say mustard seed.

He stated that the use of improved grates such as the McClave and Howe grates, had made it possible to utilize the small sizes. He was using the McClave grate with good results, and had succeeded in burning $\frac{1}{16}$ in. coal. He explained in detail his method of utilizing a maximum proportion of the heat units, by the use of the Dimmick and Smith improvement, and mud drums which were almost surrounded by flame, and which were set under the boilers. He stated that one of the greatest extravaganzas in the coal regions was the use of uneconomical steam plants and wasteful engines. He advocated the use of a better type of boilers and of a higher grade of engines. It was of as much importance to economize in fuel at collieries as at any other establishment, and it was only by the adoption of economic methods that operators could renew their acquaintance with dividends, something that few of the younger men in the trade were acquainted with. Mr. Coxe called attention to the fact that he had succeeded in cleaning and saving coal as small as $\frac{1}{16}$ to $\frac{3}{16}$ in. in size, which was cleaned by jigging in jigs, the bottoms of which were covered with felspar. He had carefully analyzed the refuse after jigging, and found that there was a very large percentage of iron pyrites in it. This pyrites can only be removed by jigging.

Mr. Coxe referred to the exaggerated statements that were continually being made regarding the vast amounts of culm available for fuel in the Anthracite regions, and stated that the banks did not contain nearly as much as was supposed. They often lay on side hills and instead of being trapezoidal in section, they were triangular, and the observer gained a false impression by seeing only the altitude and one of the long sides of the triangle, and imagined that he was looking at a bank with a trapezoidal section. He also stated that some of the banks by deterioration, due to weathering, were useless, and others that contained excessive amounts of refuse were impracticable for use as fuel. He mentioned the fact that culm from different seams and different localities was differently affected by weathering. Some of it, after a few months exposure was very low in value, while other culm that had been exposed for years was comparatively little affected.

In the course of the discussion which followed, attention was called to the use of culm as fuel at the various manufacturing establishments in Scranton. Dr. Raymond stated that the culm banks in Scranton were comparatively new, and jocularly stated that it paid to burn them, as the area covered could afterwards be sold as city lots.

Mr. Foster stated that the reason culm was utilized to a greater extent in the Lackawanna and Wyoming valleys than in other portions of the Anthracite fields, was because the seams lay comparatively level and there was not as much refuse in them as in the other localities. Consequently the refuse was gobbed or left in the mines, whereas in the Lehigh and Schuylkill regions, the seams lay on heavier pitches, and considerably more refuse was necessarily loaded in the mine cars, transported to the surface and eventually thrown on the culm banks. Therefore the culm of the latter regions was not as well adapted for fuel, unless it was prepared in some manner and this would naturally increase its cost. Mr. Moffatt stated that he was using for steam purposes at the Lackawanna Iron and Steel Co.'s Mills from 6,000 to 8,000 tons of culm per month. This was fresh culm from the two collieries owned by his company supplemented by culm from three other collieries located near the works. There were however numerous other establishments that were using culm from old banks. Several members spoke of experiments they had made in burning a mixture of Bituminous coal and Anthracite culm, but the result was not as good as when the two classes of coal were used separately.

Considerable interest was manifested by various members in regard to the practical use of the McClave grate, which had been favorably mentioned in several instances, and Mr. Foster promised to prepare a paper on the subject to be printed in the transactions in connection with Mr. Coxe's remarks and the discussions which followed them.

The meeting then adjourned, and the members and guests retired fervently hoping that the morning would prove fair, so that the social features of the meeting should be as successful as the business sessions.

THE SOCIAL FEATURES.

Thursday dawned cold and threatening, and the outlook for the excursion through the Wyoming region and to Harvey's Lake was most unpromising. However, the train was ready and the party determined to risk it, and it was fortunate this conclusion was arrived at. The rain held off and the day was a most enjoyable one. Harvey's Lake was reached about noon, and observation cars elaborately trimmed were attached to the train which was run down to the boat landing, and thence back to Mr. Albert Lewis' beautiful log residence and picnic grounds. After a stroll through the grounds an elaborate luncheon was provided by Mr. Lewis at his house, which was thrown open for the reception and use of the party. While seated at the bounteous and beautifully arranged tables, a fine orchestra furnished music that added greatly to the enjoyment of the party. Mr. Lewis proved himself a most generous and hospitable host, and after the luncheon was over tendered his guests the use of the steamer for a ride on the lake. On the return from the boat ride, and a visit to Mr. Lewis' saw mills, the cars were taken for the return to Glen Summit. A jovial and happy party filled the cars, and all united in expressing the highest appreciation of Mr. Lewis' pleasant reception and bounteous hospitality. Glen Summit was reached at 5.30 P.M. About seven o'clock, the special train was again occupied by the party and the run was made to Laurel Run, where Gen. Paul A. Oliver had prepared a "Camp Fire" for the entertainment of his guests. The entertainment was a peculiarly unique and enjoyable one. The road from the station to Gen. Oliver's grounds was bordered with blazing torches, after passing through the rustic gates a peculiarly attractive scene met the eye. The grounds were illuminated in every direction by pine-knot torches and pumpkin "Jack o' Lanterns," and a huge bonfire of pine logs. Across the driveway the word "Welcome" appeared on large illuminated pumpkins, each of which bore one letter of the word. Scattered through the woods were hundreds of carved pumpkins that showed up grotesque and humorous illuminated designs. The path down the trout stream to the dam was particularly attractive. The dancing pavilion was so trimmed with evergreens, different colored dahlias in various designs, and Japanese parasols and lanterns that no woodwork but the floor was visible. A band stand adjoining was occupied by the Ninth Regiment Band, one of the best musical organizations in the State. Gen. Oliver, assisted by Mrs. Bunnell, his sister, and a number of other ladies, received the guests at the entrance of the pavilion. After the reception the guests strolled through the grounds, and in a body visited the quaint log chapel, which was decorated for the occasion. Over the chancel the following appropriate quotation, from Job, 28th Chapter, was printed:

"Surely there is vein for the silver, and a place for gold where they find it. Iron is taken out of the earth and brass is molten out of the stone. The flood breaketh out from the inhabitant; even the waters forgotten of the foot; they are dried up, they are gone away from men. As for the earth, out of it cometh bread; and under it is turned up as it were fire. The stones of it are the place of sapphires: and it hath dust of gold. There is a path which no fowl knoweth, and which the vulture's eye hath not seen; the lion's whelps have not trodden it, nor the fierce lion passed by it. He putteth forth his hand upon the rock; He overturneth the mountains by the roots. He cutteth out rivers among the rocks; and his eye seeth every precious thing."

As the visitors entered, a quartette sang "My Country 'tis of Thee," which was followed by "Coronation" and "Old Hundred." The party then returned to the pavilion and bonfire. After all had returned, President Birkinbine stepped on a stump and called the gathering to order and called on the committee on resolutions for its report. Capt. Hunt then read a series of resolutions thanking the local committee and Messrs. Lewis and Oliver for the pleasures already enjoyed, and Hon. Eckley B. Coxe for the pleasures in store for the morrow. They also thanked the Lehigh Valley R. R. Co. for favors and courtesies received not only then but on numerous former occasions. These resolutions were unanimously adopted and cheers were given for Mr. Albert Lewis, Gen. Oliver, the L. V. R. R. Co., Messrs. Coxe, Stearns, and Lathrope, the officers of the local committee, and also for the ladies of Wilkes-Barre. This pleasant duty being ended, dancing, conversation, and strolling through the grounds occupied the time till midnight, when the Institute and its guests left for Glen Summit and the Wilkes-Barre guests left for home. On the road to Glen Summit, Mr. Oliver Williams, of Catasauqua, formed a choir in the front car, and a varied selection of local gems, more popular than classical were rendered in an enjoyable manner.

Friday morning dawned bright and clear, and at 8.15 the special train started for the Lehigh Region. Drifton was first visited and the shops and new iron breaker were examined. From there the train was run to Hollywood Strippings, where the mining of the Mammoth seam by removing the surface was examined. From there, the train proceeded to the new Oneida Colliery of Coxe Bros. & Co. A bounteous lunch was served at the picnic ground, and then the new iron breaker was inspected. The machinery was all in place, and was run so that the visitors could see the actual working of Mr. Coxe's new ideas. It was an excellent chance to witness the method of preparing Anthracite for market, and all availed themselves of the opportunity. The breaker is one of the largest in the region and has an estimated capacity of about 3,000 tons per day. All the appliances are of the latest improved order. Among other striking objects was the new compound hoisting engine, designed and built at the Drifton shops, where, by the way, a Pelzer fan is in course of erection. This will be the first Pelzer fan in operation in America.

At 3.40 P. M. the visitors again boarded the train. At Hazleton quite a number got off to take trains for Philadelphia and New York. At Glen Summit which was reached about 5 P. M. about half the remainder left, and the balance of the party were taken on to Wilkes-Barre, from whence they scattered toward their homes, all being of the unanimous opinion that the Fall Meeting of 1891 was one of the pleasantest and most interesting ever held, and that Messrs. Coxe, Stearns, and Lathrope, were model committee-men.

Don't Get Left.

In the effort to secure the best results in mining and preparing minerals, it is necessary for the man who don't want to "get left," to be thoroughly posted on the most improved ideas, machinery, and appliances. It does not cost much to "keep up with the procession." All you have to do to keep posted is to read THE COLLIERY ENGINEER, and send for the handsome and well illustrated catalogues of manufacturers of mining machinery and mining appliances. Most of them contain information of value aside from descriptions of the machinery, etc., and they should be in the hands of every operator and mine official. Our advice therefore is to

Send for Catalogues and Circulars, of mine cars, wheels, etc., to S. B. Stine, Osceola Mills, Pa.

Send for the handsome illustrated Catalogue issued by the Queen City Supply Co., corner Elm and Pearl Streets, Cincinnati, Ohio.

Send for Circulars relative to "Webster's International Dictionary," which is a revised and enlarged edition of the Authentic "Unabridged," to Messrs. G. & C. Merriam & Co., Springfield, Mass.

Send for the handsome illustrated Catalogue issued by The Lunkenheimer Brass Co., 11–17 East Eighth Street, Cincinnati, Ohio.

Send for the Catalogue of the Philip Carey Manufacturing Co., Cincinnati, Ohio.

Send for the illustrated Circulars and Catalogues issued by the Waterbury Rubber Co., 49 Warren Street, New York.

Send for Catalogue and Circulars descriptive of Packing to Hine & Robertson, 45 Cortlandt Street, New York.

Send for Catalogue issued by the Phillips Mine Supply Co., Pittsburgh, Pa.

Send for Catalogue and Circulars of the Scaife Foundry and Machine Co., Limited, Pittsburgh, Pa.

Send for special Catalogue just issued descriptive of Slate Channeling Machines to The Ingersoll-Sergeant Drill Co., 10 Park Place, New York. This is the only practical channeling machine on the market.

All the above Catalogues are sent free, and you cannot afford to not have them.

Engineering Association of the South.

The first regular meeting of the Engineering Association of the South since the summer recess was held on Thursday evening October 8, in the Y. M. C. A. Building, Nashville, Tenn., the Cumberland Publishing House in which are situated the future headquarters of the Association not yet being ready for occupation. Vice-President W. L. Dudley and President John B. Atkinson presided in turn with about twenty members and visitors present.

Communications were read from the Secretaries of the Am. Soc. C. E. from the American Society of Swedish Engrs., from the Am. Institute M. E., and from the Illinois Soc. Surveyors & Engrs., each notifying the Secretary that a system of exchanges of their publications with this Association would be adopted. The subject of the series of tests of American woods, recently inaugurated by the U. S. Dept. of Agriculture and now being carried out at St. Louis, Mo., and Ann Arbor, Mich., was discussed, and at the suggestion of Mr. John MacLeod of Louisville, Ky., the Secretary was instructed to communicate with the Secretary of Agriculture expressing the interest taken by the Association in this important undertaking and urging that the necessary appropriation of funds be secured for fully carrying out the series now undertaken.

Mr. R. L. Cobb, Chairman of the Committee on Nomination of Officers, submitted the names of two nominees for each office to be balloted for at the coming annual election in November.

Messrs. R. C. Lewis and W. L. Dudley were appointed tellers to canvas the ballots for new members which resulted in the election of the following gentlemen: Frank Cawley, Mechanical Engineer for the St. Bernard Coal Co., Earlington, Ky., Benjamin W. Robinson Mining Engineer for the St. Bernard Coal Co., Earlington, Ky., and Thos. D. Kemp, Engineer and Superintendent of the improved Wood Pavement Company, Mobile, Ala.

An application for membership was received from Lucien S. Johnson, Supt. and Engr. of the Great Western Mining Co., Peach Orchard, Ky.

The paper of the evening entitled "The estimation and Measurement of Earth-Work," was then read by Mr. W. B. Roes of Nashville, Tenn., member of the Association. The paper after a general analysis of the requirements and difficulties of earth-work estimation, presented a comparison of the several methods now in use for determining volumes, expressing the error of the several methods as compared with the geometrically rigorous prismoidal formulae. One of the conclusions of the paper was that owing to the fact that earth-work excavations are usually bounded by a concave profile, either in the road-bed cuts or in borrow pits, the prismoidal formulae gives results less than the actual volume taken out by an amount approximating to the error of excess of the method of "averaging end areas" and therefore the latter was believed to be the more accurate and just method of estimation than the prismoidal method which while giving results rigorously true for the imaginary solid on which it is supposed to be applied still gives results too small when applied to the usual form of earth solid which is rarely a prism, but usually has a middle section larger than that assigned it in the prismoidal treatment. The author presented for inspection some tables divined by himself for rapidly taking out the volumes of "three level" ground and also exhibited some graphical scales for the same purpose and to be used in finding the center of a mass of an excavation.

The next regular meeting of the Association, which will be the annual meeting, will be held on November 12th, at Nashville, Tenn., and without doubt in the new headquarters.

A Valuable and Cheap Book.

We have received an advance copy of a valuable little volume with a title page that contains in its few lines so much information regarding its contents that we reproduce it. It is as follows: "Common Sense in Making and Using Steam. Facts for the consideration of Proprietors of Steam Plants, by One Who has Paid for His Experience."

The author, Mr. William Harrison Bailey, M. E., of Rochester, N. Y., has in this little volume, compiled a vast amount of data arrived at after years of experience in steam engineering, in an interesting and popular form.

The question and utilization of steam in all industrial establishments is one of the heaviest items of expense, and collieries are no exception to this rule. Badly designed and poorly managed steam plants require annually a large expense in labor, in costs for repairs, and for fuel that could be materially reduced if proper attention were paid to the subject, and new ideas gained from practical experience were utilized. The little volume under review contains many hints whereby steam users can effect economies, and its nominal cost of 25 cents post-paid should induce every steam plant owner, engineer and fireman to purchase. It is neatly bound in leatherette, contains no advertisements, and will be sent post-paid for 25 cents, either in stamps, currency or postal note, by the Mason Regulator Co., No. 10 Central St., Boston, Mass.

PRIMARY EDUCATIONAL DEPARTMENT

FOR CANDIDATES FOR

MINE FOREMEN'S CERTIFICATES

AND FOR

STUDENTS OF MINING.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the sciences related to mining and to learn how to answer the questions in ventilation, surveying, and mechanics which are asked at the examinations for mine foremen's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine foremen and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and many calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

We shall be heartily glad to learn that our readers are profiting by the lessons on Penmanship, not only in being able to execute figures that are pleasant to look upon, but we also hope to learn that the observing faculty is by this means being developed through a process of a "Love of the Beautiful."

The first letter to engage our attention in this article

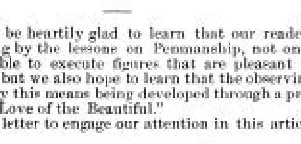

Fig. 22.

is the Capital G. At the left hand of Figure 22 the letter is shown as it ought to be drawn or written; the second letter from the left hand side of the Figure shows the development of the parts of the letter out of a series of elliptical curves. First let us notice that the stem of the bottom loop must be parallel to the major

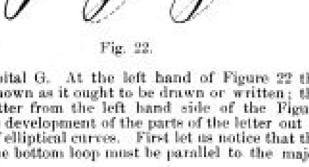

Fig. 23.

axis of the large ellipse, and that the major axes of the top and bottom ellipses must also be parallel. The third letter from the left is a deformity arising out of the non-parallelism of the respective ellipses; the same occurs in the first letter of Figure 23. The second letter shows the ellipse of the bottom loop to be so small as to offend the eye and the feelings in a remarkable manner. The bottom loop of the third letter is generated by an ellipse having its major axis too long.

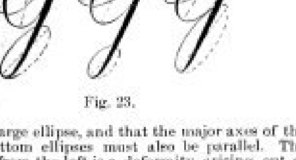

Fig. 24.

Figs. 24 and 25 illustrate the correct and incorrect development of the capital letter H. The first letter on the left hand side of Figure 24 is correctly written or drawn; the second letter from the left shows the development of the letter from elliptical curves; the first

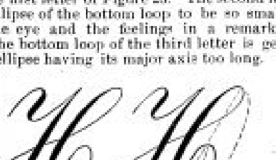

Fig. 25.

letter of Figure 25 shows two deformities, the one contrary to the first law of penmanship, and the other contrary to the third law of penmanship, namely, all strokes must be parallel, and all strokes must be proportionate in size. The stem of the initial hook of the letter is not parallel to the main stem of the letter, and the bottom loop and scroll are both too small. The second letter shows that the stem of the hook is not parallel to the main stem of the letter, but the secondary principal stem is also not parallel to the first, and the final scroll is not only not parallel but abuses the third law of penmanship by not being proportionate in size.

ARITHMETIC.

MULTIPLICATION AND DIVISION OF FRACTIONS.

The common idea is that if one value be multiplied by another the result or product will be greater in numerical value than either the multiplier or the multiplicand; this statement, however, is only true in relation to whole numbers (excepting cases where the multiplier or multiplicand is one), that is when the multiplier and multiplicand are both whole numbers; but if 2 be multiplied by $\frac{1}{2}$, the product or result is equal to 1, we now find that if a whole number be multiplied by a fraction the result or product is greater than the multiplying fraction and less than the whole number, *e. g.*, if 1 be multiplied by a $\frac{1}{2}$ the result or product is a $\frac{1}{2}$, or less than the whole number and exactly equal to the multiplying fraction; from this we learn that if a whole number be multiplied by a fraction the product will be greater than the fraction, but is always less than the whole number that has been multiplied.

When a fraction is multiplied by a fraction the product or result is always less than either of the multiplying figures, for instance, a $\frac{1}{2}$ multiplied by $\frac{1}{2}$ produces a $\frac{1}{4}$, the meaning of this is that $\frac{1}{2}$ times a $\frac{1}{2}$ must be a $\frac{1}{4}$, and it is often written "$\frac{1}{2}$ of a $\frac{1}{2}$ equals a $\frac{1}{4}$." Perhaps we cannot do better to impress these facts on the mind of the student than show a few examples; first then we will multiply wholes by wholes and show that the products are greater than either of the factors. Now the word factor is derived from *factor*, to make. If 3 be multiplied by 4, the 3 and the 4 are said to be the factors or makers of 12; $5 \times 4 = 20$, the 5 and 4 are here said to be the factors or makers of 20. Now here follow examples to show that the products of whole numbers are greater than either of the factors, except when one of the factors is 1, thus

$$4 \times 7 = 28$$
$$8 \times 9 = 72$$
$$6 \times 8 = 48$$

Now let us show that when a whole number is multiplied by a fraction the product is never less than the fractional factor, but never greater than a whole factor, as observed by the following examples:

$$3 \times \tfrac{1}{3} = 1$$
$$2 \times [illegible] = [illegible]$$
$$4 \times [illegible] = [illegible]$$
$$1 \times [illegible] = [illegible]$$

Again, two fractional factors generate a product always less than either of the factors, as shown by the following examples:

$$[illegible] \times [illegible] = [illegible] \text{ or } [illegible]$$
$$[illegible] \times [illegible] = [illegible] \text{ or } [illegible]$$
$$[illegible] \times [illegible] = 1$$
$$[illegible] \times [illegible] = [illegible]$$

It is a knowledge of details like these that makes a student sure and accurate in the application of mathematical principles. It is the readiest and surest way to succeed in the study of arithmetical values.

When a series of fractions have to be multiplied into each other they are often expressed as in the following example:

$$\tfrac{1}{2} \text{ of } [illegible] \text{ of } [illegible] \text{ of } [illegible] \text{ or } \tfrac{1}{2} \times [illegible] \times [illegible] \times [illegible]$$

Now if all the denominators be multiplied into each othes the product will be the denominator of the resulting fraction, and if all the numerators be multiplied into each other the product will be the resulting numerator of the fraction.

$$\text{or } \tfrac{1}{2} \times [illegible] \times [illegible] \times [illegible] = [illegible] \text{ or } [illegible]$$

Two words have been employed in this explanation, and let it be noticed that words are signs of ideas, and unless the meaning of the words are understood the ideas that the words express cannot exist in the mind. A good student constantly uses his dictionary, and never allows a word to pass him in reading if he does not understand it. Now the word "numerator" signifies the number of parts that constitute a fraction of a whole, and the "denominator" the number of parts into which the whole is divided, *e. g.*, three-fourths of an apple would indicate that the whole apple has been cut into four equal parts, therefore the denominator is 4, or the number of parts into which the apple has been cut; 3 is the numerator or the number of parts at our disposal, consequently this expression might be graphically written as follows:

3 the numerator.
4 the denominator.

Division of fractions presents us with conclusions the opposite of those we discovered in our investigation of multiplication of fractions. When the dividend or divisor consists of other values than unity the quotient is always larger than either divisor or dividend; if a $\frac{1}{2}$ be divided by a $\frac{1}{2}$ the quotient or result is 1, and elementary reasoning would teach us that a $\frac{1}{2}$ must be contained in a $\frac{1}{2}$ one time. A portion of the process of division of fractions is similar to that of multiplication, with this difference, the dividing fraction is always inverted, that is a $\frac{1}{2} \div \frac{1}{2} = 1$, or proceeding as in multiplication $\frac{1}{2} \times \frac{2}{1} = 1$.

The following remarkable results occur which show clearly how cautious the learner ought to be to invert the correct fraction, for example, $1 \div \frac{1}{2} = 2$, or $1 \times \frac{2}{1} = 2$, but the $\frac{1}{2}$ divided by 1 equals a half; 1 might in this case be made into an improper fraction, then $\frac{2}{2} \div \frac{1}{2} = 2$ as before, and half divided by 1, $\frac{1}{2} \times \frac{1}{1} = \frac{1}{2}$ as before.

CHEMISTRY RELATING TO MINE VENTILATION.

MINE GASES (CONTINUED).

The compound gases ought to be known and understood by the miner by their symbols or chemical expression, as follows:

Marsh gas or methyl hydride -	CH_4
Silver gas or hydride of ethyl -	C_2H_6
Sulphureted hydrogen or, hydrogen sulphide - -	H_2S
Carbonic acid or carbon dioxide	CO_2
Carbonic oxide or carbon monoxide - - -	CO

Now it is a matter of daily experience to observe that these gases stratify in air, that is, they form layers above or beneath air according to their respective specific weights. Fire-damp having a specific gravity of ·55 is always found stratified next the roof of the seam; carbonic acid having a specific gravity of 1·52 is always stratified next the floor of the seam; sulphureted hydrogen stratifies with difficulty, it being very little more than the weight of air, or 1·17. The same may be said of carbonic oxide in after-damp.

Gases diffuse into each other, that is, by some force not yet clearly understood, fire-damp will diffuse and form a mechanical mixture with air; the same may be said of all the other gases, and what is equally remarkable the gases have a power of diffusion among themselves. Now it does seem extraordinary that hydrogen gas, which is only about a fifteenth of the weight of air, should, contrary to the commands of gravitation, sink and mechanically unite with the heavier gases which constitute air, but the difficulty is partly removed when we consider that this diffusion is closely allied to another principle, viz.: solubility. Now common salt has a specific gravity of 2·1; this means to say it is a little more than twice the weight of water, nevertheless, when dissolved in water it remains suspended, notwithstanding its superior weight. Now we do not understand the operation of a natural law that comprehends what takes place when salts are dissolved or when gases are diffused. But in all cases solubility is only possible within sharply defined limits, *e. g.*, to all salts there are points or limits of saturation which never vary at given temperatures and given pressures. We know that 21 volumes of oxygen will diffuse into 79 volumes of nitrogen, or the converse, 79 volumes of nitrogen will diffuse into 21 volumes of oxygen, such proportions being the limits of the diffusion of these gases. That diffusion is limited by a point of saturation is clear from the circumstance that atmospheric air is always the same, whether found on the tops of mountains or in the depths of valleys. It is the same in all climates, and as far as we know, under all conditions of temperature and pressure. That diffusion and solution are the same in principle is shown by the solubility of air in water, but when air dissolves in water a portion of its nitrogen is rejected, showing that when three bodies dissolve or diffuse into each other, the triple diffusion to some extent alters the relationship.

The law of diffusion already known refers to the velocities with which different gases diffuse into each other, *e. g.*, the specific gravity of hydrogen being 1, and that of oxygen 16, hydrogen will diffuse into oxygen with a velocity four times greater than that of oxygen into hydrogen. The law of such diffusion is as follows: The velocities of diffusion of different gases are inversely proportional to the square roots of their densities. Now as the ratio is an inverse one, the square root of the density of oxygen is proportional to the velocity of the diffusion of hydrogen into it. The same relationship will be found true in other cases. In all the experiments tried, the velocities of diffusion were ascertained by placing a bottle of one kind of gas in an unmeasured volume of another.

That the limits of saturation are sharply defined cannot for a moment be doubted. On entering old working places of a mine where the ventilation is "slack," or even where no air current is passing, fire-damp will be found next the roof and air beneath it, showing that diffusion can only proceed within very definite limits. Any intelligent student will realize the importance of the investigation of this matter when we point out the fact that with an unlimited diffusion explosive mixtures would constantly be found, not only near the roof, but near the floor. The intelligent miner, however, never expects to find explosive mixtures near the floor, but seeks for gas near the roof, as he knows by practical experience mine gases and air stratify according to their specific weights. Where air and gas are mixed by current agitation, separation at once takes place, where the current passes under large holes in the roof; so much is this the case that screens of canvas called "sconces," or "dash doors," are erected to throw the current upwards and thus wash out the gas. We do hope, before long intelligent efforts will be made to ascertain correctly the points of saturation for diffused gases.

Pressure of fire-damp *in situ*. The following facts are taken from the North of England Mining Institute papers supplied by Lin. Wood, Esq., and Geo. May, Esq.: The experiments showed conclusively that the pressure of the gas *in situ* (in its original place) was proportionate to a water head nearly equal to the depth of the seam, that is in cases where the seams were found at considerable depths, but where the seam was shallow and the overlying strata porous and jointed, the pressure found did not coincide with this law exactly; again, even for the same depth, the pressure was greater in new workings than in the workings of old collieries. In the bore-hole experiments where the pressure was tested by gauges, it was found that the pressures increased proportionally as the square roots of the lengths of the holes. Suppose an example by way of illustration, and let the cover of the seam be equal to 1,500 feet, but let the depth from the drainage level to the seam be 1,260 feet, here the pressure of the gas *in situ* would be 546 pounds on the square inch. It will be clear to the observer that the undulations of the surface will greatly affect the law of depth. The closeness or otherwise of the strata, the age of the colliery, and the extent of the workings, will all moderate the pressure of gas *in situ*.

This matter is very important to the miner from three points of view: First. The quantity of gas or fire-damp given off by a seam will be less where the cover is thin than where it is of considerable thickness. As has been noticed a broken thin cover allows the fire-damp to freely escape from a seam; the same conditions of cover equally allow a free entry of water, so much is this the case that we may often say—much water, little gas, or little trouble from gas means much water. In the deeper seams overlaid by closer strata, and especially much further below the level of the district, we find much gas and very little water.

Second. But for the presence of fire-damp at great pressures in the coal, in many cases the seams would be very expensive to work, so that we are presented with the following apparently, opposite conclusions: first, fire-damp is a source of danger to the miner; second, fire-damp by its pressure assists the miner.

Third. In working a series of seams of different depths, great skill and sound judgment is required to retain the pressure of the confined fire-damp in the separate seams during the course of working, so that the taking out of one seam shall not entirely eliminate the gas from the other.

The range of explosive mixtures and the maximum effects are in the direct ratios of the pressures or densities of the gases. It is said that the range of explosive mixtures at sea level lies between 5 of air, and 1 of gas, and 15 of air and 1 of gas, but this range will be considerably increased under conditions of increased pressure. So much is this the case, that we have no doubt, that under a pressure of two atmospheres, 20 of air and 1 of gas would set up an explosive force equal to 10 of air and 1 of gas at ordinary pressures. But a mixture of 9½ of air and 1 of gas, under a pressure of little more than half an atmosphere or 8 lbs. on the square inch, ceases to be explosive. Here it would not be out of place to define what we mean by an explosive mixture. We mean then such a mixture of fire-damp and air, as will, if ignited, almost instantaneously produce a volume of flame equal to the volume of the mixed gases; from this intense heat a pressure is set up that may be safely called the explosive force. This force in many cases amounts to a pressure (supposing the mixture to be confined) of 90 pounds on the square inch. We may safely from this infer that the pressure set up in the neighborhood of the point of ignition in some of our great mining explosions has not been less than 50 pounds on the square inch. These deductions are founded on the supposition that explosions take place at pressures of about 30 inches of mercury, but no doubt in some of the deepest pits explosions have occurred at pressures equal to 32 inches of mercury, and should the mixture at the moment of explosion be nearly a maximum one, pressures of even 60 lbs. or more on the square inch might be produced. Supposing a pressure due to a confined volume to be 90 lbs. per square inch, under a pressure of 30 inches of mercury, the same mixture under a pressure of 32 inches of mercury would develop a static force of 96 pounds on the square inch. We mean by this that the intensity of the temperature of the mixed gases at the moment of explosion is directly proportional to the pressure of the gases at the moment before ignition.

High temperatures rarify gases, consequently a mixture previously expanded by heat is not so explosive as a relatively colder one; *e.g.*, a mixture of 9½ of air and 1 of gas at a pressure of 30 inches of mercury, and at a temperature of 700° F. will not explode. An atmosphere saturated with watery vapor, when mixed with fire-damp, is relatively safer than pure dry air.

SCIENCE RELATED TO MINING.

STEAM.

The conservation of energy is one of the greatest problems that has ever been solved by the human mind; the indestructibility of matter has long been known and understood, but the conservation of energy is a modern problem that is receiving a modern and final solution. Energy has its modes, fashions, or states, and all these modes, fashions, or states are convertible into each other; heat is convertible into light, light is convertible into heat, electricity is convertible into heat, and light and heat are convertible into electricity, mechanical energy is convertible into all the modes previously mentioned, and all the modes previously mentioned are convertible into mechanical energy; this being so the study of the subject of heat is full of interest, and confers upon the student an amount of intelligence which enables him to deal efficiently with other matters, in the daily duties of life, that would be inscrutably vague or mysterious. The modes by which heat is communicated from point to point are full of interest. In the raising of steam we first observe how heat is transported from point to point by radiation, the heat from the burning embers passes in direct radiant lines to the shell of the boiler, now the conveyance of heat from the burning embers to the boiler, let us bear in mind, is by the process of radiation. Perhaps some student might inquire for a definition of the mode, or any atomic laws by which heat is transported through space from one point to another? An answer to this query would involve a somewhat abstruse and lengthy explanation, but let it suffice for us to say that heat is the result of molecular or atomic movements by which one atom or molecule communicates its movements to another, and thus the heat is carried forward through a series of moving atoms in a brief space of time, until at last these moving atoms of air or gas impart their heat motion to the molecules of the air and plate that receives them; the heat is now passed through the plate by the process of conduction, that is to say one atom of the plate gives up its heat after another, until the heat arrives at the inner surface of the plate, when the heat is given up to the water.

Now, water is a very bad conductor of heat, that is to say, heat cannot be passed through it as it is through the shell of the boiler, but the small particle of water resting on the bottom of the plate being heated expands, and this increases its volume, becoming at the same moment lighter than the other particles of cold

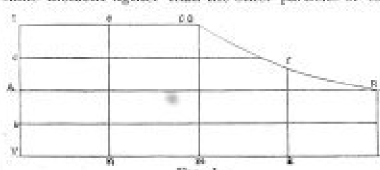

FIG. 1.

water, the result is that the heated particle of water rises or floats, while the cold particles sink and take its place. That this is so is easily shown by a Florence flask, if clear water be put in the flask with some fine particles of oatmeal, the heated particles of water carry with them particles of oatmeal upwards, until at last they are relatively cooler than other particles that are ascending. The cooler particles of the oatmeal are seen descending down the sides of the glass; this mode of conveying heat is called *convection*, and by convection the whole of the water in the boiler at last reaches boiling point, when heat still continues to act and cause the particles resting on the plate to take up so much heat that the inelastic fluid called water becomes an elastic fluid called steam.

Steam, in common with all gases, expands in conformity to the principles of Boyle's law, that is to say, the volume is inversely as the pressure, or the pressure is inversely as the volume. If a cubic foot of air was confined in a cylinder having a movable piston, and the enclosed air was situated beneath the piston and above the bottom, and if the piston be moved upwards until the volume of the space in the lower portion of the cylinder was increased to two cubic feet, the air would expand and fill this increased space, but while the air had increased its volume it would correspondingly be reduced in pressure. Suppose the pressure at first to be 15 pounds on the square inch, after the volume is doubled the air will be found to manifest a pressure of only 7½ pounds on the square inch; hence the statement, as the volume increases the pressure reduces; or, as the pressure increases the volume reduces. Suppose the same conditions as in the former illustration, and let the piston be thrust down until a cubic foot of air is compressed into the volume of half-a-foot—here the volume has been reduced and the pressure has been increased to 30 pounds on the square inch.

In the working of steam engines great advantages are obtained from the expansion of steam; the steam is said to be cut off at quarter stroke, half stroke, or two-thirds of the stroke, or at whatever fraction of the stroke the steam is cut off; the remainder of the stroke is completed by the expanding steam at a reduced pressure, capable of doing considerable work.

Watt discovered the gain to be derived from expanding the steam in a cylinder, and took out a patent to secure to himself advantages remunerative of his skill in applying Boyle's law. He not only did this, but he invented an indicator, or instrument to show on a paper diagram the varying pressure of the steam throughout the stroke, and it is to this diagram that we wish to draw the attention of our readers.

Referring to *Fig. 1*, *A L* represents the atmospheric line, or the line corresponding to the pressure of the

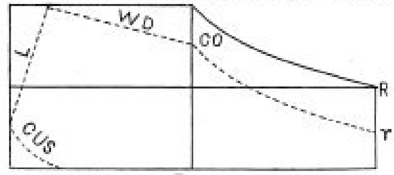

FIG. 2.

atmosphere. Now, as the pressure of the steam indicated at the boiler is not total pressure, but partial pressure, or the pressure above atmospheric pressure; to this portion of the subject the reader must confine his attention for a moment or two, otherwise, what follows will be a perfect mystery.

The zero of pressure will be about 14·7 pounds below atmospheric pressure, and this zero is represented by *V L* or the vacuum line, the zero line or the line of no pressure. Such a line as this can only be found when a vessel having a hollow space is void of all gas, air, or steam, when there will be no pressure, because pressure is a condition of matter, and if there be no gaseous matter in the vessel there cannot be any pressure, because there is no matter. Now, understanding these two lines, it is possible to make this ideal diagram understood.

From the atmospheric line to the letter *I*, the diagram indicates a pressure of the steam above the atmosphere equal to that of the atmosphere measured from *V* to *A*, therefore, if the vertical line measured from *V* to *A* be equal to the vertical line measured from *A* to *I*, and if *V* to *A* equals 14·7 pounds on the square inch, *A* to *I* also indicates 14·7 pounds on the square inch. Now, *V* to *A* is the pressure of the atmosphere, *A* to *I* is pressure above the atmosphere, therefore, the total pressure of the steam must be equal to the sum of these two pressures, or 29·4 pounds on the square inch.

Now, this 29·4 pounds on the square inch is called the total pressure of the steam. Expansion of steam cannot be calculated on the pressure from *A* to *I* because that is partial pressure. Boyle's law does not apply to a partial, but to a total pressure. Now, just let us discover the mistake we would make if we applied Boyle's law to partial pressure; from *A* to *I* is 14·7, and as the pressure is inversely as the volume, and as the steam is here cut off at *C O* in the diagram, or half stroke, if we double the volume while the piston travels the length of the diagram *B G*, on the completion of the stroke the volume of the steam would be doubled; therefore, the pressure would be halved, or it would be reduced to 7·35 pounds on the square inch. Now, consider for a moment what is this 7·35 pounds? If we consider it total pressure then the pressure of the exhaust steam would be 7·35 above the pressure of the atmosphere, which is totally incorrect, because it will be seen that the curved line in the diagram does not dip below the atmospheric line.

This 7·35 pounds cannot be pressure above the atmosphere, because the curved line terminates in the atmospheric line. Now then, calculate the expansion by Boyle's law on the total pressure, then if the steam is cut off at half the stroke, at the end of the stroke *R* it will have doubled its volume; now

$\frac{29·4}{2} = 14·7$. This is correct, because the expansion has reduced the pressure of the steam to atmospheric pressure, consequently the steam will exhaust from the cylinder at the same pressure as the atmosphere.

This diagram is a picture of the pressure of the steam during every point of the stroke, the vertical or upright lines, called ordinates, are pressure lines; the parallel horizontal lines are volume lines. Now, when the piston begins its stroke the total pressure of the steam is acting on it, that is a pressure from *V* to *I*, not that the pressure *V* to *I* is effective, because if it be a non-condensing engine the effective work done by the steam will be equal to the space enclosed by the diagram above the atmospheric line, and the work that the steam is capable of doing, and is lost, is represented by the space enclosed below the atmospheric

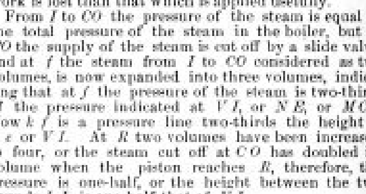

FIG. 3.

line. So that in a diagram of this character more work is lost than that which is applied usefully.

From *I* to *CO* the pressure of the steam is equal to the total pressure of the steam in the boiler, but at *CO* the supply of the steam is cut off by a slide valve, and at *f* the steam from *I* to *CO* considered as two volumes, is now expanded into three volumes, indicating that at *f* the pressure of the steam is two-thirds of the pressure indicated at *V I*, or *N E*, or *M CO*. Now *k f* is a pressure line two-thirds the height of *n e* or *V I*. At *R* two volumes have been increased to four, or the steam cut off at *C O* has doubled its volume when the piston reaches *R*, therefore, the pressure is one-half, or the height between the two pounds *L L* is one-half that of *V I*.

Figure 2 illustrates a theoretical diagram in strong lines, and enclosing an actual diagram in dotted lines. In this case the steam is cut off at one-half of the stroke or at the point *CO* when it expands to the point of release *R*. Now, in the actual diagram there are some very marked defects in the slide motion. At the bottom of the left-hand corner the dotted line is seen to be curved, this arises from the circumstance that the exhaust valve has closed before time. Now, lest there should be any misunderstanding about the explanation here given, let us carefully consider the matter.

To the uninitiated the piston or disc attached to the end of a piston rod reciprocates in a cylinder; that is, it travels from end to end during a stroke. Now, let us suppose that the piston is situated at the left-hand side of the diagram, and it is necessary for steam to propel it to the right, for this to be done there must be provided an entry for steam at the left-hand end of the cylinder, and the steam must enter between the cylinder and the piston, but between the right-hand end of the cylinder and the piston we have the steam which previously forced the piston the left. Now, before the piston can travel to the right an escape for the steam on the right-hand side of the piston must be provided for, this escape is known as the exhaust, or in other words, where one valve opens at the left to admit steam from the boiler, another valve opens to allow for the escape of the steam at the right-hand end of the cylinder. What is called a locomotive slide valve provides for the entry and escape of the steam alternately for both ends of the cylinder.

Now, fortified with this elementary knowledge we may proceed to describe the diagram: At the lower left-hand corner of the figure a dotted curve is shown marked *C U S*, this indicates that the exhaust valve has been closed before time, and the little steam there remained in the cylinder has been compressed by the piston after the manner of a "cushion." At the end of the stroke the steam is admitted too late, for it has evidently only been admitted at the moment the piston began its journey in an opposite direction, the result is instead of the dotted line being vertical it inclines to the right, and the whole pressure of the steam is not acting on the piston until it has moved onward in its stroke.

This arrangement of the line indicates that the steam is late, or the slide has what is called "negative lead." Not only so, but instead of the total pressure of the steam continuing to act on the piston until half the stroke has been completed at *CO*, it would appear that the port for the entry of the steam is too small for a fast-running engine, the result is the dotted line falls below *CO*, and this condition of the diagram indicates wire drawing or expansion without advantage. It will be seen that the dotted curve of expansion falls considerably below the normal curve as the result of the steam being wire drawn up to *CO*, further the point of release *r* indicates a final pressure inferior to *R*.

Figure 3 is in all respects the opposite of figure 2; cushioning takes place, not by compressing the exhaust steam, but by admitting the new steam before the piston has reached the left hand end of the cylinder, the result is the dotted line slopes in the opposite direction to that of figure 2, and the valve being amply sufficient for the admission of steam, there is no wire drawing up to *CO*, and the steam expands on the normal curve. It is easy to see that figure 3 is the diagram of a condensing engine, because the atmospheric line *AL* is shown at zero. The exhaust in this case is imperfect, that is to say, the steam cannot exhaust sufficiently quick into the condenser, the result is, instead of the diagram falling to the bottom horizontal line it produces the dotted line, indicating that the pressure in the cylinder at the beginning of the release is considerably above the pressure in the condenser, and this continues until the moment of cushioning, when the dotted line approaches a complete vacuum.

At the left-hand end of the diagram the scale from the atmospheric line upwards indicates pressure above the atmosphere, the scale from the atmospheric line reading downwards indicates pressure below the atmosphere.

The average pressure of the steam throughout the stroke of the piston of a steam engine is usually ascertained by dividing the sum of the lengths of the ordinates by their number, but the most correct method is not to take the sum of the ordinates, but the sum of the means of the ordinates.

The total length of the diagram in Figure 5 is divided into eight equal parts, and the means of the ordinates are shown by dotted lines, *e. g.*, the first mean on the left measures 17 tenths on the scale, but let us first make the reading of the scale clear, beginning at zero and counting to the right we have the numbers, 1, 2, 3, 4, 5, 6, 7. Now, 1 is really ten tenths, and 2 twenty tenths, 3 thirty tenths, 4 forty tenths, 5 fifty tenths, 6 sixty tenths, and 7 seventy tenths and so on, or they might be read 10, 20, 30, 40, 50, 60, and 70, in length; less than 10 tenths is measured on the left of zero. Now each tenth here represents a pound press-

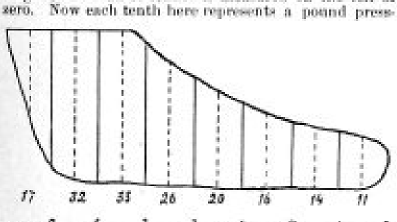

Fig. 4.

ure per square inch in the steam, then the sum of the means of the ordinates will be equal to all these measurements, added together thus:

$$17 + 32 + 33 + 26 + 20 + 16 + 14 + 11 = 169.$$

Now if the sum 169 be divided by the number of spaces included by the ordinates, namely 8, the result will be the mean or average pressure of the steam, as

$$\frac{169}{8} = 21{\cdot}125$$

the average effective pressure of the steam. The best way to measure off the mean ordinates of a diagram is to take a narrow ribbon of paper half an inch wide and twenty inches long, and by placing the extreme end of the ribbon at one end of the first ordinate make a tick with the pencil at the other end of the ordinate; then place the first tick at one of the extreme ends of the second ordinate and make a tick on the ribbon over the end, then take the tick over the second ordinate, and place it on the extreme end of the third ordinate, and tick off the other end of the ribbon, and so on throughout the series. Then measure the length of the ribbon, tick it off by the scale and divide that measurement by the number of ordinates when we have the mean pressure of the steam as before. A very good exercise could be had by measuring off with the ribbon, the ordinates in Figure 4.

MECHANICS IN MINING.

PUMPS (CONTINUED).

In vein mining the conditions for drainage to the shaft are entirely under artificial control. To realize this statement properly the coal mining student must by the aid of an idea conceive of a seam of coal being situated in a nearly vertical position; and to understand how the working galleries in a vein mine are drained, it will be quite in keeping with the description here required, to explain how the vertical coal seams are worked.

A shaft having been sunk to a depth of 1200 feet, a gallery is driven in the seam, the roof and the floor being both formed of coal. Now the student will see that this seam could not be worked by one level, consequently openings are driven upwards in the coal to a height of from one to two chains, and after an upper gallery has been driven and the lower and the upper galleries connected at intervals by vertical openings in the coal, it will be clear that pillars are left, as in horizontal working, such pillars however being on edge instead of lying horizontally. Now, if the student clearly understands what has been here stated, he cannot fail to see that in driving the galleries the gradient or fall to the shaft may be fixed uniformly at, say, half an inch to the yard to cheaply run off water that may accumulate at the working face.

The driving of the levels in vein mining are then under the same conditions as the driving of levels in the vertical coal seams; that is to say, the gradient or fall to the shaft is entirely under human control. The drainage of a horizontal coal seam cannot be effected in this manner, because nature has fixed a gradient for the seam which is often unfavorable to cheap drainage, hence the use of siphons, special pumps, etc. From the statement that has been made it will be seen that the pumps we have to consider in relation to metal mine drainage, as far as the workings are concerned, are that class of pumps used in shafts only.

We now are face to face with an arrangement for lifting and forcing sets used in the inclined shafts of metal mines, where the details are dissimilar to those we meet with in pumping arrangements for vertical shafts. The spears for the pumps in vertical shafts set up very little friction, as they are kept in a vertical position by wood guides. The guides for the spears in an inclined shaft are made as might be reasonably expected to move on rollers. There is another dissimilarity which has to be provided for in inclined shafts, viz., **V** bobs to allow the spears to accommodate themselves to the varying inclination of the shafts. It often happens that lifting sets cannot be used in inclined shafts because the varying inclination of the vein will not allow of the lifting set being straight. In such a case if the hydraulic main was put in crooked, wet spears could not possibly pass down the crooked set; therefore under such conditions dry spears and forcing sets are a necessity.

The student must carefully notice this point, the **V** bob is always fixed on that side of the spears where the two lengths are jointed and make an angle with each other of less than 180 degrees. The forcing set is precisely the same in construction as that previously described and illustrated.

Sometimes the lifting and forcing sets are combined in one arrangement and by this device a continuous flow of water in the hydraulic main is secured. The bucket is attached to the bottom end of the plunger, and to understand the arrangement the student might perform a very simple physical experiment: Fill a basin full to the brim with water and place it within a large dish; now plunge your clenched fist into the basin of water, when if the cubical contents of your fist are equal to half the cubical contents of the basin, half the contents will overflow into the dish. This simple law of displacement is a great feature of the pump in question. The plunger on the up-stroke makes a void for half the water lifted by the bucket. On the down-stroke the plunger displaces the water of the void previously made; this may be proved mathematically: Let the ram be 12 inches in diameter: this will give a sectional area of 144 circular inches, and let the sectional area of the bucket be 288 circular inches. Now, suppose the length of the stroke to be 60 inches, then $60 \times 144 = 8{,}640$ cylindrical inches, or on the descent of the plunger it will force to bank that number of cylindrical inches. Now the bucket will lift $60 \times 288 = 17{,}280$ cylindrical inches. Now study the up-stroke of this pump and you will observe that that portion of the plunger emerging out of the pump is making a void of 8,640 cylindrical inches, but the bucket has delivered into the chamber 17,280 cylindrical inches, but half of this has gone to bank and the other half fills up the void; and on the down-stroke of the plunger this remaining half is also delivered to bank. If the diameter of the ram be twelve inches that of the bucket will be twelve divided by decimal seven, or seventeen inches. If the diameter of the bucket be given the diameter of the ram may be found by multiplying by decimal seven.

MECHANICAL PROBLEMS.

Q. (*a*)—What horse-power of an engine will be required to haul to the shaft 700 tons of coal in nine hours, along an engine plane 3,000 yards long, and having an average rise to the shaft of $2\frac{1}{2}$ inches to the yard?

A.—The horse-power will be found as follows: First, find the force in pounds required to haul one ton up the incline, thus

$$2240 \times \frac{2\frac{1}{2}}{36} = 155{\cdot}55 \text{ lbs.}$$

Taking 30 pounds per ton as an average for friction on a level road for pit cars, then $155{\cdot}55 + 30 = 185{\cdot}55$ pounds of force required to haul one ton up the incline. The total load against the engine will therefore be the weight of the coal plus the weight of the cars, or, 700 tons + 350 tons = 1050 tons. Again, $1050 \times 185{\cdot}55 \times 9000$ (3000 yards $\times 3 = 9000$ ft.) $= 1{,}753{,}447{,}500$ units of work to be performed. Now taking $\frac{1}{3}$ of the time for hauling coal; $\frac{1}{3}$ of the time for hauling empty cars returning, and $\frac{1}{3}$ of the time for hauling, waiting on, and changing, then $\frac{1}{3}$ of 9 hours will be 3 hours, or 180 minutes, and allowing a modulus of ·7 on account of friction of ropes, drum and rollers, and the engine itself, the horse-power will be as follows:

$$\frac{1{,}050 \times 185{\cdot}55 \times 9{,}000}{180 \times 33{,}000 \times {\cdot}7} = 421{\cdot}7 \text{ horse power.}$$

Q. (*b*)—At what speed will the rope travel in the previous question?

A.—The average speed of the rope in main and tail rope haulage is ten miles per hour, or 880 feet per minute.

Q. (*c*)—How many 10-cwt. cars would be required to do the work required in question (*a*) at the rate of speed found by question (*b*)?

A.—To find the number of cars, divide the strain on the rope by the strain due to one car.

To find the strain on the rope, divide the units of work actually performed by the feet or distance traveled in one minute, thus

$$\frac{421 \times 33{,}000 \times {\cdot}7}{880} = 11051{\cdot}2 \text{ pounds strain on}$$

the rope.

The strain due to one car will be as follows: The pounds of force required to haul one ton up this incline are 185·55, and as a full car will only weigh $\frac{3}{4}$ of a ton, therefore

$$185{\cdot}55 \times \tfrac{3}{4} = 139{\cdot}16 \text{ pounds strain for one tub.}$$

Then, $$\frac{11051{\cdot}2}{139{\cdot}6} = 79 \text{ cars.}$$

Another method of calculating this question is the following:

The speed of the rope being 10 miles per hour, the speed per minute will be 880 feet. Now as the engine plane is 9,000 feet long the cars will take

$$\frac{9000}{880} = 10{\cdot}22 \text{ minutes in running to the pit}$$

bottom, and as they are running thus during 180 minutes, it will require

$$\frac{180}{10{\cdot}22} = 17{\cdot}6 \text{ trains per day.}$$

Now, to haul out 700 tons of coal, it will require 1,400 cars, each carrying 10 cwt. of coal, then

$$\frac{1400}{1{\cdot}76} = 79 \text{ cars nearly.}$$

Q. What should be the sectional dimensions of wood spears for a pumping set lifting water 180 feet, the diameter of the bucket being 12 inches?

A. The diameter of the set is 12 inches, or 1 foot; then

$1 \times 1 \times {\cdot}7854 = {\cdot}7854$, the area of the bucket in square feet. Now the length of the column is 180 feet. Then

$${\cdot}7854 \times 180 = 141{\cdot}372 \text{ cubic feet, and}$$

$141{\cdot}372 \times 62{\cdot}5$ (a cubic foot of water weighs 62·5 lbs.) $= 8835{\cdot}75$ lbs.

For every square inch in the section of the spears an allowance of five hundred weights for lifting power should be allowed, or, in other words, every square inch in the section of the spears has a lifting power of five hundred weights. Then, as there are 112 lbs. in a cwt., we find the square inches in the sectional area of the spears as follows:

$$\frac{8835{\cdot}75}{5 \times 112} = 15{\cdot}77, \text{ and the square root of}$$

15·77 is 4 inches nearly, so that the size of the spears required in this case will be 4 inches.

Q. What size of spears would be required for a lift of 240 feet with a 16-inch set?

A. First we will find the square feet, thus

$$\frac{16 \times 16 \times {\cdot}7854}{144} = 1{\cdot}3962 \text{ sq. ft.,}$$

and $1{\cdot}3962 \times 240 = 335{\cdot}088$ cubic feet of water in the column. Now $335{\cdot}088 \times 62{\cdot}5 = 20943$ lbs. weight of water to be lifted, and

$$\frac{20943}{112} = 187 \text{ cwts., nearly, of water to be}$$

lifted; therefore

$$\frac{187}{5} = 37{\cdot}4 \text{ the square inches of area in the}$$

section of the spears, and $\sqrt{37{\cdot}40} = 6{\cdot}1$, or the spears being square will be 6 inches on the side.

Q. What size of spears would be required for a lift of 270 feet with an 18 inch set, the water having ultimately to be delivered at an elevation of 1,560 feet?

A. Here we proceed as before to find the weight or pressure on the bucket, but to this must be added the weight of the spears to find the size demanded. Then

$$\frac{18 \times 18 \times {\cdot}7854}{144} = 1{\cdot}7671 \text{ square feet in}$$

the area of the bucket, and $1{\cdot}7671 \times 270 = 477{\cdot}117$ cubic feet of water to be lifted; and $477{\cdot}117 \times 62{\cdot}5 = 29819{\cdot}8125$ lbs., the weight of water to be lifted. A spear 1 square inch in section, and of a length equal to that given in the question, will weigh 950 pounds, as the specific gravity of spears being 1·4, including saturation and the iron fastenings. Now

$$\frac{29819{\cdot}8125}{112} = 266{\cdot}2483, \text{ the cwts. of water to}$$

be lifted; and

$$\frac{266{\cdot}2483}{5} = 53{\cdot}2496 \text{ square inches, the}$$

area of spears required for the water, but to this must be added

$$\frac{950}{112 \times 5} = 1{\cdot}69. \text{ Now}$$

$53{\cdot}2496 \times 1{\cdot}69 = 89{\cdot}991824$, the square inches in the section of the spears required to lift water and spears, and

$\sqrt{89{\cdot}991824} = 9{\cdot}5$ inches nearly, the measure of the spears in the side, or it may be said the spears ought to be 9·5 inches square.

EXAMINATION QUESTIONS ANSWERED.

CORRECTIONS.

In our September issue, Questions 49 and 50, on page 44, were incorrectly answered. Question 49 was answered in a manner that would give an answer nearly enough correct for practical purposes in mine ventilation, but it was not absolutely correct.

The correct answers are given herewith:

QUESTION 49.—If the temperature of 1,000 cu. ft. of gas be raised from 60° to 90° what will then be its volume?

ANSWER.—We will assume the barometric pressure to be 30 ins.

Then $\frac{1\cdot3253 \times B}{459 + T}$ = weight of one cu. ft.

$\frac{1\cdot3253 \times 30}{459 + 60} = \cdot07660$ lbs. for weight at 60°.

$\frac{1\cdot3253 \times 30}{459 + 90} = \cdot07242$ lbs. for weight at 90°.

The comparative volumes are then found as follows:

·07242 : ·07660 :: 1,000 : ( ) or
·07242 : ·07660 :: 1,000 : 1057·7

While it is true that air expands $\frac{1}{459}$ of its volume for each degree of heat added, it is evident that this expansion commences at 0; and what was 459 cu. ft. at 0 becomes 459 + 60 or 519 cu. ft. at 60°. Hence the proportion should be stated

450 + 60 : 459 + 90 :: 1,000 : 1057·6 Ans.

QUESTION 50.—If a room in a mine, 10 yds. long, 4 yds. wide, and 3 yds. high, be filled with fire-damp, how much pure air will be required to bring the mixture to an explosive point, and if the same was exploded to what area would it extend?

ANSWER.—In our September issue we gave the maximum amount of air that would render the mixture explosive, when we should have given the minimum amount. The correct answer is as follows:

The room being 30 ft. long, 12 ft. wide, and 9 ft. high, will have a cubical capacity of 3,240 cu. ft. To make 3,240 cu. ft. of gas explosive, we must add to it 5·5 times as much air, because as 5 parts of air to 1 of gas merely makes the mixture combustible, and each part of air added up to 9 or 10 parts of air to one of gas makes the mixture more and more explosive, it is evident that an explosion will likely ensue when 5½ times as much air is added.

Then 3,240 × 5·5 = 17,820 cu. ft. of air must be added. The volume then becomes 17,820 + 3,240 or 21,060 cu. ft.

The distance to which the explosion would extend cannot be accurately determined, but it has been found that a violently explosive mixture will expand to about 8 times its volume. As the volume before explosion is 21,060 cu. ft., the explosion will expand it to 8 × 21,060 or 168,480 cu. ft. Then as the height of the workings is given as 9 ft., the explosion will extend over an area of 168,480 ÷ 9, or 18,720 sq. ft.

In our October issue the formula given to answer Question 14, of the Iowa examination, was clearly and correctly stated, but there was an annoying error in the simple arithmetic work of getting the answer. It should have read:

The difference of twelve inches in the reading of the water-gauge shows that to overcome friction a pressure of 12 × 5·2 lbs. or 62·4 lbs. per square foot has been required; and as the velocity is 10 ft. per second in an entry of 48 square feet sectional area there is a current of 10 × 60 × 48 or 28,800 cu. ft. passing. Then the rule to obtain the effective horse power is to multiply the pressure per square foot by the volume of air passing per minute and divide by 33,000.

Thus

$$\frac{62\cdot4 \times 28,800}{33,000} = 54\cdot5 - \text{H. P.}$$

QUESTION 21.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Supposing a fire should take place in the inlet airway and your men were at work inside of the fire, how would you proceed to rescue them?

ANSWER.—I would stop the fan and send or lead a rescuing party into the mine by way of the outlet, because if the fan was stopped the fire in the inlet would reverse the usual order of ventilation, and the men could be taken out by way of the outlet, which would, for the time being, be the inlet airway.

QUESTION 22.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

What are the disadvantages of having the air travel at a high velocity? Explain fully.

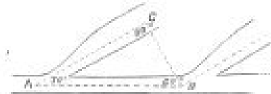
ANSWER.—The most efficient mine ventilation is secured by large airways and slow velocities. The pressure required to increase the velocity of an air current is proportional to the squares of the velocity, so that to double the velocity there must be four times the pressure, or to treble it there must be twenty-seven times the pressure, and so on. If we treble the velocity of the air we thereby cause three times the number of particles to meet the resistance in each moment of time; this alone will treble the resistance, and this with three times the speed, may well be supposed to give rise to a treble treble or twenty-seven resistance.

Again, if the air be so charged with fire-damp as to be explosive, a velocity exceeding 6 ft. per second will force the flame through the gauze of a Davy lamp and cause an explosion.

QUESTION 23.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Where the gangway is running due East, and breasts are opened 30° North of East, it is desired to maintain a distance of 45 feet for breast and pillar, what will be the distance on the gangway from center to center of breasts?

ANSWER.—The angle formed between the breasts and gangway is 30°. The distance 45 ft. is measured at right angles to the center lines of the breasts, and we thus have to solve a right angled triangle, as shown by dotted lines in cut.



Then as the sine of angle A is to length of line B C as sine of angle C is to line A B we have the following proportion:

Sine 30° : 45 :: Sine 90° : A B or

·5 : 45 :: 1 : 90 or length of line A B.

Or, we can divide the length of the line representing the combined width of breast and pillar by the sine of the angle formed at the junction of the center lines of gangway and breast, which in this case is the sine of 30° or ·5. Then 45 ÷ ·5 = 90 ft.

QUESTION 24.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania on July 6 and 7, 1891.

Which in your opinion is the best method of timbering where the top rock is hard, and inclined to creep, and the vein or seam free and lying on an angle of 10°; and which requires the larger pillar, a hard or soft top?

ANSWER.—The best method of timbering where the top rock is hard and inclined to creep, and the seam free on an angle of 10°, is to timber with double timber, or in other words, with two legs and a collar, set not more than five feet apart, and well lagged back of the legs.

A hard top requires the larger pillar because there is a greater weight to support, and as it will not relieve the weight by breaking it will crush the pillar sooner than a soft top that would break and thus relieve the pillar of some of the weight.

QUESTION 25.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In opening up a colliery having three workable seams divided by 12 and 25 feet of slate, what system or plan of mining would you adopt, and how would you ventilate the several seams?

ANSWER.—I would adopt the pillar and breast system and open the breasts directly over each other, and would leave every tenth breast in each seam solid so as to form a binding pillar through the three seams. I would ventilate with an exhaust fan having separate splits for each seam and would further sub-divide these splits as occasion and conditions required. I would have cross-holes through the slate at intervals, to assist in dividing the air, if necessary, and also for use as traveling ways.

QUESTION 26.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Supposing a gangway has been driven due East to the land line running South 40° East, it is proposed to open a breast 40 feet from the face of gangway, how far would the breast go to reach the land line when the pitch is 25°?

ANSWER.—It will depend on the direction in which the breast is driven. If it is driven South it will never reach the land line. If driven North it will reach the land line at a distance of —·- ft.

In the first place we have the land line running S. 40° E, or 40° East of South, which forms an angle of 40° on the North side of gangway. Then if the seam was flat we would have a right-angled triangle with a base of 40 ft., and an angle of inclination of 40°, and we want to find the altitude. Then to find this we multiply 40 by the tangent of 40°. 40 × ·8391 = 33·5640 ft. This would be the distance from the gangway to the land line if the seam was flat, but as it pitches 25° the distance would be 33·564 ÷ the cosine of 25° or ·906308. Then 33·564 ÷ ·906308 = 37·3 + ft.

QUESTION 27.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

What instruments are necessary for a mine foreman, and for what purpose does he use them? Explain fully.

ANSWER.—An anemometer to measure the velocity of the current of air. A water-gauge to measure the pressure. A clinometer to measure the dip of the strata, etc. A thermometer to measure the temperature. A barometer to measure the pressure of the atmosphere. A tape line or chain to measure distances. A compass or transit to make short surveys and to lay off angles. A safety-lamp to test the air for gas. A small set of drafting instruments and any other scientific instruments he can use to advantage in determining the safest and most economical method of mining the coal and securing good and adequate ventilation.

QUESTION 28.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Which in your opinion is the best safety-lamp, and why does the Davy lamp continue to burn when placed in a body of gas, and why does the Clanny lamp become extinguished when placed in fire-damp?

ANSWER.—In my opinion the Evan Thomas No. 7 is the best safety-lamp because it possesses all the good features of other practical lamps and when tested by various scientific committees it has behaved better than any other. Besides it is simpler in construction than any other of the improved types. The Davy lamp continues to burn in fire-damp because the air has easy ingress and it receives enough to support combustion through the gauze even when the gauze is filled with flame. The Clanny lamp does not have so easy an ingress for air, and if the gauze becomes filled with flame, there is not enough air admitted in the lower part of the lamp to keep up combustion and it necessarily goes out. This is theory, but in practice it is not safe to rely on the Clanny lamp becoming automatically extinguished.

QUESTION 29.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

In a mine employing 300 men, what amount of air is required, and what would be the area of the airway if the velocity is 500 ft. per minute?

ANSWER.—The Anthracite law requires a minimum of 200 cu. ft. of air per minute per employe. Therefore this mine will require 300 × 200 = 60,000 cu. ft. As the velocity is 500 ft. per minute the airway to pass 60,000 cu. ft. must have an area of

$$\frac{60,000}{500} = 120 \text{ square feet.}$$

QUESTION 30.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania on July 6 and 7, 1891.

Which should be the largest airway, the inlet or the outlet airway? Must explain fully.

ANSWER.—The outlet; because the air in its passage through the mine becomes heated and expands, requiring a larger passage-way to carry the same amount as enters the inlet, without increasing the velocity.

QUESTION 31.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

The amount of air produced by a fan is 120,860 cu. ft. per minute, and the water-gauge is 2·4 inches, what is the horse power producing ventilation?

ANSWER.—The horse power is found by multiplying the quantity by the pressure per square foot and dividing by 33,000. For each inch of water-gauge the pressure is 5·2 lbs. per square foot. Therefore we have the following:

$$\frac{120,860 \times 2\cdot4 \times 5\cdot2}{33,000} = 45\cdot7 + \text{H. P.}$$

QUESTION 32.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Suppose 30,000 cu. ft. of air is produced by a water-gauge of 1·6 inches, what quantity will a water-gauge of 2·5 inches produce?

ANSWER.—The volume varies as the square root of the water-gauge, hence $\sqrt{1\cdot6} : \sqrt{2\cdot5}$ :: 30,000 : ( ) or 37,500 (nearly) cu. ft.

QUESTION 33.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

Where should a furnace be placed so as to give the best results?

ANSWER:—At or near the bottom of the upcast shaft.

QUESTION 34.—Asked at the Examination for Certificated Mine Foremen in the Anthracite Regions of Pennsylvania, on July 6 and 7, 1891.

How could you light a furnace in a mine where the temperature outside is 90° and the temperature inside is 60°, the furnace being built at a point 100 ft. higher than the intake opening? Explain fully.

ANSWER.—Without the use of a furnace the current would naturally be the reverse of what was wanted, and it would be necessary to build as quick and as strong a fire as possible. I would have plenty of combustible material on hand, and after closing the passage-way from the inlet air course I would start a brisk fire, and gradually open the closed passage, so as to give the fire plenty of draft without having the smoke and gases carried back through the workings. As soon as I had the temperature in the upcast shaft raised to a point above 90°, I would throw the passage-way entirely open, and the current would flow in the desired direction

MECHANICAL NOTES

Requirements of a Perfect Steam Boiler

1. The best materials sanctioned by use, simple in construction, perfect in workmanship, durable in use, and not likely to require early repairs.

2. A mud drum, to receive all impurities deposited from the water, in a place removed from the action of the fire.

3. A steam and water capacity sufficient to prevent any fluctuation in pressure or water level.

4. A large water surface for the disengagement of the steam from the water, in order to prevent foaming.

5. A constant and thorough circulation of water throughout the boiler, so as to maintain all parts at one temperature.

6. The water space divided into sections, so arranged that should any section give out no general explosion can occur, and the destructive effects will be confined to the simple escape of the contents; with large and free passages between the different sections to equalize the water line and pressure in all.

7. A great excess of strength over any legitimate strain; so constructed as not to be liable to be strained by unequal expansion, and, if possible, no joints exposed to the direct action of the fire.

8. A combustion chamber so arranged that the combustion of the gases commenced in the furnace may be completed before the escape to the chimney.

9. The heating surface, as nearly as possible, at right angles to the current of heated gases, and so as to break up the currents and extract the entire available heat therefrom.

10. All parts readily accessible for cleaning and repairs. This is a point of the greatest importance as regards safety and economy.

11. Proportioned to the work to be done, and capable of working to its full rated capacity with the highest economy.

12. The very best gauges, safety-valves, and other fixtures

The Antiquity of Wire.

It is not generally known that the manufacture of those metallic filaments or shreds known as wire is one of considerable antiquity, and has been traced by good authorities as far back as the period of early Egypt. A specimen of wire made by the Ninevites some 800 years B. C. is exhibited at the South Kensington Museum. Homer and Pliny referred to similar productions in their writings. From such remote eras up to the fourteenth century wire in its general acceptation was produced by hammering out strips of metal. The operation of wire drawing is mentioned as early as the fourteenth century, for in the chronicles of Augsburg and Nurnberg, of 1351 and 1360 respectively, we find reference to wire drawers, so that it is reasonable to infer that the draw plate was known and used at that period. Rudolf of Nurnberg erected the first wire drawing mill shortly after. About the year 1500 the credit of wire drawing was ascribed in France to one Richard Archal. It was not until about 1565 that machine drawn wire was produced in Great Britain, the manufacture being introduced by a native of Saxony, C. Schultz, and Caleb Bell, who had a mill driven by water power, in Greenfield Valley, Holywell, Queen Elizabeth being supplied with toilet pins from that mill. Inferior hand drawn wire had been and was being made in the neighborhood of the Forest of Dean and elsewhere, but in the seventeenth century the improved manufacture was carried on in Yorkshire and later on in the districts of Warrington and Birmingham, where the industry is still largely located.—*London Iron and Coal Trades Review.*

Another New Nail Machine.

The ordinary wire nail machine bids fair to be superseded if the success of the Pittsburgh Iron and Nail Company in fitting a wire nail attachment to its steel plate nail mill shall prove of general adaptation. In carrying out this plan, the self feeder of a nail plate machine is removed, its place being substituted with an ordinary wire nail machine feed, operating from the left side; the bed plate, gripping and heading dies remain as in the old machine, but from the clamp at the back is attached an arrangement for cutting and pointing the wire similar to the manner in which this process is carried on in regular nail wire machines. It is said that the adapted machine turns out perfectly formed nails at the rate of 250 a minute, and that the heading die performs its work better than characterizes the ordinary apparatus; the heading arrangement of the latter works from above, and fashions the head with a quick blow, while the heading die of the transformed nail plate machine works from the right hand side, and works the heads with a more gradual motion. The nails by this method are represented as thoroughly well made, well pointed, and with large head, and without any indication of splitting. By changing the space block, four, six, eight, and ten penny sizes can be made, and the capacity of the device for wire nails is said to be from 40 to 50 per cent. greater than the common wire nail machine.—*Iron Trade Review.*

Mechanical Drawing a Part of Education.

A good many young men who have been denied the advantages of a technical education, or even a first-class public school education, but who are nevertheless desirous of standing high in their calling, even though they must work their way slowly upward from the bench, the forge, or the foot-plate, sometimes ask if there is any necessity of obtaining a good knowledge of mechanical drawing. To all such, we would most earnestly reply, "By all means obtain a thorough knowledge of drawing." A man may rise to a fair position in any of the mechanical pursuits without it, but if he really wishes to become proficient, and to avoid having his upward progress permanently arrested, his knowledge of mechanical drawing must be considerable. By such knowledge we do not mean the ability to make pretty pictures, or even handsome drawings, but rather a perfect understanding of the principles of the art, and their applicability to every-day work. We have frequently seen the intelligent shop foreman make a drawing which a draughtsman might say looked "tough," but though his lack of expertness in the use of the instruments gave his drawing that appearance, they would be intelligible and correct. Such knowledge always makes it possible for one to communicate his ideas to others, and aside from this convenience there is a drilling of the powers of conception which is invaluable, and can be obtained no other way. A still further advantage accompanying a good knowledge of mechanical drawing, is the better understanding of the fundamental principles of mechanics which almost invariably comes to the student as he becomes proficient in drawing. Every mechanic trying to rise should study drawing, even though he may never intend to work an hour in a draughting room in his life.—*The Railway Review.*

Making and Tempering Spiral Springs.

When the steel spiral spring of an instrument gets broken, it is much more satisfactory to make one than to send the instrument off, and be without it for a week or more.

To make them, use the best spring steel wire; select a smooth iron rod the size of the spring to be made; carefully draw the temper from the wire; fasten the rod and one end of the wire in a bench-vise. Now wind the wire evenly and closely around the rod, until you get the length of the wire required for the spring. Take the rod out of the vise; fasten one end of the spring to the rod; taking hold of the other end, draw it along the rod until the spirals are the correct distance apart. To give the amount of spring wanted, fasten it firmly to the rod, then make the spring and rod red hot, and quickly plunge them into cold water. After drying, rub them all over carefully with oil, and move them about in the flame of a lamp until the oil takes fire, which will give the spring the proper temper. I know there are some who make springs direct from tempered wire; but they are much more durable if shaped and then tempered.—*Dr. Wm. H. Steele, in Items of Interest.*

ENGINEERING

Railroad Matters in Peru.

An engineer engaged on the Central Railroad of Peru writes to us under date of May 6th, giving information of various matters of railroad interest.

Concerning the Inter-Continental railroad surveys he says it is not probable that the amount appropriated will permit more than reconnaissances to be made by parties in the field. He suggests that there may be some trouble from the Indians living east of the Andes, in the heavily timbered country along the headwaters of the Amazon and its branches. The local belief is that the Indians are cannibals, and that they kill their enemies by the use of poisoned arrows blown from blow-guns. He has seen a head that had been treated by these Indians in a manner similar to that employed by the Indians of Alaska. All the bones of the skull were removed, and the skin and muscles were shrunk into a mass about four inches in diameter, but the features roughly preserved. Our correspondent thinks that this will illustrate one of the possible incidents in the life of a Pan-American engineer.

Work on the construction of the Central of Peru is proceeding slowly; fifty miles are building. At the date of the letter work was a good deal delayed for want of timber for timbering tunnels, and also for lack of cement and powder. The Rimac River makes a good deal of trouble every year about the end of the rainy season. No provision was made for this contingency. March 9 the river rose, and two months afterwards no train had got through to the end of the line.

One feature of the country is avalanches of mud carrying down large stones. These sweep everything before them, and it was such an avalanche that carried away the Verrugas Bridge. One of these dammed the Rimac River this year, making considerable trouble.

Most of the laborers are Indians, and at the date of the letter they were off digging potatoes. It all planted at the same time work would have to be stopped, but fortunately there is sufficient difference in the time of ripening of the crop to enable contractors to keep some laborers at work.

It was expected that orders would be received to build a branch to Ceno de Pasco, eighty miles.

In the south Mr. Norris is building about forty-two miles of the Juliaca & Cuzco, from Santa Rosa to Sicuani. This is all light work.

Surveys are being made for an extension of the Trujillo road and others to change the location of the Chimbote. This was located and partly built in the Santa Valley and through a canon in the Black Range. It was washed out badly, and now an effort is being made to cross the range. The lowest pass is 16,000 feet. Then there would be a descent of 8,000 feet, with four-per-cent. grades on both sides of the tunnel, and very heavy work. Going up the Santa would be a continuous grade with a maximum of two per cent. If the road is built on this line it would be one of the best in Peru, as the valley is large and well-peopled. It is fertile and will produce sugar cane in the lower altitudes and wheat higher up. It also has considerable mineral deposits with good coal.

A Steel Bridge Across the Columbia.

The great steel bridge across the Columbia River, at Vancouver, will be a mammoth concern. It will be 6,000 feet from the Washington to the Oregon shore, and it will be double tracked, with roadway on top for teams, and will be erected upon pneumatic piers. The pivotal pier, or draw pier, will support a draw which will give an opening of 200 feet space on either side for vessels to pass, and the span immediately south of the draw span will be 375 feet.

Whole structure to be of steel, built ten feet above the high water of 1876, and forty feet above low water. On account of the sandy formation it will be necessary to go down eighty feet below low water to get a firm foundation. This gigantic structure will cost over $4,000,000. It will be January 1, 1892, before the cars can pass over it. The company is pushing the bridge and also the road as rapidly as men and money and their present perfected plans will permit.—*The Age of Steel.*

Cast Iron Tunnels.

Two tunnels of cast-iron for an electric railway have been built in London and put in operation for rapid transit. They are three miles in length, and lie between forty and sixty feet below the surface of London streets. The tunnels for the up and down lines are formed of cast-iron from beginning to end, save where the stations are built, and their diameter is 10 and 10½ feet. The tubes are formed of rings one foot and seven inches long, made in sections and bolted together. The tunnels are driven by means of a short cylinder, a trifle larger in its inner diameter than the exterior diameter of the cast-iron tunnel lining. This cylinder has a cutting edge, and is forced forward by hydraulic jacks, cutting a circular way into which the lining plates are fitted. The narrow space between the lining and the soil was filled with lime cement forced in under high pressure. In their course the tunnels pass beneath the bed of the Thames and through the bed of an old watercourse, where loose, wet gravel offered some trying obstacles for the engineers to overcome. The entire cost of the line, fully equipped, was less than $3,750,000.

Measuring Strains on Iron and Steel Bridges.

A new method for accurately measuring the strains in iron and steel bridges, has been invented by a prominent French engineer, and is described as follows: Two brackets are attached to the beam to be tested, at some distance apart, on one of which is placed a water chamber, closing by a flexible diaphragm, and connected with an open tube, which serves to register by the height of the tube any pressure that may be made on this diaphragm. One end of a pointed rod is connected with this metal covering to the water chamber, while the other is joined to the other bracket. The most important item of the invention is that any motion of the beam, it will be readily seen, will set the diaphragm in motion, and cause the water in the fine tube to fall. This is a first-rate apparatus, as we are all familiar with the great numbers of railroad accidents that in many cases originate from an unsafe shaky bridge.—*New York Ledger.*

Scientific Advancement

Drunkenness Cured by Dr. Keeley.

In a little town in Illinois called Dwight, on the Chicago and Alton Railroad there has lived and practiced his profession for twenty-five years past a certain Dr. Keeley. The world at large has heard little of him until recently, but during all his professional career he has enjoyed the respect and confidence of his neighbors, and has been a member in good standing of the county and state societies which determine those ethical questions which appear to be of more significance to medical men than to those in other learned professions. He has long been engaged upon investigation as to the cure of drunkenness, and, it is said, these studies have been but a continuation of those made by his father and grandfather in the same direction. For several years past the newspapers in the neighborhood of Dr. Keeley's home have contained more or less full accounts of his having cured by the use of double chloride of gold, men who had long been regarded as hopeless drunkards.

Something like a year ago Mr. Joseph Medill, the venerable editor of the Chicago *Tribune*, had his attention attracted to this new method of treatment, and he had an examination made of it. What he learned influenced him to make a practical test of the alleged cures. He therefore selected several men in Chicago who were looked upon as hopelessly addicted to the habit of drinking liquor excessively, and who also appeared to be wrecked by this long continued intemperance. These he sent to Dwight, and engaged to pay their expenses while undergoing treatment. The result was so satisfactory to him that he endorsed the methods employed by Dr. Keeley in an editorial article in his paper. Naturally enough this endorsement, a most unusual thing from a paper of a class of the *Chicago Tribune*, attracted very general attention, and soon afterwards there was a tide of patients turned towards the little village of Dwight, whither hopeless men traveled in search of something which before had seemed beyond their reach.

Arrived at Dwight these pilgrims found a straggling village, with muddy or dusty streets according to the prevalence of rain or sunshine, and there was only one thing to make it seem different from any other Western village in which twelve hundred persons had their homes. This difference was noted almost at once. There were well-dressed and well-appearing men on the streets in considerable numbers who evidently had never taken any active part in village life, and who were not now of it. These were the pilgrims, these the patients, who had gone to see whether the bichloride of gold treatment could quench their fiery thirst.

The impulse which each new patient brings with him it is said, is to conceal his identity; but as there are men from all parts of the country there—and this is but a very small world, after all, as every man who has traveled away from home has found out—this concealment is all but impossible, and the great majority are soon content to settle down, and acknowledging to themselves that their inebriety is a disease which they as sensible men are trying their best to cure, each in his own personality, and with whatever weight that may add to his words, tries to encourage the new comer," and to contribute his best to the fellowship and comradeship of the community. And, singularly enough, these patients, once dismissed as cured, never, it is claimed make any effort to conceal the fact that they have been treated at Dwight for inebriety. The idea among them seems to be that this form of disease may come as typhoid fever comes, and its cure is a matter for congratulations without any concealment whatever.

The increasing number of patients has necessitated the building of a hotel; but previous to that they boarded around at the various houses and cottages in the village. A new patient, after registering at the Keeley Institute, is given instructions as to the routine of treatment. He is given a bottle of the bichloride of gold mixture. This he must take once every two hours, and four times every day at stated hours he must fall in line with the other patients with bared arm, and receive a hypodermic injection of a medicine the nature of which Dr. Keeley has not announced to the world, but which he explains to his patients is intended as a "bracer," and also to regulate the effects of the bichloride of gold. His method of preparing his gold mixture he also retains as a secret.—*Jno. Gilmer Speed, in Harper's Weekly.*

The Possibility of Mechanical Flight.

Above us in the great aerial ocean stretching over all lands, and offering an always open way to them, yet a way that has never yet been thus trodden. Can it be that the power we have always lacked is at last found, and that it only remains to learn to guide it?

Let me in answering, compare the case to that which would present itself if the actual ocean had never been traversed because it was always covered with fields of thin ice, which gave way under the foot, which indeed permitted vessels to be launched and to float, but which compelled them to move wherever the ice drifted. Such vessels would resemble our balloons, and be of as little practical use; but now suppose we are told, "The ice, which has always been your obstacle, may be made your very means of transport, for you can glide over the thinest ice, provided you only glide fast enough, and experiments will prove not only how fast you must go to make the ice bear, but that it is quite within the limits of your strength to go with the requisite speed." All this might be true, and yet if no one had ever learned to skate, every trial of this really excellent plan would probably end in disaster, as all past efforts to fly have done. Indeed, in our actual experience with the air, men have come to the same kind of wrong conclusion as would have been reached in supposing that the ice could not be traversed because no one had the strength to skate, while the truth would be that man has plenty of strength to skate, but is not born with the skill.

The simile is defective so far as it suggests that man can sustain himself by his unaided strength on calm air, which I believe to be impracticable; but it is the object of these experiments to prove that he has now the power to sustain himself with the aid of engines recently constructed, and by means I indicate, as soon as he has skill to direct them.

If asked whether this method of flight will soon be put in practice, I should have to repeat that what has preceded is matter of demonstration, but that this is matter of opinion. Expressing, then, a personal opinion only, I should answer, "Yes." It is hardly possible that these secondary difficulties will not be soon conquered by the skill of inventors and engineers whose attention is already beginning to be drawn to the fact that here is a new field open to them, and though I have not experimented far enough to say that the relations of power to weight here established for small machines will hold for indefinitely large ones, it is certain they do so hold, at any rate far enough to enable us to transport, at speeds which make us practically independent of the wind, weights much greater than that of a man. Progress is rapid now, especially in invention, and it is possible—it seems to me even probable—that before the century closes we shall see this universal road of the all-embracing air which recognizes none of man's boundaries, traveled in every direction, with an effect on some of the conditions of our existence which will mark this among all the wonders the century has seen.—*The Secretary of the Smithsonian Institution in the Century.*

At an Altitude of 15,400 Feet.

Mr. Imfeld, the Swiss engineer who has been engaged to examine the nature of the summit of Mont Blanc for the construction there of Mr. Janssen's proposed observatory, recounts in a Zurich Journal the difficulties he is experiencing in his preliminary survey. He is staying with eight workmen and two doctors at Mr. Vallot's observatory, which has an altitude of 15,400 feet, and thence they proceed daily to their summit, where they work for several hours a day in the endeavor to ascertain the depth of the snow for the purpose of getting the necessary foundation for the building. Mr. Eiffel has expressed the opinion that the construction of an observatory will only be possible if the snow does not exceed a depth of 40 feet. Mr. Imfeld states that they have encountered traces of a ridge of rock 58 to 65 feet below the summit, and covered with about 3½ feet of snow. They have therefore commenced to make a series of lateral tunnels on three sides, at a distance equal to 40 feet below the summit, to ascertain if the ridge extends to that height. Progress is necessarily slow. Most of the men are suffering from the mountain sickness. Some, however, who are engaged at Mr. Vallot's cabin, are able to work almost as long as in the valley, and they also eat and sleep well. In spite of two coke stoves, the thermometer of the cabin never rises above zero; even ink freezes, and water boils at 83°, and they cannot properly cook meat.

USEFUL INFORMATION

Tuberculosis in Cattle.

"Few scientists now dispute that pulmonary phthisis, the most dreadful scourge of the human race, emanates from milch cattle, and is disseminated almost solely by their agency through the human family."

This broad assertion is made in the highly interesting report of the commission to test the value of Koch's lymph on cattle, as read by Dr. W. L. Zuill at a meeting of the Philadelphia Veterinary Medical Society recently. This commission was appointed by the veterinary department of the University of Pennsylvania early in January last. All through the spring and summer their experiments were carried on and the result of their labors marks an important and most interesting epoch in the study of all that relates to the most fatal of ordinary diseases.

"We all know," continued Dr. Zuill "that the greatest scourge of the human race emanates from milch cattle and is spread by them through the human family. It is an undisputed fact that tubercular diseases are found among people that use the milk and flesh of the bovine race, and that these diseases are not found among those people who do not.

"Few men of science will now dispute that pulmonary phthisis comes from cattle, and that the only people who are free from it are those who do not use the milk or flesh of the cow.

"The Khirgis, who inhabit the steppes of Asia, have no cattle. They drink the milk of mares and eat the flesh of sheep and goats. Phthisis is absolutely unknown among them.

"The Esquimaux who reside in Greenland and other Danish countries have cattle, and hardly anybody is more subject to consumption. The Esquimaux who drive their fleet-footed reindeer over the ice-covered plains of Siberia, and to whom an ox or cow is an animal as rare as an elephant is to us, know not what consumption is.

"On the south coast of Africa are tribes of natives who pride themselves on their vast herds of inbred cattle; who not only drink the milk and eat the flesh, but suck the blood from the jugular vein of living bullocks. These people die like flies from tuberculosis. One hundred miles inland on the plateaus, where the deadly tze-tze fly places a absolute bar to the existence of cattle of any kind, there is no knowledge that even one man ever died of pulmonary consumption or other tubercular disease.

"The people of Ireland have cattle, but they neither drink the milk nor eat the flesh. Among them consumption is practically unknown.

"In Australia and New Zealand, countries by nature utterly unacquainted with the bovine race, there was a time when phthisis had never been heard of. In 1820 the cattle mania seized the people. Cattle were imported in enormous quantities, and to-day these countries are hot-beds of consumption, where the mortality reaches three out of every thousand inhabitants and 6 per cent. of all deaths are attributed to this disease. In New Zealand it has made such ravages that the native Maori is to-day almost an extinct race.

"In Switzerland the carefully kept mortuary statistics show beyond question that consumption reigns in exact proportion to the number of cattle kept and used. When cattle are most numerous the deaths are many. Up in the mountain where only sheep and goats can live, the disease is almost unknown.

"The facts also show that the tendency to tuberculosis is most dangerous in the families of cattle that are inbred.

"With these facts before us, the conclusion cannot be escaped from that it is to the use of the milk and flesh of cattle that the human family owes the existence of consumption among its members. We do not say that this milk and flesh must not be used, for it has been demonstrated that under proper conditions of care and breeding the disease can be eliminated from our cattle, but we must abolish tuberculosis from among them. This can only be done by demanding and obtaining from the national or state government a proper scientific and non-political inspection of our food. This brings to mind the importance of an agency that will bring to view every case of tuberculosis in our cattle."

Success From Small Beginnings.

Too many young men at the present time have an altogether wrong impression of life. Seeing those about them in a prosperous business, employing a large capital with an immense plant, and doing business on a large scale, they are ambitious to do the same. They do not stop to consider that it has taken years, possibly generations, to develop what they see. They only see it as it is, and believe that in order to become successful it is necessary to do business in the same way, upon the same extensive scale.

A writer in the *National Grocer* says that the great industrial enterprises of the world have as it were, developed unconsciously to those who have been their principal manipulators. Many of them have commenced so insignificantly that some of our bright young men of to-day would scorn the idea of commencing life in a similar manner. It is said that one of the largest sugar-refining institutions of the world was commenced by a single kettle virtually over a kitchen fire, and we know positively of one business which was capitalized very recently for a couple of million dollars that was started in a small wash-kitchen, when the stock in trade, fixtures, machinery, and business utensils would not have brought $20 under the hammer, and the man started it lived to see it placed on the market at $2,000,000, and declare several years successful dividends. We know of another business enterprise, which to-day is worth at least $2,500,000, that was commenced on $100, and that was borrowed.

Constant dropping wears away the stone. Constant work, intelligently directed, brings success. It is idle to say that there are no opportunities and things are not what they used to be. The opportunities of to-day are just as great as they ever were, if we only have the ability and the energy to take advantage of them. Mistakes will occur, and bright prospects are sometimes blasted, but the fault generally lies with the individual, and not with the circumstances or with the opportunity. We have heard men say that they have failed to do certain things because circumstances have been against them. Our reply is that they have failed because they did not have the ability to make the most of their opportunities and guard against loss. There are many palliating circumstances, we must admit, but it is the individual who has the ability to get up and get who brings success. Many men fail; some men fail often. Yet all of these ultimately succeed, simply because they do not and will not give up. They are just as ready and eager for the fray as they were before they had been knocked down twice. Indeed the partial failure has only acted as an incentive for increased effort.—*The Manufacturers' Gazette, Boston.*

An Immense Tree.

Nearly a quarter of a century ago the *New York Ledger* gave a description of a "big tree" that was cut down in Calveras County, Cal. According to the statement of a gentleman who saw the tree and danced on its stump, the height of that tree was 302 feet. Across the stump, five feet from the ground, it measured 25 feet in diameter without the bark, and 28 feet with it. It was 96 feet in circumference at the stump. It took five men seventeen days and a half to bore it off the stump with pump augers, and two and a half more to drive and wedge it up with the butts of other trees to make it loose its center of gravity and fall to the earth. Its trunk was so straight and its branches so symmetrical that it stood without a shake even in a high wind, after it had been completely severed by the augers. Thirty-two couples danced a set on the stump, and there was room enough for the musicians and spectators besides. It was perfectly sound clear through.

The Microbe's Lot.

Pasteur's plan of growing disease germs outside the body in broth although of the utmost value, did not allow a convenient separation of different germs; but this can now readily be done by Koch's plan of sowing them, not in a liquid medium, but on solid gelatine spread on glass plates, so that the growth of the germs can be daily watched under the microscope, and inoculations made from single colonies on other plates until pure cultures have been obtained. By thus isolating the different microbes, we learn their life-history, the mode in which their growth is influenced by differences of soil, of temperature, of moisture, by the addition of various substances which either favor or retard their growth, and last but not least, the effect which one microbe has upon another when they are grown together at the same time.

For even among these minute organisms the struggle for existence and the survival of the fittest exist, like that which Darwin pointed out so clearly in the case of higher plants and animals. When two microbes are growing together, one may choke or destroy the other, just as weeds in a garden may choke the flowers; or on the other hand, successive generations of one microbe may render the soil suitable for another, just as decaying algæ and mosses may furnish mold in which higher plants can grow.

But it is not merely between different species of microbes or different cells in an organism that this struggle occurs. It takes place also between the disease germs and the cells of the organism which they invade, and the result of the struggle may be determined, not by some powerful agency which weakens or destroys either the organism or the microbe, but by some little thing which simply inclines the scale in favor of one or the other. Thus, in the potato disease the victory of the invading microbe and the destruction of the potato, or the death of the microbe and the health of the tuber, may depend upon some condition of moisture or possibly of electrical change in the atmosphere which aids the growth of the microbe disproportionately to that of the potato. These atmospheric conditions need not necessarily be antagonistic to the potato; They may even in themselves be advantageous to it; but if they help the microbe more than the plant, the microbe will gain the victory and the plant be destroyed.—*Lancet.*

The Copts—An Interesting People About Whom but Little is Known.

These people esteem themselves to be the true descendants of the ancient Egyptians, as distinguished from the conquering race of Arabians who have now overrun their land. It is a comical idea but they call upon us to note their close resemblance to the mummies. Early converts to Christianity, they have remained faithful to their belief amidst the Mohammedan population all about them. It must be mentioned, however, that they had been pronounced heretics by the Council of Chalcedon before the Arabian conquest; for they had refused to worship the human nature of Christ, revering his divine nature alone. They are the guardians of the Christian legends of Egypt. In a crypt under one of their churches they show two niches. One, they say, was the sleeping place of Joseph, and the other of the Virgin and Child, during the flight into Egypt. Near Heliopolis is an ancient tree, under whose branches the Holy Family are supposed to have rested when the sunshine was too hot for further traveling.

There are between four and five hundred thousand Copts in Egypt. They are the book-keepers and scribes; they are also the jewellers and embroiderers. Their ancient tongue has fallen into disuse, and is practically a dead language. They now use Arabic, like all the rest of the nation; but the speech survives in their church service, a part of which is still given in the old tongue, though it is said that even the priests themselves do not always understand what they are saying, having merely learned the sentences by heart, so that they can repeat them as a matter of form. Copts have been converted to Protestantism during these later days by the American missionaries.

They are not, in appearance an attractive people. Their convents and churches, at least in Cairo and its neighborhood, are so hidden away, inaccessible, and dirty that they are but slightly appreciated by the majority of travelers, who spend far more of their time among the mosques of Mohammed. But both the people and their ancient language are full of interest from a historical point of view. They form a field for research which will give some day rich results. A little has been done, and will done; but much still remains hidden. It has yet to be dug out by the learned. Then it must be translated by the middle-men into those agreeable little histories which, with agreeable little tunes, agreeable little stories, and agreeable little pictures, are the delight of the many.—From "Cairo in 1890," by Constance Fenimore Woolson, in *Harper's Magazine* for October.

ELECTRICAL PROGRESS

Invalid's Electric Chair.

Alexander Johnston, of Washington, D. C., has recently patented an electric chair for invalids which is so simple in its construction and mechanism that any one may operate it without the assistance of an attendant. It consists of an easy chair running on two large wheels, with a smaller movable wheel used as a means of guiding the device. An electric motor is placed beneath the seat and geared to the axle of the large wheels, the magnets being wound for low electric motive force. Electric power is furnished from a storage battery, which is also put under the vehicle, and the current is controlled by means of a switch conveniently placed near the arms of the chair. There is also a powerful brake. It is claimed by the inventor that a speed of eight miles an hour can be maintained for five hours, or a distance of fifty miles can be covered at a lower rate of speed from one charge of the battery. The controlling switch is provided with resistance coils so that any speed up to eight miles an hour can be reached. The weight of the chair when ready for service is but 150 pounds. It is the intention of the inventor to place his invention for the use of the visitors to the World's Fair who can thus be propelled along the aisles by electricity instead of being pushed by a time-consuming attendant, as was the case at the Centennial Exhibition in Philadelphia.

Telegraphical Handwriting.

The writing telegraph instrument, the latest invention in the telegraphic world, was on exhibition at the North American Telegraph Company's rooms, Clark and Jackson streets, Chicago, recently. The test was between Chicago and St. Paul, a distance of more than 400 miles, and despite the damp weather, which as a rule is unfavorable to a satisfactory test, the results were more than successful. The instrument itself is very simple. A case 2 x 2½ inches contains the electrical mechanism, while the only thing visible is an ordinary roll of tape—the same as used in "tickers." The operator takes a pencil and placing the point on this sensitive plate in the opening, simply writes his message, and at the receiving point it is duplicated on the tape. In this manner pictures can be traced, maps drawn, and notes signed at the distance of thousands of miles. Mr. Ethridge, who had the test in charge, said:

"This is undoubtedly the most wonderful invention on record. It will do away with the Morse system, and will soon be in use throughout the world. I can stand here and write to my friend in New York and my message is delivered to him in my own handwriting in a minute. I can send about forty-five words in a minute without much effort."

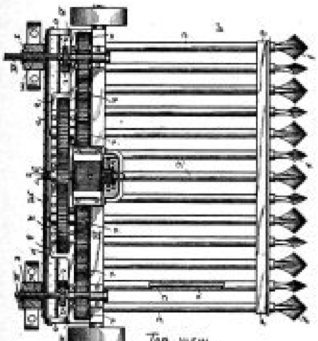
Practical tests have been made in Philadelphia, Baltimore, New York, and other places. Messrs. Cowper and Robinson are the inventors.—*Chicago Journal of Commerce.*

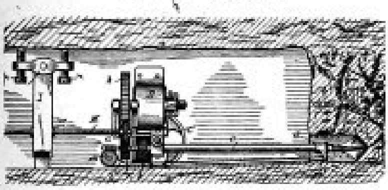
A Large Incandescent Installation.

The electrical engineers who are working on the plans for lighting the World's Fair buildings have a task of unequaled magnitude before them. The illumination of the Fine Arts Building, for instance, will require no less than 15,000 incandescent lamps. This will unquestionably be a larger incandescent installation than any hitherto attempted and will present a very pretty problem in distribution. The more one hears of the World's Fair, the more one is inclined to agree with Sir Henry Wood that at all points it will excel in magnitude all of the great expositions that have been held.

MINING MACHINE.

No. 458,868. Charles J. Van Depoele, Lynn, Mass. *Patented September 1, 1891.* In this machine much of the usual framework is dispensed with, and the machine is thereby lightened. The drills are all geared together at the rear end as shown, and two of the pinions *i i* are driven by the motor through the idler wheels *h h*. Each drill-rod runs through a tube C, and these tubes serve as ties to unite the front and rear frames *d* and B. The machine is supported on two wheels as shown. The chips are swept out of the cut by a belt of wire netting of large mesh, shown in the side

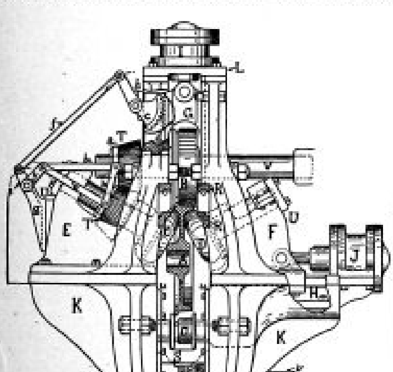




view. This belt is driven by a long roller M, which is supplied with projecting pins in sufficient number to engage the mesh of the netting. The roller is driven by a worm on the rear end of the middle drill-rod. The two outside drill-rods carry small pinions which drive the gears G and turn the feed-screws H. These screws run through nuts *m*, in the jacks or posts I, and serve to feed the machine up to its work. The machine is driven by an electric motor D. The alternate drills run in opposite directions and the cut of one overlaps that of the next, so that no coal is left standing between the holes.

ROLLING MILL FOR CAR WHEELS.

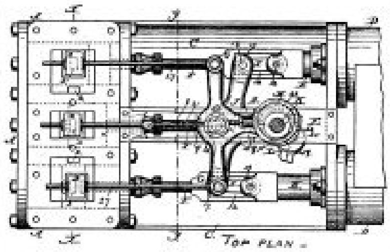
No. 457,922. John R. Jones, Philadelphia, Pa. *Patented August 18, 1891.* A blank is first cast or moulded of somewhat larger dimensions, except diameter, than the finished wheel is to have. When properly heated it is placed between the three rolls B C D as shown in section. The roll B is attached to the shaft V and is positively driven. It is carried by a sliding yoke or cross-head G, and is moved up or down by a hydraulic cylinder I. The roll C is journaled in a fixed housing E and is driven from the shaft V by the bevel gears T, as shown. The roll D is not

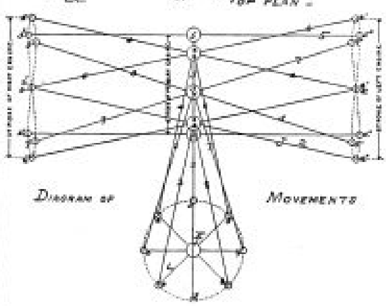


driven, and is journaled in a movable housing F, which is moved by the hydraulic cylinder J. Guide rollers O, carried on a cross-head S, are used to steady the lower edge of the wheel during the rolling operation. By forcing down the roll B, and driving the roll D forward, the metal in the rim of the wheel, and also the web next to the rim can be compressed and condensed to any desired extent. The carrying rollers O are moved downward by the screw and bevel gearing shown at the lower end of the machine, as the rolling progresses, to suit the increasing diameter.

TRIPLE STEAM PUMPING ENGINE.

No. 451,849. James H. Blessing, Albany, N. Y. *Patented May 5, 1891.* Three parallel steam cylinders are employed, all of which may take live steam; or the middle one only may use live steam and the other two receive its exhaust and expand the steam a second time. The middle piston rod is guided by a cross-head running under a guide bar E, and the other two piston rods are guided by the pump plungers H, to which they are coupled by yokes G. The two yokes are connected by links I to the ends of a T-shaped rocking beam J, which rocks on a pin II in the cross-head of the middle piston rod. The whole beam travels back and forth with the middle rod. The third end of the beam takes hold of the wrist pin of the crank L, on the

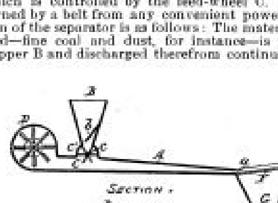


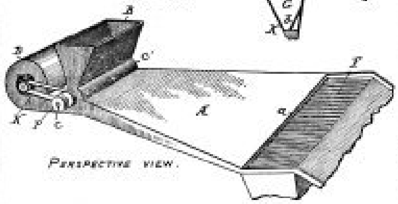


shaft K, which extends through the guide bar E on one side and the main frame C on the other. Two eccentrics M and N serve to move the valves B of the steam cylinders, (the steam chests are omitted in the drawing), and the valve rods are connected by a T-beam in a manner similar to the piston rods, adapted, however, to the shorter stroke. The diagram shows the position of the four pins in the main beam, at eight points in the revolution of the crank. It will appear on examination that two cylinders will be always driving, and that only one piston at a time can be at the end of its stroke—or "on the center." The motion is very uniform, and the stroke is always of exactly uniform length.

FINE COAL SEPARATOR.

No. 454,148. Andrew C. Smith and Marcus K. Bishop, Scranton, Pa. *Patented June 16, 1891.* This machine is designed to separate "buckwheat" and other small sizes of coal from dust, and to dry it, if it is wet. In the drawings, A is a casing or trunk through which the material to be separated is forced by a blast of air from a blower D. The trunk is relatively narrow and deep at one end and wide and shallow at the outlet end *a*. Above the trunk at its narrow end is a hopper B, having converging sides, and at the bottom of the hopper is a feed-wheel C. Near the bottom of the hopper is an apron or deflecting plate *b*, forming a contracted discharge opening at one side of the hopper, which is controlled by the feed-wheel C. This wheel is turned by a belt from any convenient power. The operation of the separator is as follows: The material to be separated—fine coal and dust, for instance—is placed in the hopper B and discharged therefrom continuously into the

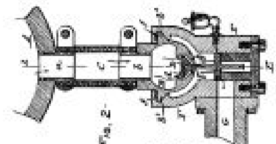


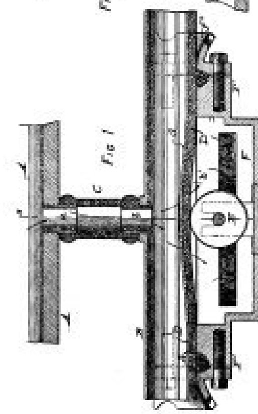


trunk by means of the feed-wheel C. The blast of air generated by the blower drives the material through the trunk and delivers it on the screen in a thin layer with considerable force. As the screen lies directly in the path of the blast, the air and with it the dust and fine particles of coal pass into the chute G, while all of the particles of coal which are too large to pass the screen are shot over it onto the chute H. Should the material be damp, the current of air passing through the particles will dry them and the impact upon the screen will shake off the dust, thus at one and the same operation drying, cleaning, and separating the coal. A second machine may be placed below the hopper G and the fine stuff may be again screened and separated if desired.

PNEUMATIC RAILWAY.

No. 454,318. Harvey W. Wiley, Washington, D. C. *Patented June 16, 1891.* This apparatus is designed to furnish a continuous supply of compressed air to street cars for propulsion. A supply pipe A runs the whole length of the road, just under the surface. A second pipe B is suspended beneath it by means of flexible connecting pipes C. Pipe B, called the "valve pipe," is slotted on the under side at b^1 throughout its whole length. A long V-shaped strip of rubber D lays in this slot and acts as a valve. It is backed by a strip of metal *d*, which stiffens it, and prevents it from being blown through the slot. An air-box F is formed to fit the under side of the valve-tube, and to slide on the flanges b^2. It is provided with soft packing at both ends, and along the gibs *f*, to prevent the leakage of air. This box is attached to the car by a slender bar running in

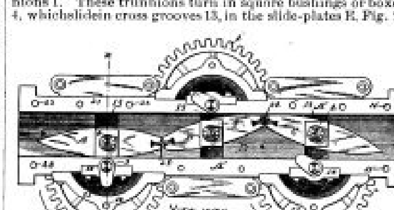




a slotted rail on the surface, like the grip of a cable car. The wheel E lifts a portion of the valve-strip D from its seat, and so permits air to pass out of the pipes into the air-box continuously. The air pipe G is flattened and passes up through the slot rail to the motor on the car above. Thus as the car moves it carries the air-box with it, and the wheel E keeps the valve open and so maintains a constant supply of compressed air to operate the motor. At crossings the valve pipes are interrupted, and the air-box slides off one section of pipe onto another on the other side of the crossing. A small tank on the car carries enough air in reserve to pass over considerable gaps in the supply pipe. It is of course provided with a check-valve to prevent the air from blowing back out of pipe G when the air-box is out of contact with the pipes. In practice the valve-pipe B is made from one and one-half to three inches diameter.

PUMP OR MOTOR.

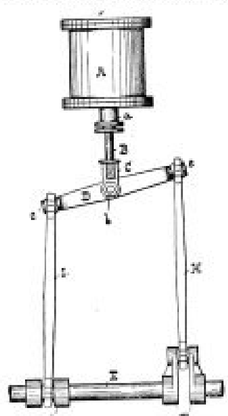
No. 457,303. Edgar Courtright, St. Ignace, Michigan. *Patented Aug. 4, 1891.* Three pistons or paddles A B C, are arranged to move transversely from one side to the other of the square tube D, and in doing so they rock on their trunnions 1. These trunnions turn in square bushings or boxes 4, which slide in cross grooves 13, in the slide-plates E, Fig. 2,



and are also keyed rigidly to the short pitmen 5, which take hold of the cranks 8, on each side of the tube. These pitmen have large flanges as shown in Fig. 3, sufficient to cover the slots 13 in all positions. The cranks are set at angles of 120 degrees apart, and are geared together so as to revolve in unison. The water passes through in the direction of the arrow. When working as a motor the parts operate as follows: Let the paddle A, as shown in Fig. 1, be located at its lower position, the water passing in above the paddle. Paddle B will then be pressed downward, the slides 4 4 moving down in the grooves 13 and the end of the paddle B most remote from paddle A turning down at the same time. This downward movement of the paddle operates through the pitmen 5 5 upon the cranks 8 8 of the shaft and cog-wheels 2^3. As the paddle B moves down and oscillates, the water rushes through, operating not only upon paddle B to press it downward, but also to oscillate the paddle C, turning the end which is connected to paddle B downward until it reaches substantially a horizontal position, and at the same time the paddle C moves downward in the groove until it assumes the position shown in Fig. 1 by A, thus operating upon the main shaft of the wheel 2. While the paddle C is moving down the paddle B oscillates upon its journals, turns the end of the paddle A which is connected to B upward, and when the paddle C has reached its horizontal position the paddle A is tilted into the position shown by C in Fig. 1 and is ready to begin its upward stroke and is moved by the power of the water bodily upward, acting through the pitmen and cranks upon the shaft 3. As the pitmen vibrate in following the crank they give the paddle a rocking motion at the same time that they move it across the tube. The up-stream ends of the paddles are always horizontally in advance in their vertical travel, thus the upstream ends of the paddles always reach the opposite side of the trunk first. The cranks, being set at angles of one hundred and twenty degrees apart, cause the downstream end of the paddle C to leave the side of the tube at exactly the same time that the upstream end of paddle A reaches it. In this position the water in the chamber formed above the paddles, having exerted its entire force against the paddles, is discharged downstream.

CONNECTION FOR STEAM ENGINES.

No. 454,814. Ambrose E. Parsons, New Berne, N. C. *Patented June 23, 1891.* The object of this device is to overcome the dead centers in a single cylinder steam engine. The cross-head C takes hold of the middle of a beam D by means of a pin *b*. This beam runs between guides of any suitable kind, and is connected to the connecting rods I and

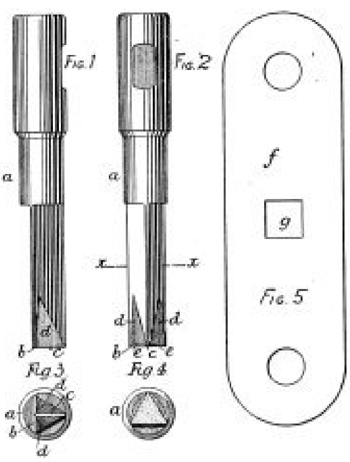


H by ball joints as shown. The main shaft E, has two cranks at right angles, to which the rods are also connected by ball joints. It will be seen that when one crank is on the dead center the other is on the quarter, and will continue the rotation of the shaft. Thus one crank relieves the other alternately.

DRILL FOR BORING SQUARE HOLES.

No. 456,258. David B. Hutton and Archibald F. Daniels, Essex, England. *Patented July 21, 1891.* The drill is provided with a shank adapted to the socket of the drill-holder. The body is made triangular, but the sides are made slightly rounding instead of flat. These rounded sides are found in practice to have a very decided advantage, as they prevent the jarring which takes place when a flat-sided drill is employed. The end of the triangular shank is ground or beveled off to form one or more cutting edges, but in such a manner that the drill shall have no central point upon which it can rotate.

As shown in Figs. 1 to 3, the drill may be provided with



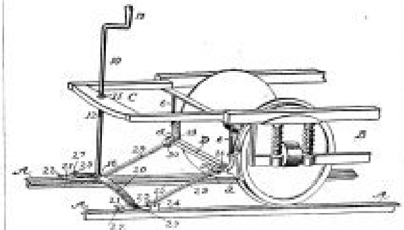
the cutting edge *b* on one of the triangular sides and with another cutting edge *c* at right angles thereto, the latter being formed by notching the other two sides of the triangular shank, as shown at *d d*. The halves of the edge *b* are beveled in opposite directions, as indicated most clearly in Fig. 2 at *e e*, and the edge *c* is also beveled in such a manner that during the rotation of the drill it will cut with the other edge. In some cases the edge *c* is dispensed with, in which case the whole of the cutting is effected by the edge *b*.

Now *f* is the guide-plate through which the drill works, the said guide-plate being provided with a square hole *g*, the sides of which are of slightly greater length than the sides of the triangular shank, the result of which arrangement is that when the drill is rotated in the hole in the guide-plate the angles of the said drill will be caused to enter the angles of the said hole, and thus insure the cutting out of the whole surface exposed inside the hole. This guide-plate may be fixed to the table of a drilling machine or attached to the rest of a lathe or to the article to be drilled. It is obvious that when rotating in the hole of the guide-plate the drill will have no central point, and it is therefore necessary to provide for a slight lateral play of the drill. This may be advantageously accomplished either by allowing the drill to fit loosely in the socket of the drilling machine spindle or by mounting the drill in an independent socket carried upon the drill-spindle by means of a universal joint. In this latter case, however, the guide-plate *f* is made of great thickness or depth so as to hold the drill at two points in its length.

Although this drill is intended for drilling square holes, it is obvious that if the drill is used without the guide and is rigidly fastened in the socket of the drilling machine it will drill round holes.

CAR BRAKE.

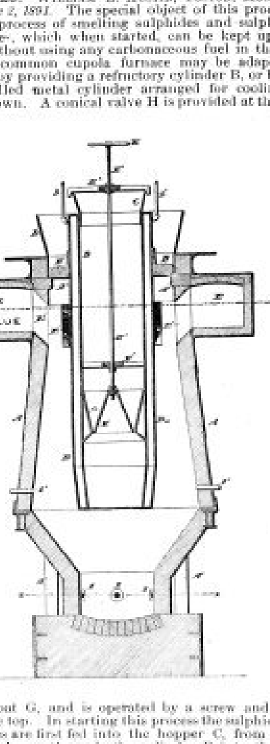
No. 456,130. William L. and Elias A. Antrim, Davenport, Iowa. *Patented July 21, 1891.* In addition to the ordinary brake beam and shoes *d*, a pair of slippers 21 are employed, which rub on the track rails as shown. They are connected by a rigid cross-bar 20, and are connected to the ordinary brake beam D by stout bars 29. The screw 12 and crank handle 11 serve to force the slippers down against the rails, or to lift them up the necessary



height to clear. At all times they serve as a pilot or "cowcatcher" to throw obstructions off the rails and prevent them from passing under the wheels. The friction of these slippers on the rails, tends to force the brake shoes *d* against the wheels, and the application of the brake to the track and the wheels is simultaneous. By applying this brake at each end of the car, the whole weight of the car can be thrown on the slippers to create friction, and the wheels will be relieved of their load, thus avoiding the evil effects of skidding.

PROCESS OF SMELTING SULPHIDES.

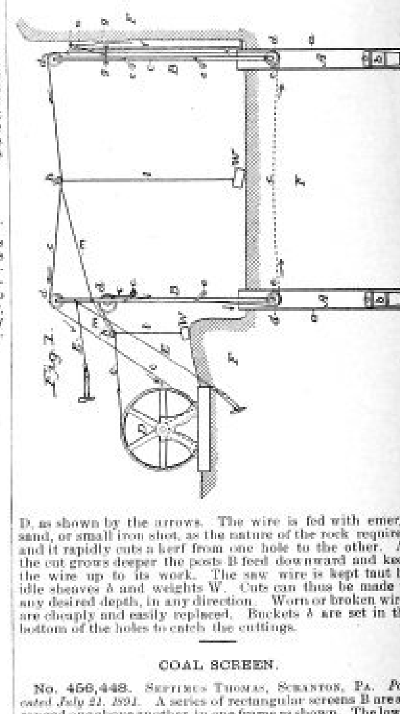
No. 453,529. William L. Austin, Toston, Montana. *Patented June 2, 1891.* The special object of this process is to provide a process of smelting sulphides and sulphurets of all varieties, which when started, can be kept up continuously without using any carbonaceous fuel in the furnace. Any common cupola furnace may be adapted to this process by providing a refractory cylinder B, or better, a double-walled metal cylinder arranged for cooling by water, as shown. A conical valve H is provided at the con-



tracted throat G, and is operated by a screw and hand-wheel at the top. In starting this process the sulphides and combustibles are first fed into the hopper C, from which they pass down through the cylinder B into the body of the furnace, the rate of their flow being dependent upon the adjustment of the bell H with reference to the hopper formed within the cylinder by contraction G, or of some other desired regulating device. When this preliminary mingled charge of sulphides and combustibles has been fired and the furnace has become heated up in the ordinary way, the normal charge containing no carbonaceous fuel is gradually introduced into the hoppers C and D. Sulphurets and other compounds which are liable to fuse and stick together, when exposed to heat and furnace gases, are fed into the hopper C, so as to be inclosed and kept away from the heat of combustion in the furnace by the cylinder B until they can reach the smelting zone of the furnace. By this means and in this manner it is possible to introduce the sulphurets and said other compounds into the furnace and feed them continuously to the smelting zone without danger of the sticking and clogging up of the furnace, which is sure to take place where it is attempted to feed them down in the usual way exposed to the furnace heat and gases before they reach such zone. Silicious ores, fluxes, and coarse material generally, which will not fuse, soften, or stick together, are fed into the outside hopper D and pass down into the body of the furnace. On the way down the annular space between the furnace walls and the cylinder B they are subjected to the action of the escaping gases, heat, and products of combustion, so that they are beneficially prepared for the subsequent fusion upon reaching the smelting zone and being subjected to the blasts from the tuyeres. They act also in their passage downward through the gases and vapors to catch and hold volatilized solids. The height of the furnace should be such that the gases and vapors rising from the combustion and smelting shall be in a comparatively cool state when they pass into the downtake, it will be observed that the object is to keep certain ingredients of the charge from the action of the heat and gases before they reach the smelting zone, while allowing the other ingredients to be acted upon by the heat, vapors, gases, and products of combustion before they reach the said zone. The two parts of the charge are kept separate until just before they enter the zone of fusion, when they commingle and descend together. The molten products pass the main tuyeres I I and immediately run out of the furnace into a receiver. They are not allowed to collect so as to form a bath in the furnace or to assist in keeping up or supporting combustion, but are continuously drawn off as soon as formed. Through the main tuyeres I I is introduced a hot blast, while through tuyeres I' I' air is admitted to consume any sulphur or other volatile product which tends to collect upon the furnace or cylinder sides.

STONE SAWING APPARATUS.

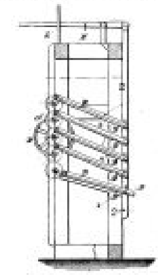
No. 454,712. George F. Clark, Rutland, Vt. *Patented June 23, 1891.* This apparatus is designed for sawing stone in place in the quarry. Two round holes A of sufficient size to admit the sheaves *d* are first drilled at the ends of the proposed cut, by a hollow core drill. These sheaves, together with other guide sheaves *a*, are attached to posts B, which are guided by guy ropes E, or by temporary timbers, in any convenient manner. An endless wire *c* runs around the guide sheaves and around the drive wheel



D, as shown by the arrows. The wire is fed with emery-sand, or small iron shot, as the nature of the rock requires, and it rapidly cuts a kerf from one hole to the other. As the cut grows deeper the posts B feed downward and keep the wire up to its work. The saw wire is kept taut by idle sheaves *h* and weights W. Cuts can thus be made to any desired depth, in any direction. Worn or broken wires are cheaply and easily replaced. Buckets *b* are set in the bottom of the holes to catch the cuttings.

COAL SCREEN.

No. 456,448. Septimus Thomas, Scranton, Pa. *Patented July 21, 1891.* A series of rectangular screens B are arranged one above another, in one frame as shown. The lower end of each screen is provided with a pin on each side which enters a slot in the hanger-bar 2. By means of a lever H the hanger bars can be moved up or down, and the pitch of all the screens can be changed simultaneously. A



separate adjustment for each screen is also provided, consisting of a rod *k* having eccentrics which bear under each edge of the screen. The screens are shaken by cams on the shafts shown under their upper ends. The shafts are geared together, and are driven by a belt on the pulley shown on the middle shaft. The lower screen receives a horizontal movement in addition to the vertical movement, being provided with hooks which engage small eccentrics on the lower shaft.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

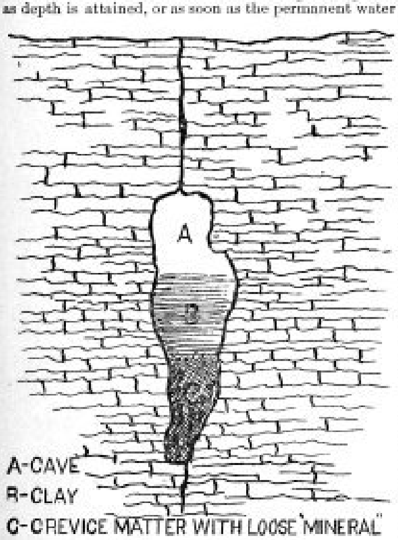
VOL. XII.—NO. 5. SCRANTON, PA., DECEMBER, 1891. WITH WHICH IS COMBINED THE MINING HERALD.

THE ECONOMIC GEOLOGY OF LEAD.

The Mineralogy, Mode of Occurrence, and Production of Lead.

BY H. A. WHEELER, E. M., OF ST. LOUIS.

Although there are a large number of minerals that contain lead, there are only three which occur in sufficient quantity as to be of any importance as lead ores, or the sulphide, sulphate, and carbonate. By far the larger portion of the world's lead supply is obtained from the sulphide or galena, and both the sulphate and carbonate are secondary products arising from the surface alteration of galena, so that deposits of these oxidized ores of lead are almost sure to change into galena as depth is attained, or as soon as the permanent water



SKETCH A—A CLAY GASH VEIN.

level is reached. The following descriptions give the prominent characteristics of these minerals:

Galenite, or galena, is a sulphide of lead carrying about 87% of lead, when pure. It is very heavy (specific gravity is 7·0 to 7·5), quite soft, has a bright metallic luster and lead-gray color, and has an eminent cleavage or splits readily into leaves, plates, or cubes. The usual miner's term for galena is simply *mineral*.

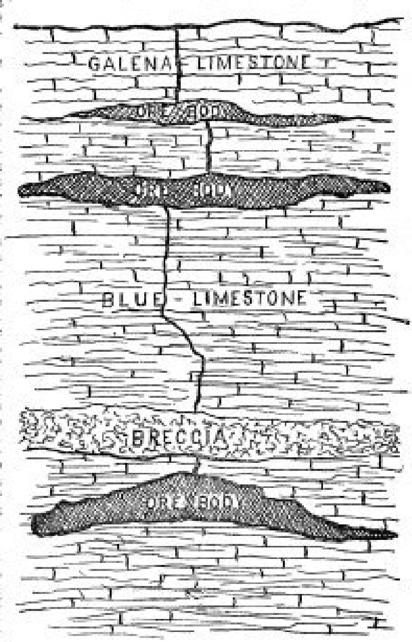
Anglesite, or "rock carbonates," is a sulphate of lead that contains about 68% of lead when pure. It is a soft, heavy, non-metallic, white to brown colored mineral that is usually very compact, and never has the loose granular or sandy structure that is so characteristic of the carbonate. The miner's name of "rock carbonate" very appropriately distinguishes it from the cerussite or true carbonate.

Cerussite, or "sand carbonate," is a carbonate of lead that contains about 78% of lead when pure. It very much resembles anglesite in all its properties, except that it nearly always occurs as soft, earthy masses, or as crystalline or granular slightly coherent masses that resemble a coarse, heavy sandstone, while it does not occur in the compact, rock-like condition so characteristic of the sulphate.

Lead occurs so extensively in association with silver and gold in the deposits of the West, that a study of the mode of occurrence of the ore deposits from which most of the lead produced in the United States is obtained would be largely a repetition of what has been previously treated under the occurrence of silver in THE COLLIERY ENGINEER of October and November. It should be mentioned that the so-called "blanket" or contact veins of Leadville and Aspen have been and, especially at the latter camp, are still very heavy producers of this metal, while the chamber deposits of the Richmond and Eureka Mines and the contact lode of the Horn Silver Mine have each been phenomenal producers of lead in the past, while a group of mines in the Coeur d'Alene district, of Idaho, are at present turning out very large quantities of lead from low grade argentiferous ores that first require concentration before they can be profitably smelted.

Colorado and Utah have been the principal lead producers of the West, making up their heavy output from a large number of silver-lead mines scattered through their respective mountains, and according to the returns of the *Engineering and Mining Journal*, the former state produced 62,000, while the Utah mines produced 24,000 tons of pig-lead in 1890. Nevada, which practically means the Eureka district, produced only 2,500 tons in 1890, whereas the former output used to amount to 30,000 to 40,000 tons per annum, while the Coeur d'Alene district has come up from a very minor output to about 22,000 tons per year, with a promise of a still greater increase.

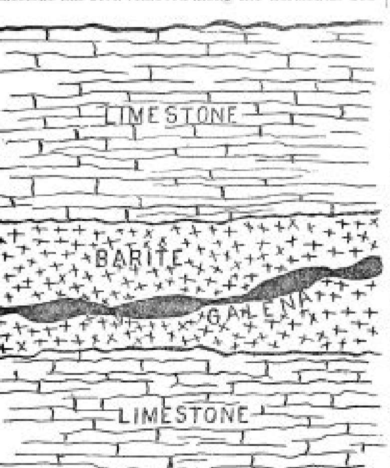
Montana, New Mexico, and Arizona contribute much smaller amounts from their lead-bearing silver mines, and the total production of the far Western mines, in which the lead is obtained as a by-product in working the ores for silver, amounted to about 130,000 tons in 1890, which is more than two-thirds of the entire product of the United States. Large as this Western production now is, and which has brought the United States up to the first rank in the world's production of lead, as it now exceeds the enormous product of Spain, and the large outputs of Germany and England, it is of comparatively recent growth, and dates from the opening up of the low grade class of Western silver mines, or say from about 1860, which have steadily increased the quantity until now their by-product has grown to the above quantity and this country is at last about able to be independent of the foreign lead miners and supply its own market. Previous to this rapid development of the silver-lead mines of the far West, the home supply of lead was practically all derived from the Mississippi Valley, which is still actively producing, though since it has been so completely eclipsed by the Rocky Mountain mines, it has lost its former importance. The Mississippi Valley lead ores carry no silver in paying amounts (or less than five ounces per ton), with few unimportant exceptions, and generally make



SKETCH B—CROSS-SECTION OF "FLAT" VEINS.

a very pure, soft quality of lead. The mines of this region can be roughly divided into three groups, or (*a*) the Upper Mississippi Group, (*b*) the South-Eastern and Central Missouri Group, and (*c*) the South-Western Missouri Group.

The first, or Upper Mississippi Valley group of lead mines, occur in a particular limestone formation, where the three states of Wisconsin, Iowa, and Illinois adjoin. This limestone, which is about 200' thick, is known as the "galena limestone" and belongs to the Trenton period of the geologists or to one of the very old formations. The lead occurs as galena, in association with zinc-blende and iron pyrites, and is found as gash veins in the limestone, with clay and calcite or lime-spar as the gangue. Sketch A illustrates a very common type of gash-veins found in this region, in which the "crevice," or "gash," is not entirely filled, and the "mineral," or galena, occurs loose as fragments in clay or crevice matter. If the "gash" is a horizontal one, it is called a "flat," or sheet vein, or a "floor," as shown in sketch B, but whose origin is identical with A, only the limestone has been removed along the horizontal bed-



SKETCH C—LONGITUDINAL SECTION OF A "PIPE" VEIN.

ding planes, instead of the vertical joint planes, before the mineral matter was deposited. Sometimes the galena occurs as long, thin, continuous threads or sheets, especially associated with barite, or "heavy spar," when it is locally called a "pipe" vein as shown in sketch C.

[TO BE CONTINUED.]

PIT-BROW LASSIE OF WIGAN, ENGLAND.

The accompanying cut is from a photograph from life, and shows an English colliery woman, dressed and equipped for work on the pit-brow. "Ow's a good un an' can do a shift wi' ony on un." To the American, the employment of women around the mines is repugnant, and we are glad to state that the number so employed in Great Britain is steadily diminishing. When Queen Victoria ascended the British throne, women were employed inside British mines, both as laborers and for hauling the small cars of coal from the working face to the main haulage roads, but to the

credit of the Queen, it must be said, she secured the passage of laws, soon after her accession, that effectually remedied the matter. Many of our older readers of British birth will recognize the familiar figure. During recent years efforts have been made to secure the passage of Acts of Parliament prohibiting the employment of women on the pit-bank as well as in the mine, and these efforts would have been successful, had it not been for the opposition of the women themselves who protested that it would deprive them of their means of livelihood.

THE PREVENTION OF ACCIDENTS IN MINES.

An Essay on the Best Methods to Secure Safety to Life and Property in the Operation of Collieries.

(The following paper is by Mr. Augustus Stinner, late Inspector of Mines, and was one of the four recommended for publication by the Committee of Judges in the *Pittsburgh Times'* Prize Competition Contest.)

How to avoid mine disasters, or at least lessen them to a great extent. To do so we must commence at the root of the evil under the system of ventilating and mode of mining. At present in the Bituminous region, no practical person will be much astonished to learn of accidents in the various forms.

I shall first and mainly treat on accidents by mine explosions, and their prevention. You will please notice plan of a drift mine containing about 370 acres; and the plan of a large shaft mine. The shaft mine consists of four different splits of air (when all worked), but in the plan, so to say, I only use the one split of air and show you two sections of work. The face entries in these sections may be 1,600 or 1,800 yards in length, and the butt (cross) entries about 400 yards wide each from face to entry. Certainly a pretty good sized mine in itself.

As you will see, I have not drawn the plan with any scale, but merely made it so you will understand it practically, and in view of that end, will reason the matters on the plan in order to prevent accidents, or to a great extent, at least, lessen them. But before I draw your attention to the plan let me say here to you, or rather ask, what causes the fearful slaughter of the men in a mine explosion? I will answer: the after gases. There are very few men in general killed by the force of the explosion, and why are there so many killed by after gas? Because we cannot get air to them in time. We have to prepare and fix stoppings and doors, which the force of the explosion has destroyed, and I know from practice the time required to fix up and patch these many blown-out stoppings and destroyed doors; and then, about the time you get the ventilation in some kind of shape, "the souls of the unfortunates have gone to eternity." The pure air was too long in coming. The after-gas had done its work. Yes, because the pure air did not come soon enough; it took too long to prepare stoppings and doors which the force of the explosion destroyed. I think humanity requires a remedy of that matter of stoppings and doors which causes mainly the death by after-gases. (I honestly believe, from my practical experience in the Bituminous region, 90 per cent. are killed by after-gases.) Just think of the idea! A lot of doors in a gaseous coal mine to direct the ventilation—I will say frankly and freely, doors are a nuisance and dangerous in mines of this kind and, besides after-gases in many cases, doors increase danger. The more doors under our present system of mining, the greater the danger. However, I don't want to be understood that there must not be a single door in the entire mine. There may be one here and there, such as I have shown in my plan, in the cross entries.

The Intake. You will notice in my plan I make the hoisting shaft the intake of air. I calculate this shaft to be dry enough to make no ice, and make the other shaft the outcast of air, that shaft being the suitable place for our pumping machinery, &c.

Of course, we can change the plan and make it a force fan. We could also sink another shaft for intake or outcast of air, but I will only treat on two shafts, such as you see them on the plan. I know it is not requested to show necessary roads, &c., about shaft, for the handling of cars, &c., consequently I have paid no attention to it. I merely want to show, as is requested, the safety of the mine, and here I will show the meaning of the marks used on the map.

For convenience and easy explanation I will call the three parallels, from which sections Nos. 1 and 2 are started north of hoisting shaft, and the face entries, and return air way thereto west.

The double door, near outcast shaft (or roadway) is for the purpose of getting to the escape shaft, and also into the return air way. Nobody is allowed to do any traveling of any kind in any part of any return airway, except men for the inspection of it; it is there for the purpose of the return air, and nothing else. None of the entries are drawn to any scale, nor any of the pillars; however, in all cases, I would make return airways as large as I could with safety and entry pillars should be left plenty strong and more so, to make matters perfectly safe so no squeeze can happen, since a squeeze in a gaseous mine is a danger in itself, and from practice it is well known that it has caused the generating of gas, and also serious explosions. In all of our mine operations we should avoid squeezes to come on our entry pillars of any kind. You will notice two overcasts in the return airway before you get into the first section. You will notice two doors into the return airway. It is made for the purpose of a small road to get into return airway, and clean airway out once in a while when required. Now, you will notice cross entries Nos. 1 and 2. That is the first entry that I would drive for room work. It is a good 200 yards from the north parallels; and from there, a good 200 yards to the shaft. I do this in case an explosion should occur, so that then the force of the explosion would do no damage to the shafts. On the south side of my hoisting shaft, when I would get ready and start my work, I could start my cross entries. I would not need to be afraid. Any gas explosion there would face my shafts, it being at least 700 yards from the shafts. I would remark here, I would drive my cross entries 400 yards in length, on each side of face entry, and make that the end of section. You will notice a door between Nos. 1 and 2 cross entries, and that is the only door used in this system. I break the entry pillar once for every 100 yards. The less the pillar is cut through, the less the danger in explosion, since the fewer cut-throughs we have the sooner we can establish the ventilation again. You will plainly see the overcast from No. 2 into the return air course.

A Different Cross Entry system. In No. 3 and No. 4 you see a different cross entry system. No door is required, but it requires an additional entry to be driven, and I know in many places that would cause an extra expense, consequently I will not advocate that cross entry system. From the explanation that I will make, regarding doors and stoppings, I will not drive three cars parallels, causing both expense, and rather weakness to the entry pillars, if they are not made additionally strong "regarding three parallels." You will also notice the cross-entry on left hand side of face-entry. Nos. 5 and 6 are about midway of the others. I would not make it opposite of Nos. 1 and 2 for the reason that if an explosion should occur in No. 2 or 1, it might blow over the overcast into 5 and 6 cross entries, and *vice versa* from 5 and 6 into Nos. 2 and 1. But if we get the force of the explosion from No. 2 into the return air course, ordinarily it will not affect cross entries Nos. 6 and 5. Hence the reason I would make the first cross entry on that side there, and where you see it marked on the plan I would work it for reasons shown upon the plan. The same reason holds good for that piece of coal on the opposite side, near north parallel, on the side of Nos. 1 and 2 cross entry, but has to be worked as is explained by writing, where the coal is located.

You will notice, I will not make any (holes) break pillars from face entry into room workings, which at last becomes pillar work, and falls, and danger is there, consequently I keep the pillar solid. A man that would direct in making holes from face entries into room workings for one cause and another, is a person with no foresight and creates danger.

This first section we can mine a great deal of coal from. For instance, when we consider that the boundary line is 1,600 yards distance on the face from north parallels, and each cross entry in this section 400 yards wide, to that strip of coal left on the plan would amount to about 280 acres of coal, or if we would work three of those sections on each side, west and east of parallels, both north and south of shaft would make a coal tract of about 1,680 acres, and the additional amount of coal contained in the pillars of north and south parallels; and I might remark here that as to the break-throughs in the north and south parallel entry pillars, I would make them apart as far as possible, say from 150 to 200 yards, and if need be, would use brattice to take the air with me to drive those distances. We might also find gas here in driving those distances, and then would need air to dilute the gas, etc. I would further remark in this and all other cases where I would need brattice, I would have it incombustible. That point, incombustible, would have prevented the late Dunbar disaster.

The regulations in this plan are so well understood by ordinary practical miners that I will not say anything on it. It might also be reasoned by some that those doors leading into the return airway should be securely locked, and the same with regulators, but since there are reasons that such should not be done I will keep silent on the matter. It will plainly be seen we can go from one part of the mine to the other by the aid of the overcast and return way and roadways shown by doors.

Cross Entries. I will now explain the workings of Nos. 1 and 2 cross entries in section 1, and the same will hold good of all the rest of the cross entries in this mine. In the first place, you see the cut-through and the door, which is needed in this system for the driver to get into No. 2 cross entry. The door must be so hung that it will require some power to open it toward entry No. 1, and will well shut itself, and in that case the air pressure will press against it. Then you see the break-throughs 100 yards apart in the pillar, and stoppings in about the middle of them, I drive the 400 yards, or to the end of the section, and commence my room work until my entry is finished, and then when I do commence room work I commence at the end of the section, say start from 10 to 12 rooms, in No. 1 entry, and the same amount of rooms in No. 2 cross entries, drive the rooms up the required distance, bring back room pillars and afterward entry blocks. And then again I would start another batch of rooms, as stated before, until the cross entries are worked out, or sufficiently worked close enough to the face entries.

That system of working would have saved the lives in 1884 of the people killed at Leisenring in an explosion. Just look at the absurdity of a system of mining to commence room work in both cross-entries, near those "face entries," rooms driven up, pillars taken out, falls taken place, doors in the face-entries and pillars broke through every 30 or 40 yards, and men working at the end of the section. Shame and disgrace to such a system! I would like to know what safety there is provided for those men who work beyond, or at the end of the section, when an explosion occurs about 100 yards from the face-entry, caused by squeeze, or falls of pillar drawing? Men, under such circumstances, are like mice caught in a trap. Why not change this ridiculous system of mining? Anybody knows danger is not so bad in the rear of you, and when you can run away from it, as when fronting you, when you must go through the danger, which in this case can seldom be done. This is part of the system that has taken the unfortunates, lives.

Stinner's System. Now, under my system of working I have the danger of an explosion beyond me, to some extent. I can get away from it. I will consider an explosion at the end of No. 2, and one cross-entry from a fall: First—The explosion is confined to this entry alone. It will not effect any of the cross-entries. Its force will go to the return air course; even if the overcast at No. 2 entry should be destroyed, all the intake of air, or at least the most of it, would go out through the overcast, and if small portions of after-damp should want to go toward No. 3 entry, the intake air would have to take it there, and in that case would not hurt the men, and, as I have already said, the great percentage of death is caused by after-gases and in not getting in time pure air to the men. I think I can show you clearly and plainly, by a new, cheap method, how to establish a pure current of air again, so to say, in no time, and I think very few will be killed with ordinary after-gases. Wherever there is a necessity for a door in a mine to direct ventilation, etc., place a door there that no force of any explosion can destroy. For instance, go in the break-through from four to six feet, and make a suitable shearing, say three feet deep on each side, and the required height. Put your half door in each shearing, and push it in even with the coal. Keep bottom clean from time to time, so this double door will work, when needed, and do the very same at every place where there is a stopping in the mine. In case an explosion occurs and destroys the door and stoppings, all one man needs to do is to pull the door (or half door) out of the solid coal, and the break-through is shut up or repaired again. You will see at a glance it will take no time to restore the ventilation again. One man, with such a system, will do more work in one hour than 100 men in two days under the present system. This is cheap and practical, and will work wonders. No practical man that has helped to rescue men in time of an explosion, will oppose this safe system and its simplicity.

Now, the next thing I will construct an overcast, and all the rest of the overcast in the mine to be the same. I will show you two kinds of constructions. In all cases, however, they shall be incombustible. To build an overcast, take suitable sheet iron for "stand-ups" in openings, also suitable stringers of iron, parallel with butt. You may then cut out roof or top, so these iron stringers will rest all along on solid strata. Sink the ends of them suitable lengths in the solid strata (or roof) and place them about one foot above top of roof. Then cover the opening with suitable sheet iron, and a covering of good cement on this iron, and on top of this cement sand, in all a covering on top of sheet iron one and one-half feet in depth, and from the level of this sand layer will be your aperture or overcast.

High Pressure Aerophones. The line you see across, between No. 2 and No. 3 cross-entries, is a small rib left permanently between the rooms of No. 2 and No. 3 cross-entries, in order that the air pressure from one entry may not effect the workings of the other entry, mainly, when the ribs are drawn out. A pressure of air from one entry will not make the gas explosive in the old workings, nor press the gas out into the other entry. By this system I want, if any gas should accumulate in the old workings (when the ribs are drawn) that it will be at rest, and be dead (non-explosive, with black damp). The same reason applies where you see the black line running parallel with the face-entries, between 1 and 2 sections. I think ribs of this kind left, the amount of coal lost hereby would be very small, I don't think in general would amount to more than about 1½ per cent. and some good men should be worked in each pair of double entries, be well drilled in case of danger, and know how to go about it. To pull out doors for overcasts—doors and stoppings. In all cases when workmen see danger of any kind, to report as soon as possible the same to the management of the mine, and every day hand about the mine should be drilled in practice in every shape, way or form, so that he would make a good fire boss, and in that way the work in examining the mine in the morning, no doubt, would be done in a very short time, certainly a sound reform from the present system. I learn some fire bosses start out four hours before the men come in.

Certificates to Fire Bosses. While I speak of the fire boss, I would remark here, a reform is needed regarding giving him a certificate from any single inspector in accordance with the law. I certainly hold and always have, that the fire boss should receive a certificate of competency only after having stood a most thorough examination before a competent board of at least three persons in place of one person, the inspector, as it now is. It has come under my observation that some people hold fire-boss certificates who should not have them, and I think if the inspectors were relieved of the duty of granting certificates of fire bosses, also serving on the board to examine applicants for mine bosses, as under the present law, and in place have one board to examine all fire bosses and all mining bosses in the entire Bituminous region; it would create a healthy reform and make matters uniform, which is not the case at present. The inspector should have power on sight when a violation of law presents itself to him. And he should have discretionary power to visit mines as he thinks necessary. He should not be bound down to visit each mine four times in the year, since some mines need more attention than others. Think of the weakness of the present law. When the inspector sees a violation of it for him to give in writing five days grace to the violators. We might just as well advocate, when the officer of the law catches a thief in the act, to tell him: "You can steal all you want yet for five days, but on the sixth you must quit." I could say more, where reform is needed in the mining law, but this matter is getting too lengthy. However, I will remark about the mining boss, recognized in the law that he must be a man of independence, and allow no strangers, under the law, to dictate to him violation of the law, and when his conscience tells him "the mine is worked on good luck only," he should report the matter to his superior, to have matters put in a shape to be satisfactory to him.

It should be provided by law that each operator leave sufficient coal on all boundary lines, so that no dangerous holing into one another may take place, and cause accidents by both gas and water. The greatest care should be practiced to have the maps of mines made very accurate. Fans, for ventilation, and fan houses, should be made incombustible, and in all cases fans should be placed some distance from the shaft, so that the force of explosions will not destroy them. A weak, tight door should be placed on top of the shaft, so that in case of an explosion it would blow this door off, and thereby save fan and fan house.

The shaft itself might be constructed of iron, but under the present system those shafts should, at reasonable times, be well cleaned of oil and dust.

As to horse stables in mines, no combustible stuff of any kind should be about them excepting, hay and the stable itself should be built of non-combustible material. Nothing but a safety-lamp to be used in the stable, and under no circumstances should any loose hay be sent into the mine; only baled hay.

In Slope Mines. And in slope mines mainly, I will mention again, incombustible overcasts should be built at suitable places to make the mine (or rather connections) safe, the traveling road (or parallel) should always be kept even with the slope. There are slopes in the Bituminous region, which, owing to the manner they are gutted, and to the system by which they are ventilated, should a forcible explosion occur in them nobody could be saved. Under the circumstances in which those mines have been worked in earlier years, openings should be made in the rear of the coal tract and connected with the farthest in end of slope, with a good system of ventilation and good working system established, as I have herein shown; the workmen would have a chance for their lives, which they have not at present.

And let me say once more, the more doors and brattices and stoppings, the more danger, and *vice versa*, the fewer the doors and brattice and stoppings in mines, the less danger. "It was the door" in 1884 in the Youngstown Mine, in Fayette County, that sent 14 men and boys to an untimely grave.

Need of Safety-Lamps. With all the safeguards that I have shown all mines, where explosive gases may make their appearance, should at least, in accordance with locality, be worked with safety-lamps. This would make matters three-fold sure, and under no circumstances should ribs be taken out with open lights. When safety-lamps are used they should, in the true sense of the word, be put in the hands of miners. The Clanny lamp is in general use in the Bituminous region. It has some advantages, it is true, over a safer lamp, but under certain circumstances the Clanny lamp is not a safe lamp. The Mueseler safety-lamp is by far the safest, and if you gentlemen wish it, I will practically prove it to you with both lamps, in natural gas in Pittsburgh. To work with those safety-lamps is no hardship for the miners. They very soon get used to them. All those glass globe safety-lamps show a very good light to work with, and even should there be a little inconvenience, it will be a safeguard if rightly attended to. It should be borne in mind that any instrument that will detect small percentages of explosive gases are valuable about mines. It will put us on our guard and inform us that the enemy is present and even here, if we find small quantities of the gas, it may put us on our guard, calculating what dangerous coal dust we may have in the mine. However, I would say here of coal dust, that without any traces of explosive gas, we need not fear any bad consequences from it.

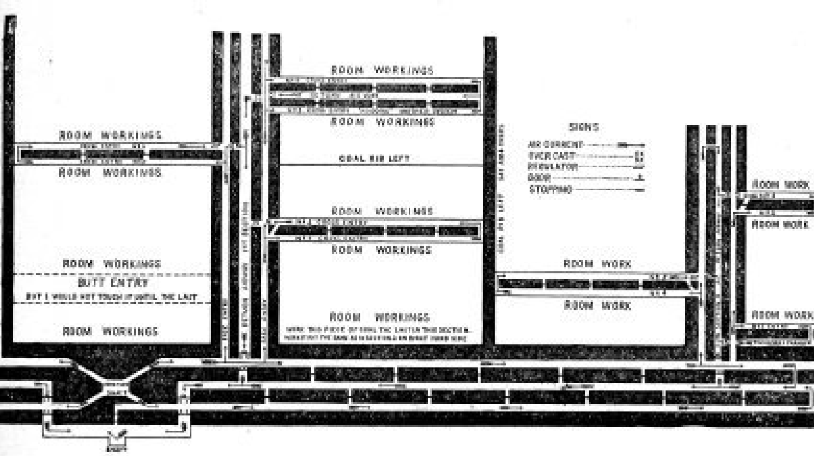


DIAGRAM TO ILLUSTRATE MR. STINNER'S PAPER.

Ventilation of Rooms. While speaking of gas, I would mention here that small room works, in the cross-entries, we should provide with a good system of ventilation, which can very readily be done, say by two canvas doors, placing them 10 or 12 rooms apart, as the case may be. Then the ventilation will go to the cut-through, and through all the room cut-throughs, and come to the cross-entry again on the other side of the canvas door, and not any sooner, because that will be the nearest course the air has to travel. I would follow, where suitable, the good system in use at present in taking out room ribs and entry blocks clean to a suitable distance near the face entry. For instance, in the first section No. 1 cross entry I would build a good, strong, substantial stopping with brick and cement, and leave No. 2 cross-entry open and put up a door, say five or six feet from face-entry in the cross-entry No. 1, and put a wire regulator in it, locked, with enough of air in it so that it may clean out of No. 2 cross-entry any stuff or gas that may press out of it into the return air course. Any stuff or gas that may come out here at No. 2 entry is not explosive. It would only fire when sufficiently mixed with air, and would not get a chance to accumulate, but would be carried away into the return air course as fast as it would press out of the old workings. This is the system that I would use all over the mine in similar cases, and in the face-entries, when near the north and south parallels.

You will notice in the second section and the No. 1 cross-entry no room work on right-hand side. You see the cross-entries laid out between, which reason is already explained. Of course, it is a little differently laid out from first section. The reason practical men will see at a glance, "because we are 1,000 yards from the hoisting shaft."

From the level of that floor make a suitable long grade until it strikes bottom in cross-entry, or entry pillar, in order to save overcast in case of explosion. But having safety in view, we must calculate on the destruction of overcast, and in this case and all other cases, we must not speculate on good luck. To mine on good luck has proven itself dangerous. We always should provide before we complete the permanent overcast, for a temporary overcast, to be used in case the permanent overcast should have been destroyed by the force of the explosion. The construction of it is something similar to that already shown, by placing those safety-doors, namely: Cut in the coal on each side of opening (where the openings are) and shove those doors even with the coal, making the same cut on top on each side of opening horizontal, and shove those temporary doors even with coal, and no force of any explosion will ever hurt any such temporary doors.

Another Style of Overcast. But I will show you a different overcast. Commence about 2½ feet above the top roof of your face entry, and from that level on each side drive three or four yards in the course of your overcast; then cut towards your openings, butt course (or, as the case may be, in different part of the mine); in other words, you leave on each side of this face entry 3 or 4 yards of solid coal to roof, with the addition of 2½ feet high, 3 or 4 yards in length, and from the end of those 4 yards run a suitable grade until you strike bottom in entry. I am certain no explosion will ever blow out those four yard blocks left on each side, and for the top of such overcast construct it in the same manner as mentioned in the overcast before. The temporary construction, also the same on top (those double closing doors on top to be cut in the strata horizontally.) Those top horizontal doors are all that are needed for temporary overcast of this kind. This is the kind of overcast that should be used in the entire mine. I might mention here (for double safety) it would not be amiss in case of overcast destruction to have a few high pressure aerophones at each time to enable us to work in after-gas, etc. The cost of them is but little.

Now there are more things that I could mention, but the matter is getting lengthy and therefore I will say in conclusion that with good discipline about a mine, everybody at his post of duty with military exactness, and independence, and the practical and simple reforms that I have pointed out I would feel myself completely safe and could swear with an uplifted hand "I am not working the mine on good luck."

AUGUSTUS STINNER.

P. S.—I would say any person holding a certificate of any kind to entitle him to a position in or about the mine, and if found guilty of violation of law, said certificate should be taken from him and none to be granted to him again in the State of Pennsylvania.

P. S.—As all practical men can see, the different reforms that I have shown, can well and with good results be adopted in most all of the old mines in operation, and will add very much to their safety, which this miserable system of working, and ventilating is greatly in need of.

A. STINNER.

TANDEM TANKS FOR HOISTING WATER FROM FLOODED SLOPES.

BY J. H. BOWDEN, WILKES-BARRE, PA.

(Glen Summit Meeting, October, 1891.)

The water-hoisting tanks herewith illustrated have been designed for removing large quantities of water from recently-flooded mines, through their hoisting-slopes, with rapidity proportional to the capabilities of the hoisting machinery available, the tanks being adaptable to slopes of small sectional areas and varying pitches.

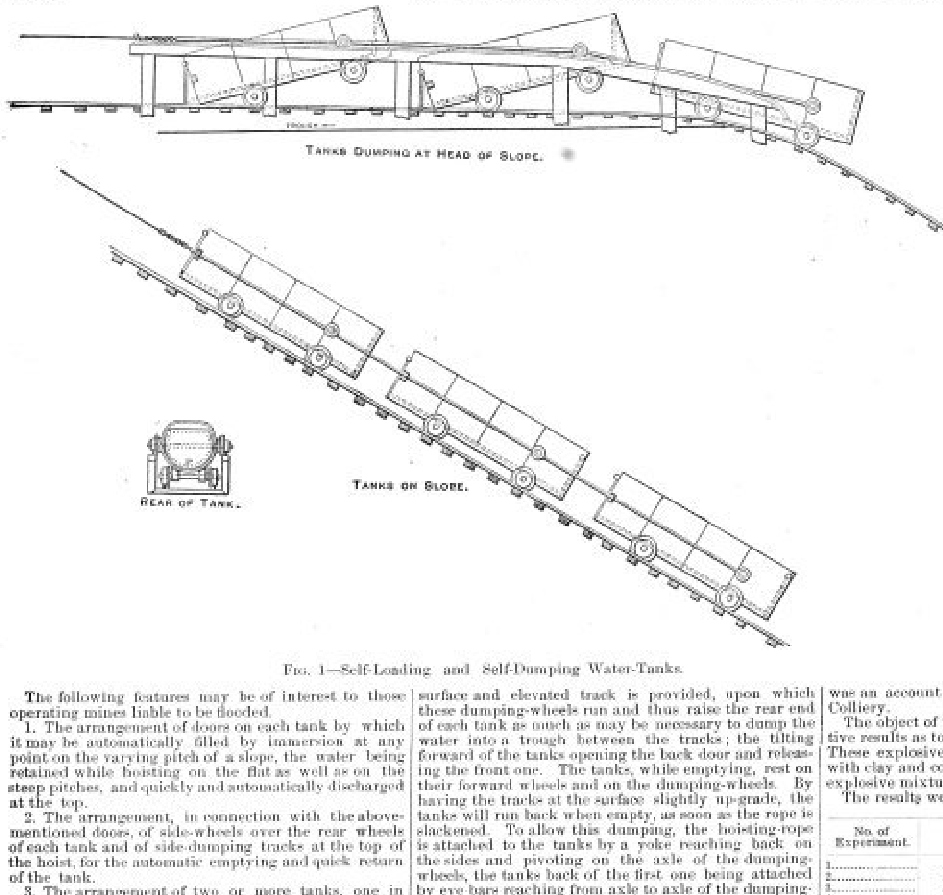

Fig. 1—Self-Loading and Self-Dumping Water-Tanks.

The following features may be of interest to those operating mines liable to be flooded.

1. The arrangement of doors on each tank by which it may be automatically filled by immersion at any point on the varying pitch of a slope, the water being retained while hoisting on the flat as well as on the steep pitches, and quickly and automatically discharged at the top.

2. The arrangement, in connection with the above-mentioned doors, of side-wheels over the rear wheels of each tank and of side-dumping tracks at the top of the hoist, for the automatic emptying and quick return of the tank.

3. The arrangement of two or more tanks, one in front of the other, so as to give as large a capacity in a single hoist as the engine-power will permit, yet without making any tank too large for the sectional area of the slope, or of unwieldly length, or of such a shape that it cannot easily pass over vertical curves; and without concentrating too much weight on any one pair of wheels or on any point of the track.

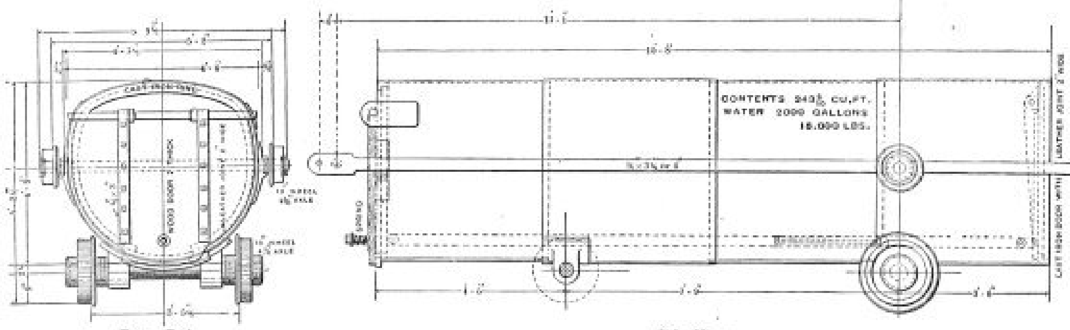

Fig. 2—Self-Loading and Self-Dumping Water-Tanks.

The details of construction and method of operating are shown by the accompanying sketches (Figs. 1 and 2), and the following more detailed description:

At the end of each tank is a large iron door of almost the full size of the end of the tank, opening inwards, so that when immersed the tanks fill almost instantly. To provide for holding the water while it is hoisted up flat pitches, a wooden door is attached to the front of each tank, opening outward. Each front door is attached to the door at the back by an iron rod, provided with a sliding link, so that the back door can open independently of the front; but the latter is held closed as long as the rear door is closed. This connecting-rod, as shown in Fig. 2, passes through the front door and through a spiral spring in front of it, so that the amount of pressure necessary to keep the water from leaking out may be readily applied.

The tanks are mounted on self-oiling closed wheels, so arranged as to exclude water from the bearings while the tanks are immersed, and to retain the lubricant.

Each tank is provided also with side-wheels, vertically over the rear axle, which have a gauge sufficiently wide to clear all other portions of the tank; and on the surface and elevated track is provided, upon which these dumping-wheels run and thus raise the rear end of each tank as much as may be necessary to dump the water into a trough between the tracks; the tilting forward of the tanks opening the back door and releasing the front one. The tanks, while emptying, rest on their forward wheels and on the dumping-wheels. By having the tracks at the surface slightly up-grade, the tanks will run back when empty, as soon as the rope is slackened. To allow this dumping, the hoisting-rope is attached to the tanks by a yoke reaching back on the sides and pivoting on the axle of the dumping-wheels, the tanks back of the first one being attached by eye-bars reaching from axle to axle of the dumping-wheels on the tanks. A stop is provided, to prevent the yoke on the forward tank from dropping and catching in the track when the rope is slackened.

This plan of "tandem tanks" was designed and used to hoist about 25,000,000 gallons of water which had been admitted to extinguish a mine-fire in one of the Susquehanna Coal Company's mines. The slope was small in section, and 3200 feet long, with single track, and with pitches varying from 4 to 20 degrees. The hoisting-plant consisted of a pair of 26 inches by 60 inches direct-acting engines with cast coned drum 9 to 12 feet in diameter, carrying 1½-inch steel rope. These engines had been previously hoisting five cars, weighing about 4 tons each when loaded.

THE PROGRESS IN MINING.

Reviews of the Important Papers Relating to Mining Published in the Proceedings of the Mining Institutes and in the Mining Publications of Europe, United States, and Canada.

Mining Education in England. All over the mining districts of England the local government authorities are awakening to the fact that increased prosperity is best attained by an increase in the intelligence of the working classes. To afford full facilities for improved technical knowledge the County Councils of Notts, Derbyshire, Warwickshire, Yorkshire, and Northumberland have founded a scheme of free lectures. Competent professors are appointed at salaries ranging from $1,500 to $2,000 a year to travel from district to district and deliver popular evening lectures to the miners. We boast of our go-aheadativeness: here is a suggestion for our Legislature.

Coal Cars. The Mining Institute of Scotland has recently published a series of detailed descriptions of forty-one different kinds of "hutches" or cars for conveying coal under ground. These descriptions give full details of the capacity of the "hutch," the material it is made of, the inclination and thickness of the seam it works in, and two estimates of the cost of making each, given by two of the most prominent "hutch" makers in Scotland. There are also detailed working drawings of each "hutch." The inclinations of the various seams where these "hutches" are used run at all angles from vertical to horizontal. The seams vary from 12 feet thick down to 14 inches, and the gauge of the rails from 1 ft. 4 in. to 3 ft. 2½ in. The costs of construction run from $28 for a "hutch," the body of which is made of iron plate, ⅛" thick, to $9 for one made with Larch and Elm.

The Use of Explosives in Mines. At a recent meeting of the North of England Mining Institute two papers were read dealing with the above subject, but from different points of view. The first, was a paper read by Mr. L. W. Chicken, on "Experiments with Explosives" and was an account of some experiments made at Risca Colliery.

The object of the tests was to find out the comparative results as to flame emitted by various explosives. These explosives were fired from a mortar, tamped with clay and coal-dust, into a chamber filled with an explosive mixture of coal gas, air, and coal-dust.

The results were as follows:

No. of Experiment.	Name of Explosive.	Nature and Length of Tamping.	Results.
1........	Ammonite.	6 in. of Coal-Dust.	No Flame.
2........	Ammonite.	4 in. of Coal-Dust.	No Flame.
3........	Ammonite.	2 in. of Coal-Dust.	No Flame.
4........	Dynamite.	6 in. of Coal-Dust.	Flame.
5........	*Gelatine dynamite	2 in. of Coal-Dust.	Flame.
6........	Securite.	6 in. of Coal-Dust.	Flame.
7........	Stonite.	6 in. of Coal-Dust.	Flame.
8........	Tonite.	6 in. of Coal-Dust.	Flame.
9........	†Carbonite.	None.	No Flame.

*Without water cartridge and supports.
†No coal-dust was used in this experiment.

The other paper was one read by Mr. W. J. Orsman "On the Products of the Combustion of Explosives when Strongly Confined."

The experiments were conducted in a hollow sphere with a shell of mild steel ½ in. thick and an internal diameter of 4½ in. There was an outlet valve at one side and an opening on the top closed by a screw-plug to confine the gases generated by the explosion. Ten grammes, ($\frac{22}{1000}$ lbs.) of the explosive were used in each case. They were fired by electricity.

The following are the results obtained:

Name of Explosive.	No. of Experiments.	Total Volume of Permanent Gases from 10 Grammes. Cubic Centimeters.	Mean Percentage Results of Analysis. Carbon Dioxide.	Carbon Monoxide.	Marsh Gas.	Nitrogen.
Carbonite	10	2,100	19	15	26	40
Gelignite (Nobel)	8	4,990	26	7	...	67
Tonite	3	.....	30	8	...	62
Roburite	12	4,790	32	...	...	68

It will be observed that carbonite gives off the greatest percentage of inflammable gases, and by opening the outlet valve on the side of the chamber these gases could be ignited, in which case they would burn with a pale blue flame. This explosive is largely composed of carbonaceous ingredients with the object of damping down the heat generated by the explosion. In the case of roburite a similar result is obtained by the addition of ammonium nitrate, and it will be noticed that in this case the gas freed by the use of roburite contains a large percentage of nitrogen.

Transmission of Explosions. A paper on this subject was recently read before the Manchester (England) Literary and Philosophical Society by Messrs. H. B. Dixon and B. McLean, and was a description of a series of experiments made to test the effects of explosions in transmitting their forces across intervening columns of air. The results showed that for a given mass of a gaseous mixture there is a certain minimum mass of air which will, if interspersed between it and another explosive mixture, guard this last like a shield, and they also found that it was immaterial whether this air was enclosed as a short and broad, or long and narrow column. These experiments are instructive, therefore, as dispelling the idea that the force of an explosion can be transmitted from one isolated accumulation of fire-damp to another across yards of a gallery or working face free from fire-damp and dust.

Boring into Old Workings. Mr. W. Wardle, author of "A Reference Book on Practical Coal Mining," in a letter recently published in *The Colliery Guardian* (Eng.), describes a method of tapping and successfully draining standing water in old workings accomplished under his supervision. A heading was driven in the seam to within 20 yards of the old workings and drill-holes were then pushed forward 9 feet by a Macdermott drilling machine. These holes were sufficient to admit a pipe 3 in. diameter to be driven into them. When the pipe was forced tightly in, a groove was chiselled out of the coal all around the pipe 18 in. deep and ½ in. wide. This groove was wedged up with rope-yarn to make the outer edge of the pipe perfectly water-tight. When the pipe was thus secured a wrought iron flange was attached to it and to this flange was fixed a large plug-tap, the hole in the plug of the tap being sufficiently great to allow 2½ in. bore rods and bits to pass through it; at the front of the tap a piece of timber 12 in. square was fixed with an elastic joint-ring between that and the tap to make a water-tight joint; the ends of the timber piece were well cut into the sides of the heading and secured fast. Before going any further with the bore a line of pipes was brought up from the sump at the pit bottom. Boring was then commenced, the rods being passed through a hole in the piece of timber, through the plug tap, and carried on through the coal seam to the old workings, the water being thus successfully tapped. The rods were then drawn in one length down the head without unscrewing and immediately they were withdrawn, one of the men shut off the plug tap until connection was made with the pipes leading to the sump, when the tap was opened and the entire area of old workings drained without any water being turned loose in the heading.

The Prevention of Overwinding. Mr. Archibald E. Pinching, Vice-President of the Mining Association of Cornwall, describes an ingenious contrivance for the prevention of overwinding, which was inspected by the members of the Mining Association of Cornwall at the Lens Colliery, Lille, during their recent Continental excursion. Mr. Pinching says: "While being shown around the surface works by the chief engineer and director-general, who combines both offices in himself, and watching the fine engines at work hauling the coal with wonderful rapidity from underground, I was electrified to see the gentleman in question—while a large engine was winding on and off a 36 ft. drum a cage containing six full tubs of coal and a cage loaded with men proceeding underground—motion the engine-man away from the handle and make him stand quite clear of the engine—and from the expression of the man's face it was quite evident that this had not been rehearsed—and thus leave the powerful machine entirely to itself. Almost immediately a warning bell rang, and we became aware that a powerful automatic brake—which I afterwards ascertained was on the Westinghouse principle—had been applied to the engine, and the drum was visibly slackening speed. The engine-man, however, was still told to remain where he was. Shortly after another bell rang, steam was completely cut off, and the cage drew up to its platform exactly as if the engine had been controlled by the most practiced driver. The apparatus consists of an arrangement of valves, which come into play directly the cage reaches a certain point in the shaft and, if the engine should at that moment not be under control, immediately apply the powerful air brake. This, however, allows the cage to proceed at a certain speed, but should another point in the shaft be passed and the engine be still out of control, the brake is increased in power, steam entirely shut off, and the cage brought to a standstill. The arrangement imperfectly described above, is the invention of M. Reumaux, who is the director-general of the society or corporation.

A Peculiar Case of Subsidence. The church of St. Chad, at Wybunbury, Cheshire, England, has been destroyed and rebuilt ten times, and it is now about to be restored once more. The cause of this destruction has been some subsidence of the surrounding ground and the committee for rebuilding called in Mr. De Rance, a geologist, to inspect and report. Mr. De Rance has given the results of his investigation in a paper read before the Manchester Geological Society.

At first he thought the displacement was due to removal of sand by springs, but he found a similar disturbance going on in the neighborhood where no such theory could be conclusive. The town of Wybunbury is in the district of the salt works of Cheshire and his next idea was that the pumping operations were causing a cave-in to take place. The nearest works were, however, seven miles distant. In the immediate neighborhood of the church and in various directions from it there are several "meres," or pools of salt water caused by outbursts of brine, and in one case the liquid is so elastic, owing to its strong saline properties, that a stick thrown with full force into the water rebounds back on to the bank, and Mr. De Rance has come to the conclusion that the subsidence is due to a natural solution of the rock salt underneath, independent altogether of artificial conditions brought about by brine pumping. If the solution was due to such pumping the surface springs would cease to flow.

The Premium Plan of Paying for Labor. A paper was recently read before the American Society of Mechanical Engineers, by Mr. F. A. Halsey, of Sherbrooke, P. Q., Canada, on "The Premium Plan of Paying for Labor." As the subject is of interest to both employer and employed, in all branches of industry, we submit the following description of the scheme: The three existing methods of payment are (1) The day's work plan. (2) The piece work plan. (3) The profit sharing plan.

By the first, a workman having no great incentive to exertion settles down to an easy-going pace that causes the employer to pay the highest rate for his product.

The second plan is an attempt to overcome this objection. The employer argues that some piece of work which is costing him a dollar by day's wages could, by an increased effort on the part of the workman, be produced for 80 cents. He, therefore, offers to share the profit from decreased cost by giving the man 90 cents for every piece. This goes very well at first, until either the workman finds that after working hard he cannot make wages at it, or else he produces such a large number of pieces that the employer begins to curtail the price and in this case the workman reduces his exertions until the same evils exist as were before. The *profit-sharing plan* gives to all the workmen an *equal* share in the profits of the business. This very *equality* is the evil of such a system. A hard working man is paid the same share as a lot of lazy fellows and he has no personal gain from his individual exertions. Then there is no provision made for the bad years, and the workman who shares the profits of a good year grumbles at the idea of bearing his share in the losses. From the employer's point of view he is paying the men profits with which they have no connection, such as reduced expenses in the commercial department, or more systematic shop management. The workman when he begins this profit sharing is glad to obtain anything, and welcomes it as a *bonus* over and above what was formerly his entire income, but, as time wears on, he thinks he is not being treated according to the terms of his agreement and the trouble begins. The only way to settle the matter is for the employer to show his books, and even if he is agreeable to do so, which every master is not, there are few workingmen's committees which are sufficiently well versed in profit and loss to comprehend the matter.

The *premium plan* is an effort to cure all these evils, and we will now consider it.

First of all a reasonable estimate is made of the number of hours required to do a certain piece of work and hourly wages decided upon; then for every hour the workman saves in doing the job he obtains a premium based upon a given scale. This hourly premium must be less than the hourly wages, so that if an hour is saved the cost of the piece to the employer is less, and at the same time the earnings of the workman is greater. Take a case based on the following table:

1	2	3	4	5
Time Consumed.	Wages Per Piece.	Premium.	Total Cost of Work = Col. 2 + Col. 3	Workmen's Earnings Per Hour = Col. 4 ÷ Col. 1
Hours.	$	$	$	$
10	3.00	0.00	3.00	0.30
9	2.70	.15	2.85	·317
8	2.40	.30	2.70	·333
7	2.10	.45	2.55	·364
6	1.80	.60	2.40	·40
5	1.50	.75	2.25	·45

If a man takes 10 hours to finish a piece of work and his hourly rate is 30 cents, the amount of his wages would be $3.00. If, however, he finishes the work in eight hours he will receive 8 times 30 cents = $2.40 as his usual wages and in addition the premium of 15 cents per hour for the two hours saved, so that his total earning for the eight hours will be $2.70, or 33⅓ cents per hour, while the cost in wages to the employer for the piece of work will be reduced by 30 cents. In this case the cost to the employer is reduced 10% while the workman's hourly wages is increased at an equal rate. The hourly premium must be fixed carefully and then adhered to, unless improved machinery or like causes raise a new basis for calculation. If the employer be greedy and tries to reduce the premium he will squeeze the lemon too dry and defeat his own object, as the workman will simply take it easier, and on the other hand if the premium be excessive the employer will be paying too high a rate of wages, but still it will be cheaper than before the premium system was adopted.

Safety-Lamp Experiments. A series of tests with various types of safety-lamps has recently been made by Mr. C. E. Rhodes, General Manager of the Aldwarke Main Collieries, Rotherham, England. The lamps tried were divided into two classes as follows:

(1). Obsolete lamps.

(2). Lamps of the most approved type.

Amongst what were termed "obsolete" lamps were the Davy and Clanny lamps, similar to those used in this country, and the wisdom of the mine law which forced the abolition of these lamps in a gaseous mine was proved in that the unbonneted Davy and Clanny *exploded in currents of gas and air traveling at velocities which are now commonly met with in most mines.* The great advantage of the shield or bonnet was amply demonstrated by the protection it afforded lamps which would otherwise have immediately exploded in a strong current.

The most approved types of lamps were those which had been commended by the Royal Commission on Accidents in Mines, and these proved satisfactory in the presence of excessive currents of explosive mixtures.

On the same line of experiment, Prof. Clowes, in a paper recently read before the Chemical Science Section of the British Association, describes an apparatus for testing safety-lamps, for examining their relative merits as fire-damp detectors. The apparatus was a wooden box with an inlet tube for gas at the top and an outlet for air at the bottom. The mixture could be so varied that any desired percentage of gas could be obtained in the air. He was unable to verify the general belief that an ordinary Davy lamp could detect 3% of gas, and indeed, with any of the newer patented lamps, the percentage had to be greater to show any indication on the flame. The one exception was Ashworth's Hepplewhite-Gray lamp fitted to burn benzoline through a sponge. This lamp gives a brilliant light and by a very delicate arrangement the flame can be lowered until it assumes the character of the Bunsen burner flame. The glass of the lamp is also "frosted" a certain distance up so that any minute elongation of the flame can immediatly be detected with this lamp. Prof. Clowes was able to detect ¼ per cent. of gas.

These two series of experiments are only a small item in the many tests which have from time to time been made in various parts of Europe, and the effect of these has been to convince the authorities on the other side that it is positively unsafe to venture into a gaseous mine with such a lamp as an unbonneted Davy or Clanny.

On the other hand, there has never been any tests which show any increase of danger from using a glass in a safety-lamp to replace the part of the gauze.

The only sensible conclusion that we can, therefore, arrive at regarding the Davy lamp is

(1). That while it gives the poorest light it is also the most unsafe in any but a very weak current.

(2). That the substitution of a glass around the flame increases the light and does not add to the risk of explosion.

(3). That it is *not* the best gas detector.

These are the results of so many and varied experiments that we will some time or other have to acknowledge their correctness, and why not now before more lives are lost.

The Utilization of the By-Products of the Coke Industry. Dr. Bruno Terne, in a paper recently read before the Chemical Section of the Franklin Institute, states that the economy displayed in Europe, in the utilization of these by-products, is far in advance of our American manufacturers.

Since 1850 the coke makers of England, France, Belgium, and Germany have been saving their by-products, while in our coal region to-day the sky is nightly illuminated by the fires from the coke ovens, all bearing witness to the waste going on. Our country is rich in resources, but not so rich as to warrant such a continual extravagance, and not only that, but the more careful European coke manufacturer saves his ammonia and sends it over to us in the form of sulphates.

Two years ago a manufacturer visited the Dahlhausen works of Dr. Otto, at the mines of Millensiven, near Dortmund. The ovens there are in two sets of thirty each, which are charged alternately every other day. The gases are conducted by large iron pipes to a large basin, where a part of the tar is condensed. From there it is led to the coolers, where the remaining tar and ammoniacal products are absorbed, and the gas, purified, is returned to a gas holder, and from there is redistributed to the coke ovens or boiler fires, or used in illuminating the works. That part of the gas which is returned to the coke ovens is mixed with hot air.

The coke is excellent, and although it has not the steel color of the Connellsville coke, it is of as good quality. The same gentleman, who is one of the best authorities on the subject, informed Dr. Terne that while the Connellsville Bee-hive oven only yielded 55% to 60% these ovens of Dr. Otto's gave from 70% to 80%.

But here is a sure proof of the value of such a process. Dr. Otto is not a coke manufacturer in the commercial sense of the term. He is a chemist. He constructs the ovens at his own expense, brings the coal from the mines, and delivers the coke to the mine company, simply to enable him to obtain the yield of tar and ammonia. He runs the ovens for twelve years and then hands the entire plant over to the mine owners, so that he must in that time make sufficient from the by-products to pay for the ovens, pay the interest on capital invested, and at the same time secure to himself the legitimate profit of a manufacturer, and he is successful in doing so, why should not we in America?

Taking the results obtained from a similar coal in Europe the by-product of ammonia alone which went to waste in one year at the coke ovens of America was 151,804,838 pounds, which at three cents per pound only is equal to $4,554,746. This was in 1887. In the same year the percentage of coke obtained from coal in Pennsylvania, which is the principal coking district, was 65%. The coal used was 8,938,849 short tons. If the by-products had been secured, as at Dr. Otto's works, the saving would have been $3,432,480, or, in other words, 28,604,316 pounds of ammonia, which has an agricultural value of eighteen cents per pound, have been lost in one year.

If the question be asked if the Connellsville coke would yield the same percentage of ammonia, the answer is given in the result of several experiments made by Dr. Terne which showed an average of 1·70% of ammonia. Dr. Terne gives illustrated descriptions of various kinds of coke ovens which have been tried in Europe to assist in the capture of the by-products and he says the question as to whether it will pay to gain these by-products is practically solved in the affirmative, and the question now before manufacturers is only what kind of oven will best suit the individual requirements of each kind of coal.

In the discussion which followed Dr. Terne's paper the question of first cost was raised and the following figures indicate the comparative costs of the Bee-hive as compared with the improved ovens.

Bee-hive Oven	$ 280.00
Otto Oven (without condensation apparatus)	337.00
Otto Oven and Condensation Apparatus Combined	1,150.20

It must, however, be borne in mind that the condensing plant will outlive the life of the ovens many times, so that the first cost will be limited to the first system erected.

Compound Air Compressors and Motors.

This was the subject of a paper read at a meeting of the South Wales Institute of Engineers by Professor A. C. Elliott, D. Sc., Edin. After giving his opinion that the use of compressed air as a power in underground work, is superior to the slow and cumbrous machinery of hydraulics, and is even preferable to electricity in that it is safer in presence of gas and is at the same time more desirable for its beneficial effects on the ventilation of workings. Prof. Elliot goes on to consider the increased duty obtained by compounding the compressors and motors.

The author compares this method with the ordinary simple system and claims for it that the result is either (*a*) with the same pressure of transmission a substantial gain in efficiency, or (*b*) with a higher pressure of transmission and the same efficiency, a reduction in the size of the supply pipes and the plant generally. In the ordinary system of compressed air transmission, the available energy per pound mass passed through the compressors consists of two distinct parts:

(1.) The reservoir energy.

(2.) The elastic energy.

The reservoir energy is the energy supplied direct by the compressor piston on the surface to the motor piston underground just exactly as if the two pistons were directly coupled by some rigid system of gearing.

This transference of power takes place between the opening of the eduction valve of the compressor and the closing of the expansion valves of the motor, and no part of the energy is transformed into and retransformed from heat. The internal work of a perfect gas like air is practically zero, so that the work spent in compressing up to the time the eduction valve closes is transformed in to heat. This heat is dissipated by absorption in the water jacket and in the long line of feed-pipes leading to the motors, and none of the work spent in mere compression has any counterpart in the work appearing in the motor.

This principle of zero internal work cuts both ways, and the energy gained in the motor by expansion is less than the energy spent in the compressor on mere compression.

It is evident therefore that the work done in compression over and above the actual force supplied to the motors from the moment the eduction valve opens is a waste product transformed into heat, and the system of compression and cooling therefore which will be most economical, is that in which the heat generated is least.

There are two ways of effecting this, (1) by removing the heat as rapidly as it is formed and (2) by compressing completely and then cooling the air. The first is called isothermal compression and the latter adiabatic compression. By the isothermal method the air leaves the cylinder in the state in which it reaches the motor, but with the other system the contrary obtains. Cooling takes place by the adiabatic system practically at constant pressure, and the compressor piston has to follow up the constant shrinkage of volume by sweeping a proportionately larger volume per pound mass of air delivered. From all sides the advantage of isothermal compression is apparent, but the difficulty has been to realize it in actual working. Injecting water into the compressor cylinder has been generally adopted, but opinion is divided as to whether it has any real advantage over the water jacket. The injection of water is the best heat dispeller, but it is objectionable where there is any difficulty in freeing the water from grit.

To obviate these inconveniences it has from time to time been suggested to cool the air by an intermediate process, and it has also been proposed to compress in two or more successive stages and this is the idea of compound compressors.

From tests made Prof. Elliott states the fact that compound compression would require 13 per cent. less and a triple system 16·7 per cent. less horse power than a simple adiabatic compressor, and he points out that to obtain the highest efficiency the exit temperature in each receiver must be as near the temperature of the atmosphere as possible. Taking the cases of an ideal isothermal compressor and an ordinary simple compressor, both accomplishing the same result, between the I. H. P. of each, there is difference which we consider as a dead loss in the ordinary system, and this loss is proved to be 23·8 per cent. The loss on a compound compressor would be 12 per cent., and on a triple and quadruple compressor 8 and 6 per cent. respectively.

Having thus considered the compounding of compressors, Prof. Elliott now turns to the question of compound motors and he suggests that just as in the former case we have the temperatures of the receivers reduced to nearly atmospheric pressure, by application of air or water at that temperature so on the other hand the temperature of a receiver of a compound motor could be *raised* to equality with that of the atmosphere by identically the same means, or in other words, it is possible to derive mechanical energy from atmospheric heat. The work spent in mere compression in the compressor, went as heat to the outside atmosphere, but if by means of some perfect conductor stretched from the compressor to the motor, we could apply this heat as work, after the expansion valves of the motor are closed we thus recover some of this wasted energy. As such a conductor is of course impossible, we must borrow by cutting off the stroke and drawing heat from the surrounding air to raise the cold air to as near the atmospheric temperature as possible in delivering it into the low pressure cylinder. By such a system and upon calculations based on the results of the reduced temperature obtained by compound compression we have for a simple motor an efficiency of 46·1% ; for a compound motor an efficiency of 59·8% ; and for a triple motor an efficiency of 65·2%. In conclusion, Prof. Elliott says that the compound system strikes at the root of three difficulties in the development of compressed air plant, viz.:

(1.) The rapid decrease in efficiency attendant on increase of pressure.

(2.) The small ratio of expansion obtainable in ordinary motors, and

(3.) The formation of ice on the exhaust passages.

The first point has here been dealt with. The second cannot wholly be dissevered from the third. There is a greater difficulty in effecting an early cut-off with an air engine than with a steam engine, as the air has twice the density of steam and shows more marked inertia effects. There are these advantages, however, that by the compound principle a considerable degree of expansion is consistent with fairly late cut-offs, the time given to effect expansion is greater, and the chilling action of the motor cylinder walls is reduced. The ice difficulty will vanish with the adoption of the compound principle as a very large proportion of the moisture originally present in the air will be condensed under the action of cold and pressure in the receivers, whence it can be readily withdrawn.

ELECTRIC LOCOMOTIVES.

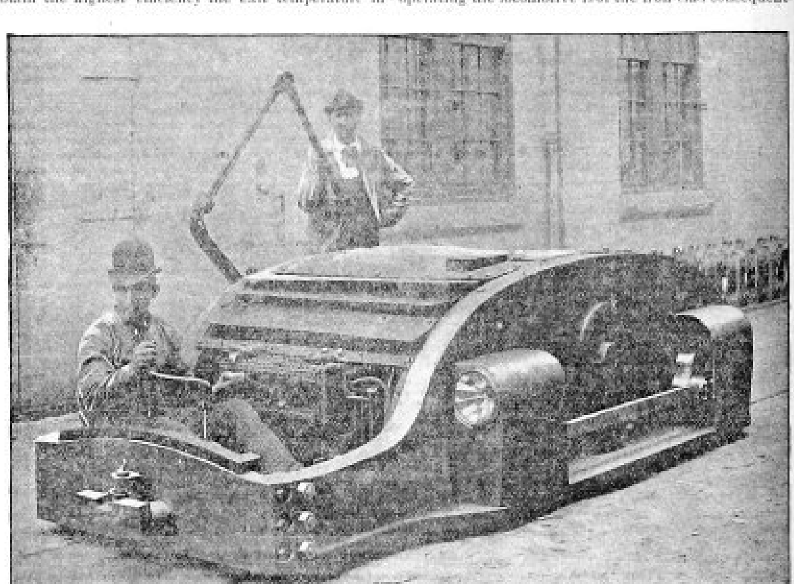
While electricity has been used for some time in mining work for the purpose of lighting mines, it attained no prominence in the field of underground haulage until the Thomson-Houston Electric Company designed and installed in the Erie Colliery, of the Hillside Coal Company, the first successful electric mining locomotive of the country. This was in October, 1889.

Requirements of other mines, however, have led to the production of a locomotive differing essentially from that in the Erie Colliery, a type known as the "Terrapin Back," and which is shown in the accompanying illustration.

It is most substantially and solidly built, the interior mechanism being entirely protected by a heavy iron armor, and possesses in a marked degree the important features of strength and solidity. The motor for operating the locomotive is of the iron-clad consequent-pole type, having a Gramme ring armature.

It is provided with the radial type carbon brushes and elongated commutator segments by means of which the most durable connection with the armature coils is obtained. The motor is situated midway between the axles, the proper speed reduction being attained by means of a train of gears. The locomotives can be run at various speeds, the motors being wound for any speed as a maximum from four to ten miles an hour.

The locomotive is provided with the necessary controlling devices, all placed within easy reach of the operator. A special type of rheostat composed entirely of mica and German silver is employed, and a new and improved brake lever and reversing switch. The trolley arm through which the current is conveyed to the motor is of the double elbow pattern, which accommodates itself automatically to the varying heights of the conductor and permits the operation of the car in either direction. On each side of the locomotive is placed an incandescent lamp, which serves the double purpose of signal and headlight. A 220-volt generator supplies the necessary current. The Thomson-Van Depoele Electric Mining Company, which designed this locomotive has also in process of construction several new types suited for the requirements of different mines, hard and soft coal, iron, and other metals, and for high and low entries, and for gauges varying from eighteen inches to the standard. The company having had such valuable experiences in the field of underground electric haulage is particularly fitted to design and manufacture any locomotive of any type demanded by local conditions. The success of the apparatus already installed has given great impetus to this branch of applied electricity and will result in the still further use of electricity in mining operations.



The Jeffrey Manufacturing Co., Columbus, Ohio, report business as good in their different lines of specialties. They have many large orders on their books for elevators and conveyors for handling material in bulk or package, and have recently purchased a tract of land adjoining their present extensive works, on which they have erected a large and substantial brick building, that they may be better able to take care of their growing business.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.
All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.
The Editor is not responsible for views expressed in this Department.
Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.

Pumping.

Editor Colliery Engineer:

SIR:—In reply to "Beginner," of Mount Pleasant, Pa., in August number, I submit the following:

The water is to be raised 100′, which will require $100 \times \cdot434 = 43{\cdot}4$ lbs. pressure per square inch; if the pump is 5 ft. from water, discharge $= 95 \times \cdot434 = 41{\cdot}23$ lbs. pressure.

Vacuum in suction $= 5 \times \cdot434 = 2{\cdot}17$; $41{\cdot}23 + 2{\cdot}17 = 43{\cdot}4$ when the pump is 20 ft. from water.

The discharge is $80 \times \cdot434 = 34{\cdot}72$;

Vacuum in suction $20 \times \cdot434 = 8{\cdot}68$, then $34{\cdot}72 + 8{\cdot}68 = 43{\cdot}4$.

The water being pumped 100 ft. high requires 43·4 lbs. pressure per square inch and it does not make any difference whether part of the work is done by creating a vacuum or all done by pressure.

Some are of the opinion that because the pressure of the atmosphere fills the vacuum as it is created that such is clear gain, but it is not so, if we raised water 10 ft. we must create a vacuum of 4·34, if we raise it 20 the vacuum must be 8·68, and 30 ft. will require a vacuum of 13·02 and so on until we reach the perfect vacuum, then the water will not raise any higher.

Yours, etc.,
F. B.

Maccan, N. S., Oct. 12th.

Examination Question.

Editor Colliery Engineer:

SIR:—In reply to "J. W. S.," in the October issue, I would say that his solution is wrong in assuming water to be 833 times heavier than air.

The weight of one cubic ft. of water at 40° temperature is 62·69617 lbs., weight of one cu. ft. of air at 40° temperature $= \cdot0796767$ lbs.

$$\frac{62{\cdot}69617}{\cdot0796767} = 786{\cdot}88 + \text{ times heavier than air.}$$

Now, by apportioning this correction with the assumed 833, and the results of "J. W. S.'" solution, we have

$$\frac{144{\cdot}47° \times 786{\cdot}88 +}{833} = 137{\cdot}29° \text{ temp. in upcast.}$$

If we use an assumed proportion we must remember that the answer is not correct, but is wrong in proportion to the difference of the assumed and correct proportions. I think we cannot find a shorter or more correct solution of the question of "J. W. S." than the following:

$$\frac{1{\cdot}32529 \times 30}{459 + 40°} = \cdot0796767$$

weight of one cubic ft. of air in the downcast.

$$\cdot0796767 \times 400 = 31{\cdot}87068 \text{ lbs.}$$

= the weight of a column one foot square from top to bottom of downcast shaft. Now, the weight of a similar column in the upcast will be 5·2 lbs. lighter $= (31{\cdot}87068 - 5{\cdot}2) = 26{\cdot}67068$ lbs.

$$\frac{26{\cdot}67068}{400} = \cdot0666767$$

weight of one cubic foot of air in the upcast shaft.

$$\frac{1{\cdot}32529 \times 30}{459 + T} = \cdot0666767.$$

By transposition

$$\left(\left(\frac{1{\cdot}32529 \times 30}{\cdot0666767}\right) - 459\right) = 137{\cdot}29 + \text{degrees}$$

temperature of upcast. I am sorry that "J. W. S." could not appreciate some of the several solutions of his question. I have tried to make the work as plain as possible believing that plain mathematics should be used in solutions where algebraic formula is unnecessary.

Yours, etc.,
F. B.

Maccan, N. S., Oct. 12th.

Certificated Mine Officials.

Editor Colliery Engineer:

SIR:—I am pleased to notice the rapid strides THE COLLIERY ENGINEER is making not only in its own improvement but in educating its readers as well. I have sometimes heard it said, by miners, that it is necessary to have a fairly good education before an interest can be taken in the articles that are published in THE COLLIERY ENGINEER. This cannot now be said, as the Primary Educational Department is just the thing that will assist the uneducated to get a clear conception of the laws and elements that are treated upon, and will be the means of overcoming the wrong impressions against certificated officials. Those that have the most to say against certificates are the ones that never try to improve their condition. I was surprised that the miners' convention, held at Columbus, Ohio, should pass a resolution, as reported by Mr. Andrew Roy in THE COLLIERY ENGINEER, not favoring certificated mine officials, also, that the inspectors of the State of Ohio should entertain such a feeling as was manifested at a late meeting of the Ohio Institute. It seems to me that an intelligent comprehension of the natural laws which govern the different elements connected with mining, and the benefit of the experience of others will benefit the operator and miner alike, and raise the standard to a higher level.

The new mining law which was prepared by our last Legislature shows that our operators and miners, after five years' trial, are in favor of the certificate. That some candidates have obtained certificates that are not worthy of them does not prove that the law is at fault. The damage done by the law is so insignificant compared with the good that it has accomplished that it is not worthy of mention.

Yours, etc.,
J. W.

Lindsey, Pa., Oct. 5th.

Pumping.

Editor Colliery Engineer:

SIR:—The following question was asked in the August issue of your journal, and has been answered by "J. V.," of Punxsutawney, Pa., and "T. S. A.," of Anita, Pa.:

In a shaft 100′ deep a pump is placed with 5′ suction and 95′ discharge. Will it require more or less power, if the pump is placed up the shaft with 20′ suction and 80′ discharge?

In their answers they claim there would be a difference in pressure of 6·51 lbs. to the square inch. Now, I am not satisfied with this result. If I understand their answers aright the same powers that "sucks" the water 5′ will "suck" 20′. According to the question the water must be lifted 100′, and 100′ of water weighs 43·4 lbs. on every square inch at bottom of said depth, that is, if we fill a pipe 100′ in height with water, there will be a pressure of 43·4 lbs. on every square inch of area at the bottom of the pipe. When our suction pipe is 20′ long, we must exhaust the air in this pipe until the pressure of air on the water outside will force the water up the pipe 20′, and this is practically the same as if we discharged the full 100′ without any suction. It can be all summed up thus—water is to be lifted 100′ and it does not matter how, as the weight is the same. The "suction" is only an indirect way of lifting it. In the suction pipe there is a pressure of 14·7 lbs. of air to the square inch. Now, without computing anything for friction, in order to get water up to the piston of the pump we must exhaust the air until only a pressure of 6·02 lbs. remain. Twenty feet of water will weigh 8·68 lbs. per square inch of area at bottom of the pipe, and in order for the atmospheric pressure to force the water up the pipe we must exhaust a pressure of air from the pipe of 8·68 lbs., which is the same as if the water were lifted. My experience with pumps has taught me that the 5′ suction would probably give the best satisfaction, and I can't see as there would be any difference of power. This is as I understand the question, if I am wrong I hope to be corrected by some of your able correspondents.

Yours, etc.,
J. N. K.

Mansfield Valley, Pa., Oct. 9th.

Examination Question.

Editor Colliery Engineer:

SIR:—In the October issue of your journal "T. S. C." says I prove one mistake by making another, and says:

$$M = D\,\frac{T - t}{459 + t}$$

Should be

$$M = D\,\frac{T - t}{459 + T}$$

The Colliery Engineer Pocket-Book, on page 73, gives the last rule for finding motive column, but E. B. Wilson, on page 127 of his book on mine ventilation, gives the first rule. Which is correct? I supposed Mr. Wilson was correct and used his formula.

In either case the answer is arrived at by simply reversing the formula, or rather, the known quantities of the formula to find the unknown quantitity. I should have used air at 40° F. and 30″ barometer instead of 60° F. and 30″ barometer.

Yours, etc.,
H. L. D. W.

Dagus Mines, Pa., Oct. 15th.

Examination Question.

Editor Colliery Engineer:

SIR:—In answer to "J. W. S.," I submit the following: In his question the pressure is given as 5·2 lbs., and as the pressure is the weight of the motive column, its temperature being 40°, the weight of one cubic foot of air in the motive column

$= \cdot07967$, and

$$\frac{5{\cdot}2}{\cdot07967} = 65′, \text{ instead of } 69{\cdot}4′$$

as he reckons it to be by assuming the comparative densities of air and water to be as 1 is to 833. In this case it is not correct, as a cubic foot of water divided by 833 $(62{\cdot}5 \div 833)$ equals ·07503, which is the assumed weight of a cubic foot of air and which, as I have demonstrated, is not correct. This difference makes the difference in the answers, that have been given and his own. Hoping that my explanation will be understood by "J. W. S.," I remain

Yours, etc.,
T. S. C.

Gardner, Ill., Oct. 10th.

Mining.

Editor Colliery Engineer:

SIR:—I wish to submit the following question in hope that some of your able correspondents will express their views:

Suppose a mine was to suspend operations for several years, and it was desirous to leave it in condition to resume as quickly as possible, would it be best to close the various openings or leave them open, so as to have no air current, or current due to natural ventilation? Under which condition would most damage occur to sides and roof of gangways?

Yours, etc.,
S. U. P.

Lawsonham, Pa., Oct. 10th.

Pumping and Surveying.

Editor Colliery Engineer:

SIR:—Please insert the following in reply to "T. S. A.," of Anita, Pa., in the October issue:

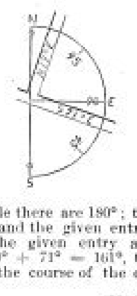
(1.) Six boilers of 288 nominal horse-power would require 288 cubic ft. of water per hour, therefore

$288 \div 60 = 4{\cdot}6$ cu. ft. of water per minute, or, as there are 1728 cubic inches in a foot, we have

$4{\cdot}6 \times 1728 = 7948{\cdot}8$ cubic inches, then,

$7948{\cdot}8 \div 231 = 34{\cdot}41$ gallons per minute.

(2.) The following diagram represents the given entry and cross-heading as it should be:



In the semi-circle there are 180°; the angle between the south point and the given entry equals 71°; the angle between the given entry and cross-heading equals 95′, and $90° + 71° = 161°$, then $180° - 161° = 19°$, therefore the course of the cross-heading will be north 19° E.

Yours, etc.,
J. T. G.

Braidwood, Ill., Oct., 12th.

"Agricultural Phenomenon on Coal Land."

Editor Colliery Engineer:

SIR:—I think if your correspondent, W. W. Cable, had stated the *kind of soil or soils* existing in Jefferson Co., Ohio, where the apple-tree phenomenon referred to occurs, the explanation of it would have been made more easy. In the absence of this data I beg to suggest that it is possible, and even probable, that above the coal seam the soil is "warm" and sandy, whereas that below the coal is "cold" and clayey, which latter causes sterility of the apple trees. I am no horticulturist or agriculturist, but it would naturally seem to me that the quality or character of the soil in which those trees grow, has chiefly to do with the case.

Yours, etc.,
W. S. GRESLEY.

Erie, Pa., Oct. 11th.

Colliery Management.

Editor Colliery Engineer:

SIR:—I wish to submit the following in reply to "S.," of Wilkes-Barre, Pa.:

Where and how can the best results be obtained from a furnace at a coal mine, whether at the top of upcast or at the bottom of upcast and state reason why?

The best results are to be obtained from a furnace at the bottom of the upcast, since the furnace causes the current to move by rarification and the heated air being lighter than downcast air rises, the cool air flowing towards the furnace to be heated and rarified in its turn. The depth of shaft is a measure of pressure produced by the furnace. In a deep shaft the column of heated air is longer than in a shallow shaft and consequently lighter than an equal column of the downcast air, hence the deeper the shaft the greater will be the pressure with the same amount of fuel used. If the furnace were placed at the top of shaft very little current could be produced, as the only heating surface would be at the grate-bars, and the chances are the current would be from the outside instead of from the mine. At any rate the furnace would not give good results, since to be effective the furnace must heat the air in the shaft, thus making it lighter than the downcast or outside air.

Yours, etc.,
S. U. P.

Lawsonham, Pa., Oct. 12th.

Colliery Management.

Editor Colliery Engineer:

SIR:—Please insert the following in reply to "S.," of Wilkes-Barre, Pa.:

The best results can be obtained from a furnace placed at the bottom of the upcast, say 30 or 40 feet from the bottom, when it is possible to have the airway on a rise to the shaft. By having the furnace at the bottom of the shaft the heat is nearly all utilized. If the furnace were at the top of the shaft a large amount of heat would be wasted. Furnace ventilation is reckoned according to the square root of the depth of the upcast shaft, or the height of the column of heated air.

Yours, etc.,
O. K.

Rock Point, Pa., Oct. 20th.

The So-Called "Novel System of Coal Hoisting."

Editor Colliery Engineer:

SIR:—I am rather amused to see this announcement made, which is going the round of the coal mining papers. The introduction of the system described may probably be a *novelty* in the coke regions of Pennsylvania, and possibly in America, but it reads to me very like what in South Wales is called the "water balance"—a method of hoisting coal and other minerals, etc., more or less adopted in Europe from the days of Agricola, (A. D. 1550). See "Mining in the Middle Ages," by George Blake Walker, Barnsley, England, 1888.

For "*novel*," therefore, read "*ancient*."

In order to show that this self same apparatus, at any rate in *principle*, is nothing *new*, I beg to quote:

In "Fossil Fuel, the Collieries, and the Coal Trade in Great Britain," by Holland, London, 1835, p. 204, we read: "It should be mentioned that previously to the application of steam, by what was at first termed the "fire engine," a great variety of expedients for drawing coals were devised. "The most ancient machine to my knowledge now (1797) in use," says Mr. Curr, "is that invented by Menzey; but there are few situations that afford the requisites necessary to that invention. A stream of water with a fall of about half the depth of the pit is necessary, if any business of *consequence* might be done. Its construction consists of two wheels fixed upon one horizontal axis, which are so proportioned to the depths of the water pit and coal pit as to reach the separate depths of the pits by the same revolutions, and the power applied is a tub of water large enough to overbalance the weight to be drawn." This is from "Coal Viewer and Engine Builder's Practical Companion," published in Sheffield in 1797, or nearly 100 years ago.

Again, we find in "A History of Coal Mining in Great Britain," by Robert L. Galloway, 1882, p. 112. "The steam engine being at this time (that of James Watt, in 1768) only a *single-acting* machine, was ill-adapted for producing an even rotative motion directly. The attempts to use its power indirectly in raising coal were more successful. One of the earliest arrangements to effect this—the invention of Mr. Michael Menzies—was applied at Chatershaugh Colliery, Co. Durham, on the river Wear, in 1753. The basket of coals was raised by the descent of a bucket of water, a steam engine being employed to re pump the water to the surface. By this means a basket of 5½ cwt. of coal was drawn from a depth of 50 fathoms (300 feet) in 2 minutes. An arrangement on the same principle, known as the *balance-tub system*, was subsequently largely employed, more especially in collieries where the water used in raising the coals could be run off by an adit without requiring to be pumped up again."

It was about the year 1774 that water-wheels were introduced for hoisting purposes. This was due to one Sorocould, at Alloa, in Scotland. The plan was to fill reservoirs or large cisterns with water on the surface, from which the water engines took their supply of motive power; a double set of buckets, placed in opposite positions on the rim of the water or driving wheel, producing the reversion of the drum.

In the year 1852 was published the second edition of Dunn's celebrated "Mining and Working of Collieries" (a most entertaining and very fully illustrated all-round work on the then state of mining coal in Britain). Mr. Dunn says, on p. 217: "A rude method of drawing coal is practiced in Cumberland, and in some of the southern counties, by means of *water balance*, viz.: that a cistern of water, heavier than the loaded tub of coals, is attached to the opposite rope, so as as to overbalance it and draw it up, the water being discharged at the bottom of the pit, either to pass to surface by a natural level, or to be pumped up by an engine, as the case may be. Accidents are constantly occurring by this description of machinery, and the inconveniences arising from the leakages of water are such as ought to abolish such an antiquated application at a period when steam engines can be so advantageously applied and can be procured so cheaply."

That is what the great Matthias Dunn, of North of England fame fifty years or more ago, said about this thing.

Warington W. Smyth, F. R. S., etc., (in his excellent little popular work, "Coal and Coal Mining, 1866,") said on p. 161: "In Wales another mode of employing water power came into use, which is still to be seen at many of the collieries, as well as some of the slate quarries, where this power is abundant. A large sheave fitted with a powerful brake is fixed above the pit-top, and has a rope or chain passing round it, to one end of which is attached an empty cistern carrying over it a wagon of coal, to the other a cistern which, when filled with water, is heavier than the loaded wagon and empty cistern together. Suppose now the former is at bank, the latter at pit-bottom; the cistern is filled from a tank placed close by, and is regulated in its descent by the brake; when it reaches the bottom a self acting valve is opened, which lets the water flow out, meanwhile the loaded wagon is taken off the empty cistern, and by the time the latter is filled with water from same tank, the cistern at bottom is empty and the load of coals placed upon it, and thus the action is reversed, and a cheap, although slowly working machine, kept in reciprocating movement."

Then, in "Glossary of Terms Used in South Wales, Bristol, and Somersetshire," by W. Fairley, M. E., 1868, p. 3, "Balance Pit, a shaft so called when the coal is drawn by the weight of water," etc., adding "this method of getting coal up a shaft is adapted where water is plentiful, pits are shallow, and on top of a hill, so that the water taken down may run out of the hillside by means of an adit, or when it is raised by a water-wheel near top of shaft."

In Collins' "Principles of Coal Mining" (elementary science series), London, 1877, p. 92, the "water balance" is fully described, in which it is stated that the system is not used for depths exceeding 600 feet. In some cases the machines are placed at different levels so that the same water is used five or six times, over as many successive lifts. Trams holing 12 to 20 cwt. are raised. The water buckets are made of ¼ inch boiler plate, often circular in form, and some have a capacity of two or more tons of water. A speed of 300 to 400 feet per minute is easily attained by the machine, and the total cost of hoisting the stuff is about 1½ d. (3 cents) per ton per 300 feet. Similar machines are in use at some of the iron mines of Cumberland and elsewhere."

The "water balance" is referred to on p. 279 of the writer's "Glossary of Coal Mining Terms," 1883, and doubtless in other books besides. The writer recollects seeing "water balances" in use on the hillsides in the tin mining region of Cornwall, England, in 1873. These were erected and working on the surface, the vertical fall of the water tanks being about 35 feet, wire ropes connected them with hoists or other machinery for raising a load or for doing certain work way back in the levels, etc., or at mine mouths.

It is probably not generally known that most of the mine machinery at many of the iron, copper, and silver mines in Sweden is operated by water power, and in many places applied in the most primitive and yet economical manner. The author of "Mining in the Middle Ages," already referred to, states in a foot-note on p. 16, "A winding machine almost identical with the one here described, is mentioned in a paper by Mr. W. S. Gresley, in vol. VII., of *The Journal of the British Society of Mining Students*, as being still in use at the great Dalecarlia copper mine, in Sweden. From Mr. Gresley's account it would seem that in spite of the invention of the steam engine, water is still used in preference in Sweden for almost all purposes, on account of its greater economy; in fact, speaking generally, it would seem that most of the methods described by Agricola are still practiced in Sweden with excellent results."

It does not, therefore, seem likely that the Southwest Coal and Coke Co., of Pennsylvania, will be doing anything that may be called *progressive* if they adapt the antiquated water balance hoist, especially if they will have to pump back the water to the surface, as the Mt. Pleasant *Journal* implies will be the case.

While on this subject, the fact that Anthracite is hoisted from the mines near Carbondale, Pa., by water power (or was in 1889) may be cited; an over-shot breast water-wheel and drums operated by friction clutches being employed.

Yours, etc.,
W. S. GRESLEY.

Erie, Pa., Nov. 7th.

Certificated Mine Bosses.

Editor Colliery Engineer:

SIR:—A review of the coal mining industries of Western Pennsylvania, for the past six years, gives very little evidence that the ideal illiterate mine boss, of Mr. Hazeltine's standard, who, previous to the passage of the Bituminous Mining Act, of June, 1885, was in the majority, gave as good results as his now better informed brother is giving. The first was a child of favor, in some instances a man of ability full of hard common sense and practical knowledge, or, again, the favorite of some sentimental egotistical superintendent, or the tool of some petty tyrannical one. And the mine went drifting and dragging along in a happy-go-lucky devil-may-care manner too well known to be needful of comment here. And how in all fairness to Mr. Hazeltine's opinions and with due regard for his position he could have made so dwarfed and weak an assertion is beyond intelligent comprehension. Is not illiteracy the very seven-headed dragon which the mining craft have been fighting lo! these many years? And what crime have we committed and what law have we broken that consigns us to toil on in ignorance at our cheerless occupation? Is there any sin save that of omission visited from parent to child? And now that the child's feet are learning to walk should they not rather be guided than tripped up? When the Bituminous act, of June, 1885, became a law, light and prolonged life became the heritage of the miner who seems to have never inherited a birthright. The mine boss who, previous to that time, knew more of drain cutting, mule driving, and road laying than of natural philosophy laid aside the tools of these occupations and became his brother's keeper.

Some one says, is it really necessary for the mine boss to be certificated?

Just as necessary as the licensed pilot who guides the ship safely by the shoal and bar, or the competent educated engine-man who rides his machine and hauls the great thundering express trains safely from daylight to dark and morning. It is also very necessary that the superintendent possess a certificate of competency similar to that of the mine boss. Sometimes it might enable him to know why timber was needed in the mines and why expenses could not be cut down, and would it not help him to co-operate more intelligently with the mine boss instead of being a barrier to his progress? It is not the intention, spirit, or meaning of this article to throw hints to that broad-minded class of well-informed superintendents and managers who thoroughly understand how to manage their work. But the barnacles who know not how to do it, the Uriah Heeps who are promoted from a dry-goods and grocery store with instructions to "keep an eye on the business" at which they sometimes take a shy are here alluded to.

Let every craftsman who toils below the daisy roots, be of good cheer, THE COLLIERY ENGINEER is your friend, do not doubt or dodge that fact. Every department is a treasure-trove for you, and its future holds more and more promises. Give it your substantial support and aid because of the aid it has given you and will give to others.

Yours, etc.,
EYE SEE.

Loyal Hanna, Pa., Oct. 20th.

Pumping and Surveying.

Editor Colliery Engineer:

SIR:—I submit the following in reply to "T. S. A.," of Anita, Jeff. Co., Pa., in your October issue:

(1). Edwards, on page 209 of "Practical Steam Engineers Guide": "Each nominal horse power of boilers require one cubic foot of feed-water per hour." Consequently 288 cu. ft. × 6¼ imperial gallons in one cubic foot = 1800 gallons per hour as required for 288 H. P. in boilers.

(2). S. 71° E + 90° turned to the left = 161°. There are 180° in a semi-circle. The needle points at 71° and a right angle will cover 90° more or 161° of the semi-circle. From the 180° subtract 161° and 19° are left. The semi-circle is in two quadrants which are read from S. to E. and from N. to E., there being 90° in each quadrant. We began at the South and read 71° + 90° = 161°, this brings us into the N. E. quadrant leaving only 190° E. from due North. So the course is 19° N. E.

Yours, etc.,
H. L. D. W.

Buffalo, N. Y., Oct. 18th.

Mensuration.

Editor Colliery Engineer:

SIR:—The following is in answer to "Trackman," of Reynoldsville, Pa.:

A tree 80′ long, 6′ diameter at butt end, tapers to 1′ diameter, how long a rope will it take to coil around it, the coils to be close together, also how long will the rope have to be, allowing 12″ between coils?

First,

$$\sqrt{(6' + 1' \div 2 \times 3{\cdot}1416 \times 960^2 + 80^2)} = 10556{\cdot}07'$$

of rope 1″ in diameter.

Second,

$$\sqrt{(6' + 1' \div 2 \times 3{\cdot}1416 \times 80'^2 + 80^2)} = 879{\cdot}65'$$

nearly of 1″ rope 12″ from center of coils. If "Trackman" wants the amount of rope required at 12″ between coils, instead of from center to center, substitute 73·846 revolutions for 80 in last equation. See Haswell's book, page 355.

Yours, etc.,
H. L. D. W.

Buffalo, N. Y., Oct. 17th.

Arithmetic.

Editor Colliery Engineer:

SIR:—The following problem is given in Fairley's book:

$$\sqrt{25000^2 + 22000^2} = 33{,}301.$$

It is on the combined effect of furnace and steam jet. Thus far I have been unable to solve it, and obtain the same result as given; would some of your able correspondents work it out fully?

Yours, etc.,
A. A.

Buena Vista, Allegheny Co. Pa., Oct. 16th.

Trigonometry.

Editor Colliery Engineer:

SIR:—Will some of your readers kindly explain how the decimal is found for any number of degrees such as 35°? Is it by multiplying by the sine of one degree? ·017452 × 35° is not correct.

Yours, etc.,
R. L. T.

Reynoldsville, Pa., Oct. 20th.

Ventilation.

Editor Colliery Engineer:

SIR:—Please publish the following in reply to questions by "A. B.," of Hanna City, Ill., in your September issue:

(1). An airway 8′ × 8′ × 1000′ is passing 40,000 cu. ft. of air, what diameter should a circular airway 1200′ long be to pass one-half the quantity, the pressure remaining the same?

As the pressure is the same for the two airways, we find the area of the circular one by the following formula:

$$\frac{Q}{v} = a,$$

and from it the diameter, thus

$$20{,}000 \div 625 = 32', \text{ and}$$
$$32' \div {\cdot}7854 = 40{\cdot}71' +$$

the square of the diameter, the square root of which is the diameter, or

$$\sqrt{40{\cdot}71} = 6{\cdot}38' +.$$

(2). A mine is ventilated by natural ventilation passing 10,000 cubic feet of air per minute with a pressure of 3·5 pounds, the temperature in the downcast being 42°. The air current is reversed by erecting a furnace at bottom of the downcast producing 14,000 cubic feet of air per minute, what is the effect on the pressure and temperature?

By erecting a furnace at the bottom of the downcast and reversing the current the temperature of the downcast will remain the same (42°), but by erecting a furnace the upcast is changed to the downcast. For every degree of heat the furnace will add in the upcast the volume will increase at the ratio of $\frac{1}{459}$, and as the volume has increased, the pressure will increase as the square of the velocity.

Yours, etc.,
L. P. H.

Avoca, Pa., Oct. 15th.

Certificated Mine Superintendents.

Editor Colliery Engineer:

SIR:—Your correspondence on certificated mine superintendents is becoming interesting. With your permission I would say this in favor of it: If a compulsory examination for superintendents will cause as much study of mining as the examination of Mine Foremen has, then by all means, let them be examined. The Mine Superintendent in England has to pass an examination and hold a certificate before he can serve. But before presenting a bill to that effect to the Legislature of this State would it not be well to publish it in THE COLLIERY ENGINEER and other mining journals, so that those interested may have a chance to criticise it? Our latest mining laws are a disgrace, as for instance: the law requiring miners to hold certificates. The good this law has accomplished is *nil*. It has done much evil in creating parasites who enforce the law for the paltry fifty cents there is in it for them. A man must be hard up for an office, indeed, when he will accept a place on these Boards. The "fire bosses" now must go through the same ordeal as the mine foremen in order to enable them to hold certificates. The law makers themselves in this case did not understand the law they created.

Suppose a person holds a certificate as a superintendent, as many now hold mine foremen's certificates, what good are they in a community where the mines are owned by large corporations. The appointing power is vested in the hands of one person. The Reading owns forty-five of the best collieries in this region; they have adopted a system of promoting their employes, and stick to it pretty closely. If a person happens to be out of favor with the "powers that be," his name is "Dennis." Some may say to those who are aspiring for such promotions, "get friends." Mark Twain says in the Gilded Age: "You don't need brains, get friends." But I am inclined to think that unless a person *has* brains, friends can not always help him. I know a man who lately took charge of the fag end of what had been for many years an excellent colliery. Of course there is an end to everything, and so there was to the colliery I am alluding to. A change was made, but if it was badly managed before, the change made things ten times worse because friends, not brains, were most influential in making the appointment.

Yours, etc.,
O.

St. Clair, Pa., October 22d.

Answers to Miscellaneous Questions.

Editor Colliery Engineer:

SIR:—Please insert the following solutions to questions by "S. W.," of Irondale, Ohio, in the November issue:

(1). How is a water-gauge affected when the air course is suddenly contracted or enlarged?

ANSWER.—The revolutions of the fan remaining constant, there will be a loss of water-gauge when contracted and a gain when enlarged.

(2). By what means is density increased and diminished?

ANSWER.—The density of air is increased by compression, as with the force fan; and diminished by rarefying the air as is done with the furnace by heating it, or by the use of the exhaust fan in tending to create a vacuum.

(3). It is proposed to increase the quantity of air circulating in a mine 10,000 cubic feet per minute, by building a chimney on to the upcast shaft; the original volume is 60,000 cubic feet, and the upcast shaft is 400′ in depth, what must be the height of the chimney?

ANSWER.—The pressure will be in proportion to the depth of the shaft, the temperatures remaining the same, and the quantity as the square root of the pressure. Therefore, the quantity will be as the square root of the depth, and the depth as the square of the quantity. Then as the height of chimney is equivalent to so much being added to the depth of upcast, the new depth will be as

$$60{,}000^2 : 70{,}000^2 :: 400 : x, \text{ or}$$
$$36 : 49 :: 400 : 544{\cdot}44$$

= new depth, and then

$$544{\cdot}44 - 400 = 144{\cdot}44',$$

the height of chimney.

(4). There is a cistern 20′ square, and 10′ deep placed on the top of a tower 60′ high, what power is required to fill this cistern in 30 minutes; and what will be the diameter of pump, when the length of stroke is 2′, and making 40 strokes per minute?

ANSWER.—The capacity of the cistern is found thus:

$$20' \times 20' \times 10' = 4{,}000 \text{ cubic feet.}$$

Then,

$$\frac{4{,}000}{30} = 133\tfrac{1}{3}$$

cubic feet that the pump must be able to discharge in one minute, and

$$133\tfrac{1}{3} \times 1{,}728 = 230{,}400$$

= the number of cubic inches per minute. Velocity of pump equals

$$2 \times 40 \times 12 = 960$$

inches per minute, and the area of pump is

$$\frac{230{,}400}{960} = 240.$$

Then

$$60 \times {\cdot}434 = 26{\cdot}04 \text{ lbs.}$$

pressure per sq. in. on the water end, and

$$26{\cdot}04 \times 240 = 7249{\cdot}6 \text{ lbs.},$$

load on piston;

$$\overset{p\,a}{7249{\cdot}6} \times \overset{s}{80} = 579{,}968$$

= the units of work. If we add $\frac{1}{3}$ for loss and friction we have 773,290 units, or

$$\frac{773{,}290}{33{,}000} = 23{\cdot}4 \text{ horse power.}$$

$$\text{Diameter of pump} = \sqrt{\frac{240}{{\cdot}7854}} = 17{\cdot}48''$$

or by formula

$$\sqrt{\frac{\text{Galls.}}{3{\cdot}3}} = \frac{230{,}400}{231} = 997 \text{ gallons,}$$

$$\sqrt{\frac{997}{3{\cdot}3}} = 17{\cdot}4'' = \text{diameter of pump.}$$

Yours, etc.,
T. S. C.

Gardner, Ill., November 9th.

Ventilation.

Editor Colliery Engineer:

SIR.—I submit the following in reply to question asked by "S.U.P.", of Red Bank, Pa.:

The pressure is found thus:

$$p = \frac{k\,s\,v^2}{a}$$

substituting their given values we have

$$p = \frac{{\cdot}0000000217 \times 24000 \times 250{,}000}{128} =$$

$$\frac{130{\cdot}200000}{128} = 1{\cdot}017 + \text{lbs.}$$

the pressure required. In the next case we have the following formula to find the quantity:

$$q = \sqrt{\frac{p\,a}{k\,s}} \times a.$$

By taking the total pressure which has been found to be 130·2 lbs. and divide it by k and s, and substituting their values we have

$${\cdot}0000000217 \times 32000 = {\cdot}0006944,$$

and

$$130{\cdot}2 \div {\cdot}0006944 = 187500,$$

and

$$\sqrt{187500} = 433{\cdot}01 +$$

multiplied by 128· the area of the two shafts, we have 55·425 cubic feet, the quantity that will pass. It can also be solved in this way: Air courses will pass quantities in proportion to the square root of their rubbing surfaces. Hence we have the following simple proportion:

$$\sqrt{64} : \sqrt{48} :: 64{,}000 : x, \text{ or}$$
$$\sqrt{4} : \sqrt{3} :: 64{,}000 : x,$$

and by extracting the root it becomes

$$2 : 1{\cdot}73 :: 64{,}000 : 55{,}360 \text{ cubic feet.}$$

The slight difference is owing to not carrying out the decimal places further.

Yours, etc.,
O. K.

Rock Point, Pa., November 11th.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to question (1) asked by "A. B.," of Hanna City, Ill.:

(1). An airway 8′ × 8′ × 1000′ is passing 40,000 cu. ft., of air, what diameter should a circular airway 1200′ long be to pass one-half the quantity, the pressure remaining the same?

Let a denote area airway No. 1 = 64 sq. ft.
Let o denote perimeter airway No. 1 = 32′.
Let l denote length airway No. 1 = 1000′.
Let q denote quantity airway No. 1 = 40,000 cu. ft.
Then,

$$\left(\frac{q}{a}\right)^2 = \frac{q^2}{a^2} = \text{sq. of velocity} = \frac{40{,}000^2}{64^2},$$

and k = co-efficient of friction = ·0000000217.
Let x denote diameter of airway No. 2.
And ·7854 x^2 denote area of airway No. 2.
And 3·1416 x denote perimeter of airway No. 2.
And L denote length of airway No. 2.

And $\frac{q}{2}$ denote quantity of airway No. 2.

And

$$\left(\frac{\frac{q}{2}}{{\cdot}7854\,x^2}\right)^2 = \frac{q^2}{4 \times {\cdot}7854^2\,x^4} = \text{square of velocity.}$$

Then,

$$\frac{k\,o\,l\,\frac{q^2}{a^2}}{a} = p = \text{pressure,}$$

and

$$\frac{k\,3{\cdot}1416\,x\,\mathrm{L}\,\frac{q^2}{3{\cdot}1416 \times {\cdot}7854\,x^4}}{{\cdot}7854\,x^2} = p = \text{pressure.}$$

Hence,

$$\frac{k\,o\,l\,\frac{q^2}{a^2}}{a} = \frac{k\,3{\cdot}1416\,x\,\mathrm{L}\,\frac{q^2}{3{\cdot}1416 \times {\cdot}7854\,x^4}}{{\cdot}7854\,x^2} \quad (1).$$

Canceling k and reducing (1)

$$\frac{o\,l\,q^2}{a^3} = \frac{\mathrm{L}\,q^2}{{\cdot}7854^2\,x^5} \quad (2).$$

Dividing (2) by q^2,

$$\frac{o\,l}{a^3} = \frac{\mathrm{L}}{{\cdot}7854^2\,x^5} \quad (3).$$

Reversing (3)

$$\frac{a^3}{o\,l} = \frac{{\cdot}7854^2\,x^5}{\mathrm{L}}, \quad (4).$$

Dividing (4) by $\frac{{\cdot}7854^2}{\mathrm{L}}$

$$\frac{a^3\,\mathrm{L}}{o\,l\,{\cdot}7854^2} = x^5. \quad (5).$$

Substituting the symbolic values

$$\frac{64^3 \times 1200}{32 \times 1000 \times {\cdot}7854^2} = x^5. \quad (6).$$

Extracting fifth root of (6)

$$\sqrt[5]{\frac{64^3 \times 1200}{32 \times 1000 \times {\cdot}7854^2}} = x, \text{ or}$$

x = 6·98′ diameter of required airway.

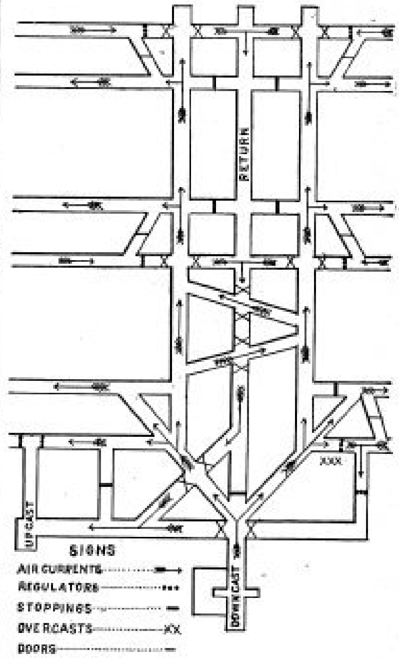
Yours, etc.,
R. M. S.

Wyoming, Pa., November 9th.

Ventilation.

Editor Colliery Engineer:

SIR:—In answer to Joseph Cain, in your June issue, I submit the enclosed plan, which will show the overcasts he speaks of and the method of ventilation I referred to. By close study of the sketch he will understand the reasons for placing the overcasts where they are, also that there is no door in any of the main entries. Again, that all full cars from the right hand entry will come



through the first cross-cut and from that point the left hand entry will be the full track and the empty cars for the left hand entry will pass through the second cross-cut. An equilibrium is maintained in both intake currents when drivers are actively engaged in hauling coal. There are also other reasons which might be mentioned, why they are placed there in case of accidents, etc., which the readers of THE COLLIERY ENGINEER can study out from the plan if they wish.

Yours, etc.,
P. HORNEL.

Moon Run, Pa., Nov. 5th.

Ventilation and Mechanics.

Editor Colliery Engineer:

SIR:—Would some of your able correspondents kindly answer the following questions in the next issue of your journal:

(1.) Assuming that a fan making 80 revolutions per minute produces 40,000 cubic feet of air, how much more would it produce if the revolutions were doubled?

(2.) How would you practically test the safety-catches of a cage in a shaft?

Yours, etc.
J. M.

Morrisdale Mines, Pa., November 20th.

Correction.

Editor Colliery Engineer:

SIR:—Will you allow me to offer a correction to "L. P. H.'s" reply to my questions which appeared in your November issue:

He has misplaced the decimal point in his first proposition and in carrying it out thus makes the entire answer wrong. It should be self-evident that placing a brattice in the shaft would not reduce the volume from 64,000 cu. ft. in the 8′ × 16′ shaft to 17,484·8 in the two 8′ × 8′ shafts.

The answer should be as follows, using the formula $p = \frac{k s v^2}{a}$: substituting values we have

$$p = \frac{\overset{k}{\cdot 0000000217} \times \overset{s}{24{,}000} \times \overset{v^2}{250{,}000}}{128} = \frac{129 \cdot 2}{128} = 1 \cdot 01,$$

instead of 0·101326.

Then

$$q = \sqrt{\frac{p\,a}{k\,s}} \times a, \text{ and substituting the values}$$

$$\frac{1 \cdot 01 \times 64}{\cdot 0000000217 \times 16{,}000} = \frac{64 \cdot 64}{\cdot 0003472} = 183237,$$

the square root of which will be the velocity, or

$$\sqrt{183237} = 428.$$

And

$428 \times 64 = 27{,}392 \times 2 = 54{,}784$, or a difference of 9,216 cu. ft. lost by adding the brattice.

The formula used by "L. P. H." is correct, but by misplacing the decimal point in the first operation and following out the error it makes the entire operation wrong.

Yours, etc.,
S. U. P.

Lawsonham, Pa., Nov. 10th.

Answers to Miscellaneous Questions.

Editor Colliery Engineer :

SIR:—I wish to submit the following in reply to questions 1, 2, and 3, asked by "S. W.", in your November issue:

(1.) When the air course is contracted the water-gauge is raised, since "drag" is increased; and when air course is enlarged, the water-gauge is lowered as "drag" is lessened.

(2.) Density is increased and diminished by fans—increased when fan is acting as a force, or blower, and diminished when an exhaust.

(3.) The volume varies as the square root of the depth, hence we have the following proportion

$60{,}000 : 70{,}000 :: \sqrt{400} : \sqrt{(x)}$, or $60{,}000 : 70{,}000 :: 20 : 23 \cdot 3$, the square of which is 542·89 the required depth, or 400 + 142·89.

Proof

$$\sqrt{400} : \sqrt{542 \cdot 89} :: 60{,}000 : x,$$

solving

$$\sqrt{400} : \sqrt{542 \cdot 89} : 60{,}000 : 69{,}100.$$

The difference is caused by not carrying out the decimal in the first proportion. By making the root 23·4 gives a volume of 70,200.

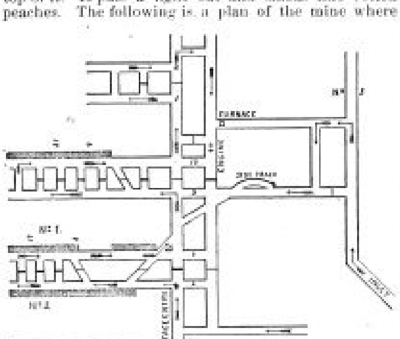
Yours, etc.,
S. U. P.

Lawsonham Pa., Nov. 10th.

A Peculiar Mine Gas.

Editor Colliery Engineer :

SIR:—I wish some of your able correspondents would enlighten me as to the possible name and composition of a gas that would come with a large fall and stay on top of it. It puts a light out and smells like rotten peaches. The following is a plan of the mine where



the gas was noticed, all of the workings being to the rise, with no accumulation of black damp. There is a natural gas pipe line nearly over head on the surface.

No. 1 in the sketch shows where rooms caved in and the gas accumulated. At No. 2 the elevation is about 20 feet from face entry, and at No. 3 the coal is worked out and the space filled with some kind of gas that will put the light out and of a peculiar odor.

Yours, etc.,
JOHN A. CARROLL.

Coal Center, Pa., November 16th.

Fans in Mining.

Editor Colliery Engineer :

SIR:—Please insert the following questions in your journal for solution by some of your correspondents;

(1.) The fan on a certain mine has an equivalent orifice of 37·81 square feet, the mine's equivalent orifice is 19 square feet; the size of the fan is 12 ft., making 90 revolutions per minute. What is the fan's efficiency?

(2.) What size fan giving an efficiency of 50% would you apply to the ventilation of a mine 500' deep, the quantity of air required being 40,000 cu. ft. per minute and the equivalent orifice of the mine being 20 sq. ft.?

Yours, etc.,
E. R.

Hopwood, Pa., Oct. 29th.

Mechanics.

Editor Colliery Engineer :

SIR:—I submit the following in answer to the fourth question asked by "S. W.," of Irondale, Ohio, in your November issue:

There is a cistern 20' square and 10' deep placed on the top of a tower 60' high, what power is required to fill this cistern in 30 minutes; and what will be the diameter of pump, when the length of stroke is 2', and making 40 strokes per minute?

First

$$20 \times 20 \times 10 \times 6\tfrac{1}{4} = 25{,}000 \text{ imperial gallons.}$$
$$25{,}000 \div 30 = 833 +$$

gallons per minute to be elevated.

The length of stroke is given at 2' and number of strokes at 40, which give a piston speed of 80' per minute in a double-acting force pump, therefore,

$$\frac{833}{80 \times 6\tfrac{1}{4}} = 1 \cdot 666,$$

perhaps the cylinder, through leakage, etc., will lose 10%, then we have

$$\frac{1 \cdot 666 \times 100}{90} = 1 \cdot 851 +, \times 144 = 266 \cdot 544 \text{ inches.}$$

And

$$\sqrt{\frac{266 \cdot 544}{\cdot 7854}} = 18 \cdot 4$$

or, say, 19" as diameter of water cylinder.

The final head which the pump will have to deliver against will be height of trestle 60' + height of tank 10' = 70';

$$70 \times \cdot 434 \times 266 \cdot 544 = 8097 \cdot 60 \text{ lbs.}$$

pressure required to elevate water into tank.

If we assume the effective steam pressure at 60 lbs. per sq. in. (which can reasonably be expected under these circumstances because boiler would very likely be placed close to pump) and divide 8097·60 by it we have 135" area of steam cylinder. Making same allowance for leakage, etc., as in water cylinder, we have

$$\frac{135 \times 100}{90} = 150,$$

and

$$\sqrt{\frac{150}{\cdot 7854}} = 14''$$

nearly as diameter of steam cylinder; and

$$\frac{14^2 \times \cdot 7854 \times 80 \times 60}{33{,}000} = 22 \cdot 4 \text{ H. P.}$$

We have found that we will require a 19" water cylinder, but it is just as plain that to use a 19" discharge column would be out of the question. If the water only moves at 80' per minute in the water cylinder we will have to give it a greater velocity in pipes. This will increase the friction and decrease the efficiency of the pump, but I think the allowance of 10% will also cover this defect as the length of discharge column is short.

It might be said in passing that most pump builders, in estimating on ability of pumps, generally make the margin between 25% and 50%; and some make an extra 10% allowance on steam cylinder over water cylinder.

Pump builders adopt different speeds for water in pipes varying from 100' to 400' per minute when determining the size of discharge and suction pipes to be used for a given size of water cylinder of pump. We will take the average and assume a speed of 200' per minute, then

$$\frac{833 +}{200 \times 6\tfrac{1}{4}} = 0 \cdot 66 \times 144 = 95 \cdot 04,$$

and

$$\sqrt{\frac{95}{\cdot 7854}} = 11''$$

as diameter of discharge column.

If we assume a water speed in pipes at 300' per minute this same rule will give us 9" + as diameter of discharge pipe; again, if we assume a speed of 400' this rule gives us 7·8" as the diameter of discharge pipes. Suction pipes to suit these sizes should be about 2" greater in diameter.

On page 37 of "Knowles' Revised Catalogue for 1885," at the foot of the page, the dimensions of a pump are given as follows:

Steam cylinder 18"; water cylinder 14"; stroke 24"; gallons per stroke 16; gallons per minute 640; suction 10", and discharge 8".

Now, if we reverse the formula given for finding diameter of pipe we will get the speed of water in pipe in full per minute.

$$8^2 \times \cdot 7854 \div 144 = \cdot 35,$$

and

$$640 \div \cdot 35 = 1830 \div 6 \cdot 25 = 293 \text{ feet.}$$

There are 16 gallons per stroke, or

$$640 \div 16 = 40 \text{ strokes} \times 2' = 80'$$

piston speed, while the speed of water in pipe is 293 feet. If this example is good practice, then we would be safe in adopting a speed of 300 feet per minute and using the pipe 9 inches in diameter to do the work for "S. W.'s" question.

I have not carried the figures carefully into decimal places considering that the principle and practical results were wanted.

This increased speed of water in pipes over that in cylinder is the answer to Samuel Lewis' question in July issue, viz., what is the reason for reducing the column pipe of air engine, etc.

Yours, etc.,
H. L. D. W.

Cincinnati, Ohio, November 13th.

Ventilation.

Editor Colliery Engineer :

SIR:—I submit the following solution to question by "A. B.," of Hanna City, Ill.:

An airway 8' × 8' × 1000' is passing 40,000 cu. ft. of air. What diameter should a circular airway 1200' long be to pass one-half the quantity, the pressure remaining the same?

$$D = \frac{\sqrt[5]{\dfrac{64^2 \times 3 \cdot 1416 \times 1200 \times 20{,}000^2}{4 \times 8 \times 1000 \times 40{,}000^2}}}{\sqrt[5]{\cdot 7854}} = 7' \text{ nearly}$$

Yours, etc.,
W.

Hornsby, Ill, Nov. 14th.

Ventilation.

Editor Colliery Engineer :

SIR:—On page 9, of the August issue of THE COLLIERY ENGINEER, "S. U. P.," of Red Bank, Pa., in answering the question by "Inquisitive," viz., "Using Atkinson's co-efficient, what would the w. g. be in a mine having 3 circular shafts, two downcast, 11' and 10' in diameter respectively, and one upcast 800' deep, 8' in diameter, the quantity being 100,000 cubic feet per minute";—uses the formula

$$\sqrt{\frac{a}{s}} \times a.$$

Now, I would like to know how he gets the cubic feet (·49502) for the 10' shaft, and ·57175 for the 11' shaft, the figures being the relative quantities for each shaft. If "S. U. P." will work out the above formula as plainly as possible showing how he obtains the above figures he will help a student.

Yours, etc.,
MINER.

Middleport, Ohio, November 21st.

Pipe and Boiler Covering.

The importance of fully protecting the surfaces of steam pipes, boilers, heaters, and other steam using, conveying, and generating apparatus in and about mines is a subject that has not attracted as much attention in the past as it deserved. This state of affairs, we are glad to state, is changing, and all progressive colliery managers recognize the necessity for pipe and boiler covering wherever steam is used, whether in large or small quantities.

There is quite a variety of pipe and boiler coverings on the market, but many are deficient in the great essential of durability. The Philip Carey Mfg. Co., of Cincinnati, Ohio, whose card appears on page z of this issue, have succeeded in producing a covering that meets all requirements.

They claim that their Standard Asbestos Removable Pipe Covering is the highest grade of steam pipe covering on the market, and that it is unequalled in durability, non-conducting qualities, neat appearance, and all other essential features. It lasts as long as the pipe will, and this quality of durability makes it especially cheap. It is made in sectional form, and for every size of pipe from one-half inch to eighteen inches, and can be readily applied or removed by any one, without the use of special tools or previous experience. As a good pipe covering effects a saving in fuel, equalling in a few months the cost of the covering, this saving becomes in a short time a clear profit if this covering which needs no renewal is used.

In addition to the saving in fuel, the covering of steam pipes is the most efficient and economical method of securing dry steam at the cylinders of pumps, hoisting and other engines, for as a rule pumps and other types of engines are located some distance from the boilers, the loss of steam from condensation, and the loss of power in the engine by inability to get dry steam to it is very large. The only way in which these losses can be overcome is by the use of a first-class steam pipe covering, and by covering the boilers, domes, heaters, breechings, etc., with Carey's Standard Asbestos Felting. The manufacturers (The Philip Carey Manufacturing Company, Cincinnati, Ohio,) will cheerfully furnish samples, and quote special prices to all colliery owners or managers.

Mr. John Hale, Inside Foreman of the D. L. & W. R. R. Co.'s Bellevue Mine, this city, states that the production of coal at the Bellevue Mine during the month of October, was the largest of any month since the mine was opened in 1854. The shipments were nearly 32,000 tons, mined and prepared in 27 days. There were no serious accidents of any kind.

Mr. David J. Lloyd, Vice-President of the Edinburg Coal Mining Company of Edinburg, Ill., writes us that he is at present putting in air compressor and coal cutting machines of the Ingersoll-Sergeant type at his colliery.

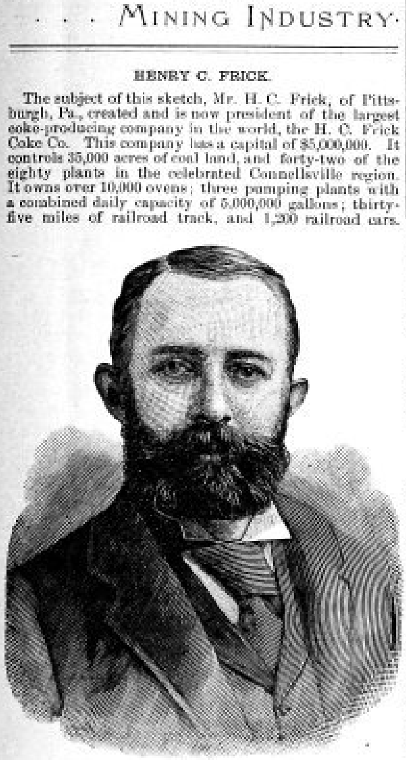
PERSONALS

Mr. Joseph G. S. Hudson, of the International Coal Company, Limited, of Sydney, Cape Breton, Nova Scotia, has been chosen President of the newly-organized association for the advancement and discussion of all matters relating to mines and mining, formed by the colliery officials of Cape Breton County.

Familiar Faces in the Mining Industry

HENRY C. FRICK.

The subject of this sketch, Mr. H. C. Frick, of Pittsburgh, Pa., created and is now president of the largest coke-producing company in the world, the H. C. Frick Coke Co. This company has a capital of $5,000,000. It controls 35,000 acres of coal land, and forty-two of the eighty plants in the celebrated Connellsville region. It owns over 10,000 ovens; three pumping plants with a combined daily capacity of 5,000,000 gallons; thirty-five miles of railroad track, and 1,200 railroad cars.



HENRY C. FRICK.

For the equipment of their plants, they have twenty-three locomotives, seventy-two pairs of stationary engines, 172 steam boilers, and 816 horses and mules. Mr. Frick is also the leading spirit in the Southwest Coal and Coke Co., and is chairman of the combined Carnegie Associations, which give employment in round numbers to 20,000 men. There are few men in America that equal him in executive ability. He was born in the coke region, just forty years ago, and was among the first to recognize the value and importance of the Connellsville coal. He had barely entered his majority when he engaged in the coke business, and from that time has been unflagging in organizing capital, providing transportation facilities, and consolidating and systematizing the business into the superb condition it now is.

Mr. Frick commenced in the coke business in 1871, forming with Messrs. A. O. Tintsman and Joseph Rist, the firm of Frick & Co. They started with 300 acres of land and 50 ovens, known as the "Frick Works." In 1872 they added 50 ovens to the Frick plant, and built the Henry Clay Works of 100 ovens on the Youghiogheny River, near Broad Ford. In 1876 Mr. Frick bought out Messrs. Tintsman and Rist and continued alone. In 1877, at the time of the greatest depression in the iron business, during the long dull period between 1873 and 1879, he leased the Valley Coke Works from Wilson, Boyle, and Playford, which were then idle, and put them in charge of Mr. Thomas Lynch, now General Manager of the H. C. Frick Coke Co. Notwithstanding the dull times and low prices, the works were started and operated every working day during the whole year except Christmas. In the Fall of the same year, Mr. E. M. Ferguson, (who owned a plant on the Fayette County Branch of the Pittsburgh & Connellsville R. R. consisting of seventy ovens) was taken into partnership by Mr. Frick, and they operated under the firm name of H. C. Frick & Co., having at this time the two works at Broad Ford of 100 ovens each, the Valley Works, under lease, of 102 ovens, and the Ferguson Works of 70 ovens. In the Spring of 1878, they leased the Anchor Works, which were at that time idle and in the hands of an assignee, and later leased the Mullen Works, near Mount Pleasant. In the same year, Mr. Walton Ferguson, a brother of Mr. E. M. Ferguson, was admitted into the firm. This partnership was continued until 1882, and during the four years of its existence they continued to buy coal lands and build coke ovens, until the firm owned 1,026 ovens, and 3,000 acres of coal land.

In the meantime, Mr. Frick organized the Morewood Coke Co., Ltd., and built the Morewood Works of 470 ovens, at that time the largest works in the region. In January, 1882, Carnegie Bros. & Co. Ltd., were admitted into the firm of H. C. Frick & Co., and in the following April the corporation known as The H. C. Frick Coke Co., was incorporated with a capital of $2,000,000 and Mr. Frick was made President. In 1883 the capital was increased to $3,000,000 and in 1889 it was further increased to $5,000,000.

During all these years the work of buying coal lands and building ovens was vigorously prosecuted, until now this corporation owns the magnificent property described in a previous paragraph.

The collieries are all supplied with the best obtainable machinery and appliances, and each plant of the H. C. Frick Coke Company is a model one. Mechanical devices are used in every place where machinery can advantageously supersede man or animal power, and the inside haulage arrangements are particularly effective. There is no coal company in America that so extensively uses the most advanced systems of rope haulage.

Mr. Frick is always ready to take advantage of all machinery, appliances, or methods, that will conduce to the health and safety of his employes or the more economical production of coal and coke. Notwithstanding the great labor connected with the business management of the various industries of which he is the executive head, he is constantly in communication with his efficient lieutenant, Mr. Lynch, for whose technical ability he justly has a very high regard. Every plant purchased by the Frick Company has been materially improved after the purchase, and in every case the management exceeds the requirements of the mine laws, and requires that subordinate officials must either have every portion of each colliery in the safest possible condition, or cease work there until it is put in such condition.

Mr. Frick's success in organizing capital and building up the great corporation that bears his name is abundant evidence of his business capacity and managerial skill. He is a very pleasant gentleman socially, and is highly esteemed by men of all classes who have been thrown in personal contact with him.

WILLIAM CONNELL.

Mr. William Connell is an excellent type of the American self-made business man. He was born in Cape Breton, Nova Scotia, on September 10, 1827. His father being a native of Scotland, and his mother a Nova Scotian of Irish and American descent. Though his parents were worthy people, he had few educational advantages, as early in life it became necessary for him to assist in the support of the family. However, he made good use of his meagre opportunities and acquired the rudiments of an education.

In 1844 his parents settled in Luzerne County, Pa., and he found employment as a driver boy in the mines. He worked in various capacities at several collieries in the Wyoming and Schuylkill regions until 1856, when his intelligence, industry and energy secured him a position as superintendent of the colliery owned by the Susquehanna & Wyoming Valley Railroad and Coal Company, at Scranton.

In 1870 the charter of this corporation expired, and Mr. Connell, who had judiciously managed the colliery for fourteen years, purchased the property. Twenty-one years have passed and the business has grown to large proportions, and although others are interested in the firm of William Connell & Co., he owns the controlling interest and is the head and front of the enterprise. The property originally consisted of a single colliery, but for some years past the firm has operated two. Mr. Connell as President and principal owner of the Connell Coal Co., also operates a third colliery at Duryea Luzerne County, Pa. The total salable output

WILLIAM CONNELL.

of these three collieries has up to date exceeded 7,000,000 tons.

Mr. Connell is largely interested in the banking business. He is President of the Third National Bank of Scranton, Pa., and a director of the Scranton Safe Deposit and Trust Company. His enterprise, liberality, and business sagacity have been important factors in the remarkable growth of Scranton, and he is interested in almost every important manufacturing enterprise in the city. He is a director in the Dickson Manufacturing Company, President of the Hunt & Connell Company Limited; President of the Scranton Button Manufacturing Company, Limited; President of the Lackawanna Knitting Mills Company, President of the Weston Mill Company, and Vice-President of the Scranton Forging Company. He is also a large stockholder and director in the Scranton Packing Company, the Lackawanna Lumber Company, and many other business enterprises. He is Treasurer of the Lehigh Salt Mining Company, a new corporation developing an extensive salt property at Le Roy, N. Y. His capital and business knowledge have aided many undertakings and his work in the Scranton Board of Trade has been influential and effective. Thousands of dollars have quietly passed from him to the aid of charitable causes and for every worthy public purpose he may be relied upon for assistance.

He is a man of independent character. He has, therefore, some enemies as all men of force have. His nature is kindly, but he will not swerve from a purpose that he thinks is right. When interested in any undertaking whether it be of a business, religious, or social character, his whole heart is enlisted.

Few men have his capacity for work and probably fewer still the need he experiences for constant activity. When not engaged in business matters he is a great reader of the best works of standard authors. His library, which is large, is a remarkably well selected one.

He is a friend of popular education and has contributed liberally to the Free Library about to be established in the handsome Albright Memorial building now nearly completed in Scranton. His aid and counsel have been frequently sought by various educational institutions and he is a Trustee of the Syracuse University, the Wesleyan University, and the Drew Theological Seminary.

He was President of the commission to revise the Anthracite Mine Laws authorized by the last session of the Legislature, and his name is mentioned in connection with the nomination for congress from the district of which the City of Scranton forms a part.

William Connell is a business man in whom all interested in Anthracite coal mining, either as capitalists, superintendents, or workingmen justly feel proud. He is also one of the citizens who by their liberality and progressiveness are making Scranton a large and important city, and who, long before the coal resources of this neighborhood are seriously impaired will have so advanced its manufacturing interests that its property and future growth will be assured independent of such adventitious circumstances as the gradual curtailments of coal shipments from the neighborhood.

A Great Improvement in Electric Motors.

A most severe and very interesting test was made a few days ago by Wm. Sellers & Co., of Philadelphia, upon a motor operated under the new principle invented by Mr. H. Ward Leonard. The motor used was a 10-H. P. Standard Shunt-wound Sprague Motor; the motor's normal speed was 1500 revolutions a minute. The motor was belted to a counter-shaft, and upon the counter-shaft was placed a brake, and in addition to the brake there was placed on the counter-shaft a large fly-wheel such as is used upon punching machines, the purpose of the fly-weel being to duplicate the inertia and momentum met with in practice in a great many kinds of work.

The motor was made to operate in either direction at any rate of speed desired, and it was found possible to run the motor perfectly and regularly under the full brake load, at 15 revolutions per minute, that is, one per cent. of its full speed. While operating at full speed in one direction the motor could be instantly reversed, the reversal being perfectly gradual and entirely without spark or troublesome feature of any kind.

In order to get the most marked effect in overcoming the momentum of the fly-wheel the brake was taken off, and when the fly-wheel was running at its full speed of 300 revolutions a minute the motor was reversed instantly. In thirteen seconds the motor had brought the fly-wheel to rest, and in thirteen seconds more had it running at full speed in the opposite direction, the entire operation being effected with the greatest smoothness and without any spark whatever. The performance of the motor was extremely satisfactory to all concerned, and showed its perfect adaptability to any class of work met in practice.

We learn from H. Ward Leonard & Co., that among the concerns of importance who have recently retained them as consulting electrical engineers are Wm. Sellers & Co., the well-known machine tool builders, of Philadelphia, Otis Brothers & Co., of elevator frame, and the Ingersoll-Sergeant Drill Co.

No large manufacturing or mining concern whose product involves the use of power can afford to neglect the rapid progress of electrical motor applications.

H. Ward Leonard & Co. charge a definite sum per year for their services as consulting engineers, and the manufacturing concerns seem to like this feature of definiteness rather than a percentage charge or a retainer and individual charge for individual service.

Doing a Large Business.

The firm of J. A. Parker, at Terre Haute, Ind., always being on the alert for something, report recent shipments of Revolving Coal Screens to the Corona Coal and Coke Co., at Corona, Alabama; P. Erlich & Co., Seeleyville, Ind.; St. Louis and Big Muddy Coal Co., Carterville, Ill.; Coal Bluff Mining Co., at their Pratt Mine; Pittsburgh Coal & Coke Co., Old Pittsburgh, Ind. Mining Cars to the Hazel Creek Coal Co., Clinton, Ind.; Thompson Hill Coal Company, Clinton Ind.; Firn Hill Coal Company, Clinton, Ind.; Keelleyville Coal Co., Danville, Ill.; Glendale Coal Co., Danville, Ill.; Eureka Block Coal Co., Carbon, Ind., and have orders on hand for screens for the Great Kanawha Coal Co., Mount Vernon, West Va. Elevators and Conveyors for the Hazel Creek Coal Co., Clinton, Ind. Mining Cars for The New Kentucky Coal Co., Clinton, Ind., and the Norton Creek Coal Co., Clinton, Ind.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED 1881. INCORPORATED 1889.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
ALEX. DICK, MINING ENGINEER, ASSISTANT EDITOR.
THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed
THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Scranton, Pa.

Cable Address—"Retsof, Scranton."

Vol. XII. December, 1891. No. 5.

STATISTICS OF COAL MINING IN PENNSYLVANIA IN 1890.

WE have received the "Reports of the Inspectors of Coal Mines of Pennsylvania," for 1890. These reports as they come from the inspectors are, as a rule, full of valuable information, though a uniform system of tabulation would be a great improvement. There has been an attempt on the part of the Department of Internal Affairs to tabulate the statistics from the whole State. It has been only partially done, however, and several important errors detract greatly from the value of the tables published. It is to be hoped that hereafter this work will be done as it should be, and that the reports will be published in such season that they may not so much resemble a last year's almanac in point of usefulness.

The aggregate production of coal in Pennsylvania in 1890, including that shipped from collieries, made into coke, used at the operations, and sold for local consumption, was 80,830,876 tons, of which 40,090,355 tons were Anthracite and 40,740,521 Bituminous. These figures show an increase of 6,715,467 tons in the Bituminous output and 1,116,406 in the Anthracite, a total increase of 7,831,873 tons over 1889. There were 368 collieries in operation in the Anthracite districts and 631 in the Bituminous, making a total of 999 in the State. There were also reported 22,483 coke ovens with a total output of 8,311,941 tons of coke. The number of persons engaged in coal mining was 183,624, of whom 116,232 were employed in the Anthracite mines, and 67,392 in the Bituminous. The average number of tons mined for each employe was 344·8 in the Anthracite, an increase of 19 tons over 1889, and 604·5 in the Bituminous, an increase of 45·5 tons. The average in all the mines in the State was 440·2 tons. The aggregate number of kegs of powder (25 lbs. each) used in the State was 1,116,930. Of these 1,030,710 were used in the Anthracite districts, or one keg for 38·89 tons, and 86,220 in the Bituminous districts, or one keg for 472·5 tons.

The number of horses and mules in the Anthracite districts was 12,892, and in the Bituminous 5,243. There were 235 mine locomotives in use, not counting those in the Fifth Anthracite District and the Sixth Bituminous, which are not reported.

In the Anthracite regions the greatest average number of days worked was 221·5 in the Fourth, or Hazleton District. The smallest was 166·1 in the Sixth, or Ashland District. The average for all the Anthracite Districts was 190·4 days, an increase of 22 days over 1889. In the Bituminous regions the greatest average number of days worked was 242 in the Fifth, which is the great coke producing district. The smallest average number was 181 days in the Second District. The average for all the Bituminous districts was 211·9 days an increase of 11·9 days over 1889.

FATAL AND NON-FATAL CASUALTIES.

The whole number of fatal casualties in the State was 524, of which 378 were in the Anthracite districts and 146 in the Bituminous.

This is in the ratio of 3·25 lives lost in the Anthracite and 2·166 in the Bituminous for every 1,000 employes. In 1889 the ratio of fatal accidents in the Anthracite regions was 3·218 per 1,000 employes.

This year there were in the Third Anthracite District five accidents from fire-damp in which 51 persons were killed. These arose from causes which are uncommon, and not counting these the ratio in the Anthracite districts was only 2·72 lives lost per 1,000, a record which has been bettered only once, and that was in 1886 when the ratio was 2·707 per 1,000. The number of employes per fatal casualty and the ratio of deaths per 1,000 were as follows:

ANTHRACITE.

No. of Dist.	Name of Inspector.	No. of Fatal Casualties.	No. of Employes Per Fatal Casualty.	Ratio of Fatal Casualties Per 1,000 Employes.
1	Patrick Blewitt	64	370	2·695
2	H. McDonald	40	394	2·538
3	G. M. Williams	100	189	5·277
4	John M. Lewis	52	277	3·605
5	William Stein	66	292	3·421
6	William McMurtrie	39	468	2·136
7	Samuel Gay	17	342	2·92
	Total Fatal Casualties	378	Av. 307	3·252

BITUMINOUS.

No. of Dist.	Name of Inspector.	No. of Fatal Casualties.	No. of Employes Per Fatal Casualty.	Ratio of Fatal Casualties Per 1,000 Employes.
1	Henry Louttit	15	442	2·261
2	Wm. Jenkins	20	588	1·7
3	Thomas K. Adams	5	1088	·918
4	James N. Patterson	8	804	1·242
5	Wm. Duncan	50	194	5·146
6	J. T. Evans	15	655	1·526
7	James Blick	9	928	1·077
8	Austin King	24	384	2·602
	Total Fatal Casualties	146	Av. 461	2·166

The number of fatal casualties was again, as last year, proportionally lower in the Sixth than in any other Anthracite district, being in the ratio of 2·136 per 1,000 employes, and it was highest in the Third, which showed 5·277 deaths per 1,000 employes. In the Third, Fourth, and Seventh Bituminous Districts the proportion of fatal accidents to the number employed was very small, but the Fifth District shows a high ratio on account of the Hill Farm disaster, in which 31 lives were lost.

Last year the average number of employes per fatal accident in the Anthracite districts was 311, or a ratio of 3·218 deaths from accidents per 1,000 employes, and in the Bituminous 591, or 1·69 deaths per 1,000. This year it is one for every 307 employes in the Anthracite, or 3·252 per 1,000, and one for every 461 in the Bituminous, or 2·166 per 1,000.

The following table shows the causes of the fatal casualties and the ratio of deaths from the different causes per 1,000 employes:

ANTHRACITE.

	No.	Ratio of Deaths Per 1,000 Employes.
By Falls of Roof and Sides	132	1·135
By Mine Cars	69	·594
By Explosions of Gas	61	·524
By Falling Down Shafts	21	·18
By Explosions of Powder and Blasts	18	·154
By Machinery	11	·094
Miscellaneous	66	·567
Total	378	3·252

BITUMINOUS.

	No.	Ratio of Deaths Per 1,000 Employes.
By Falls of Roof and Sides	81	1·201
By Mine Cars	15	·222
By Explosions of Gas	31	·46
By Falling Down Shafts	2	·029
By Explosions of Powder and Blasts	4	·059
By Machinery	2	·029
Miscellaneous	11	·163
Total	146	2·166

By these accidents 275 wives were made widows and 823 children became orphans.

It will be noticed that the number of fatal accidents and their ratio per 1000 employes is one-third greater in the Anthracite than in the Bituminous districts. This is true of accidents from each of the causes specified with the exception of those from falls of roof and sides of which proportionately more occur in the Bituminous regions, the veins are thinner and each man mines a greater amount and area of coal than in the Anthracite, thus making a proportionately greater extent of working area and of roof to support, which account for the greater relative danger from falls of roof and sides. It is also true that as a rule, the roof is not as strong in the Bituminous as in Anthracite seams.

There were, however, a larger proportion of accidents from mine cars in the Anthracite than in the Bituminous mines. The Bituminous seams are usually flat, and the cars are hauled all the way in and out, while many Anthracite seams are on short pitches in which slants are worked where the empty cars are hauled in by mules and run out by gravity; from this cause many accidents arise.

Owing to the use of more machinery in the Anthracite districts, accidents from being caught by it were proportionately three times more frequent than in the Bituminous. The very large use of blasting materials in mining Anthracite coal also accounts for the fact that accidents from powder explosions are proportionately nearly three times more frequent, though it appears that powder is handled more safely in the Anthracite than in the Bituminous Mines, for while there was nearly 12 times as much powder used in the Anthracite Mines, the proportion of accidents from this cause was not three times greater.

The proportion of accidents from miscellaneous causes was also three times greater in the Anthracite than in the Bituminous mines. This may be partially accounted for by the fact that nearly all the Anthracite coal is mined from openings below water level and that as a rule the Anthracite operations are much more extensive and involve the use of much more machinery than the Bituminous operations do.

There were reported in the Anthracite districts 1007 non-fatal accidents, and in the Bituminous 381, making a total of 1388. In the Anthracite districts the ratio of non-fatal accidents to the number of employes was one in 115, and in the Bituminous, one in 177.

It is, however, unsafe to attempt to draw comparisons from these figures as in some districts only serious accidents are reported, while in others comparatively trivial ones are included.

The average production of coal per life lost in the Anthracite districts was 106,059 tons, against 101,231 tons in 1889, and in the Bituminous districts 279,044 tons against 330,547 tons in 1889, showing a comparative increase in danger in the Bituminous and a slight improvement in the Anthracite Mines. In the Bituminous districts the number of tons mined per life lost varies from 129,421 in the Fifth district to 508,036 in the Seventh, and in the Anthracite from 69,077 in the Third district to 161,197 in the Seventh.

There is much that may be done in the way of increasing the safety of the mines, both in the Bituminous and Anthracite districts of Pennsylvania. It is true since 1870 the production to life lost has increased 95·2% and that the production per life lost was 13·2% more in 1890 than it was in 1889. Yet it is also a fact that the proportion of fatal accidents to the number of employes in this country is greater than in many foreign countries in which more dangerous conditions exist. The best way to secure greater safety in American collieries is to advance the standard of education and intelligence among the superintendents, foremen, assistant foremen and fire bosses, and to establish more strict discipline in the working of the mines. This opinion we have heretofore frequently expressed in these columns and there is no doubt it is correct because there is no reason that can be assigned why accidents should be more frequent in American than in European collieries, except that the officials in charge of them are not as well educated as men occupying similar positions abroad, and that there is greater carelessness and recklessness on the part of the workmen.

AMBULANCE WORK.

THE Mine Laws of Pennsylvania require that proper ambulances and stretchers be provided at each mine to be used in case of accident. Such a provision is wise, but before the benefit of these appliances can be fully utilized it is necessary that instruction on first aid to the injured be given to some men at each colliery.

Doubtless an injured man can be more comfortably carried in an ambulance than by the old-time method of hustling him along rough roads in a springless cart half filled with straw or old sacking, but it is not in this that the first and greatest danger arises. Take the case of a broken leg; unless the limb is first carefully and comfortably placed in a rigid position between splints (even although the man is placed in a well appointed ambulance) what was originally a simple fracture may be aggravated into a compound or comminuted fracture, and the patient runs a risk of losing his leg altogether. Or in a case of a severed artery all the ambulances in the the world are of no use unless the immediate danger of bleeding to death is averted.

We wonder how many men in an average Pennsylvania colliery could be of use in such a case? As matters at present stand we are afraid that for the want of a few simple appliances and a knowledge of how to use them the man's life would be lost.

How do we stand in this matter, in comparison with other countries? In England the St. John Ambulance Association has extended its ramifications throughout the length and breadth of the land until there is not a colliery which cannot at least muster eight or ten men capable of attending to the injured. In the case of fractures they can set the limbs in an easy position; they can stop bleeding; they can aid in restoring the asphyxiated or apparently drowned, and indeed their valuable services in the cause of humanity are daily being recorded in the "case-books" of all colliery doctors. We have been told that the doctors in America would not approve of such a scheme. We refuse to believe it. A similar fallacy arose and was as speedily dispelled in England. If, by the intelligent attention of a fellow-workman, a collier can be made comfortable until medical aid arrives, surely the doctor would prefer it so, rather than to find on his arrival that owing to the blundering of well meaning but ignorant hands a fellow creature had lost his life. A doctor's mission is to save life, and anything which aids him in doing so will obtain his support.

It must be borne in mind that the first instruction of the St. John Association is, "Send for a doctor," and the second is, "Until he arrives, make the patient comfortable," and the ambulance student is not a *substitute* for the doctor, but is his *assistant*.

In June, 1890, General Lord Wolseley reviewed an army of over 20,000 ambulance men at Woolaton Park, Nottingham, and these were principally colliers. Many of them had never before marched in procession, and although they did not look quite as smart as soldiers, and perhaps had not enough music in their souls to enable them to keep step to the beat of the drums, as they marched past the saluting post they presented a living argument in favor of the system such as was never before seen.

All this has been accomplished at such a small cost that the wonder is that it was not done long ago. This is the method adopted in Britain. The aid of the colliery doctor is first obtained, and application is made to headquarters, in London, for the loan of a few illustrative charts and diagrams. Each man is provided with a small text book, and an Esmarch triangular bandage, at a total cost of about 25 cents. The class meets as often as convenient, and the doctor during the course delivers a series of five lectures, each of half an hour's duration, and by the aid of the text-book instruction is given in bandaging, fixing of splints, carriage of the injured, &c. As soon as the class is satisfied of its proficiency, an examining doctor arrives. The members are ranged up in line and put through an examination on the general structure of the human body, the functions of the blood, nerves, and muscles, and the means to be adopted in cases of poisoning, fits, &c. The class is then taken into the open air, men are stationed all over a field with tickets fixed to their bodies, stating the nature of their supposed injury, and on a given signal a squad of students runs to each man, fixes him up, and carries him into the improvised hospital where their work is inspected.

These classes of instruction are carried on for three successive years, and after three annual examinations have been passed, the student is awarded the bronze or silver medal of the Association. The doctor's time will not exceed eight hours in a year. The student can learn all by devoting two hours each week to the instruction given, and the cost per man will not exceed a dollar a year. And what is the result? Let any miner recall the accidents that have occurred in his own knowledge, and after he has gained a little ambulance skill, he will remember some case where a life, or at least a limb, might have been saved, if he had known then what he knows now.

If there is philanthropy amongst our coal operators there is no better opening for its display than in furthering such a cause. If the workmen are of the right grit they will see the advantages and claims for the Ambulance Association, and we venture to affirm that there will be no obstacle thrown in their way by the medical profession when the benefit so manifestly accrues to the doctor.

The St. John Ambulance Association in England, and The St. Andrew Ambulance Association in Scotland, are kindred societies of a purely philanthropic nature, sustained by voluntary contributions, and neither of them is in any way connected with any particular sect or religion, but they are in every respect national in their aims. To these Associations is due the credit of Field Ambulance work, such as was done on the battle-fields of the Franco-Prussian and subsequent European wars, and the good work which was then begun is now being extended to the field of mine labor, where accidents are of every day occurrence.

The philanthropic feeling which prompts the members of such benevolent institutions as the Women's Christian Temperance Union, the Young Men's Christian Associations, and other similar schemes, can have no nobler and no more needy field for work than in the formation of an American National Ambulance Association. It does not need a great capital; much can be accomplished with but little money, and the necessity of such an institution is of the first importance. More especially is this so in colliery districts, and we write this with the hope of inducing philanthropists and others in the great colliery centers to give this important and worthy matter their consideration.

ELECTRIC MINERS' LAMPS.

THAT the electric safety-lamp will eventually be a success is almost a certainty. But those persons, who, unfamiliar with the conditions existitg in mines, try to adapt the ordinary incandescent lamp in circuit to this purpose are on the wrong track. Such a plan will never be successful, for reasons that are too obvious to our readers, to require enumeration at this time.

The ideal electric safety-lamp must be self contained, light in weight, simple in construction durable, and not too expensive.

Except at the bottoms of shafts or slopes, the main gangways or headings do not require much light, as they are chiefly employed for passageways for the trips of mine cars, and their transportation can be effected in semi or almost total darkness. Where the light is most required is where the miner is at work, and as he is constantly shifting his position, it is essential that he should have a portable light. From time to time attempts have been made to produce such a light as is actually needed, and with a view to ascertain how far such attempts have been successful, the French "Society of Mineral Industry" some time ago appointed a committee consisting of Messrs. Fevre, mining engineer, of Place, manager of the Rochebelle mines, Bessard, manager of the Cessons mines, and Lange, engineer of the Rochebelle mines. The trials were conducted at the Rochebelle mines with four types of secondary battery lamps—the Pollak, Edison, Breguet, and Stella. The Pollak lamp is a two-cell accumulator lamp, weighing 4·18 lbs., and it gives one candle power for nine hours before requiring recharging. The Edison lamp has three cells and weighs 24·2 lbs. It yields about two and a half candle power for ten hours, which is more than is actually required, and owing to its great weight it requires alteration before it can be adopted in mines. The Breguet lamp is a three cell lamp, weighs 6·38 lbs., and gives one candle power for eighteen to twenty hours. The Stella lamp, in the opinion of the committee, is the best adapted for mining work. It weighs but 3·08 lbs., and its duration of light is normally twelve hours. No faults as far as the connections were concerned were detected during the month it was under test.

As a result of the tests and comparisons made, the committee regard the Breguet and Stella lamps as those nearest adapted for successful use in the mines. The former, however, as at present constructed should not be put in the hands of the workmen, as it is not easily handled, there is too much exterior copper, the connections are not sufficiently insulated, and the salts formed entail great expense and trouble in maintenance owing to their excessively corrosive action. Nevertheless, the lamp shows a marked progress, and in spite of its excessive weight, the results as regards the amount of light given, and its duration were remarkable, and the faults pointed out can undoubtedly be remedied.

Mr. Petit, in discussing the report, stated that it would have been interesting to know the results obtained had the lamps been tested in a fiery locality. Such tests, however, would be difficult and dangerous, if attempted under circumstances which approach near to what would obtain in practice, therefore experience alone can demonstrate this matter. A good miner's lamp must be of simple and solid construction, as light as possible, and easy to maintain and recharge. It should yield a constant light of one or one and a half candle power for not less than eight hours, and it should be cheap.

The question of expense is closely related to the life of the plates, and the tests were not carried on for a sufficient length of time to furnish absolutely exact data, but approximate figures can be arrived at by calculation. Plates of old lamps, fed by accumulators have been submitted to M. Le Chatelier, engineer in chief of mines, who found them in good condition after two years of service. Therefore, it will not be out of the way to estimate the duration of the plates at one year on a basis of ten hours work per day for 300 days, or 3000 hours in all. These accumulators cost at most $5.50, and the expense of maintenance would therefore be about 2 cents per day of ten hours. The cost of a glow lamp is at most 90 cents, and it will last 800 hours, making this expense about one cent per day of ten hours. The cost per day of charging the accumulators is not much, as the dynamo employed can charge a very large number at one time, and at collieries where there is a dynamo used for lighting the surface at night, it can be utilized in the daytime for charging the accumulators. The average cost for light from portable electric lamps, will not, therefore, on this basis, exceed three or four cents per day of ten hours.

M. Petit, summarizes the advantages of substituting portable electric lamps for the safety-lamps at present in use as follows: The light obtained will be better, as the oil lamps only furnish from ½ to ¾ candle power; the miner will be able to work more easily and will accomplish more work; and the noxious products of combustion from the oil lamps will be dispensed with.

The results arrived at by these tests certainly show a marked advance in the construction of electric safety-lamps, and it is to be sincerely hoped that the day is not far distant when the present oil lamps will be used only for testing purposes, and a cheap, practical, and convenient incandescent lamp, will be used for working.

EDITORIAL NOTES.

IN the United States Circuit Court, held at Pittsburgh, Pa., on the 18th ult. Judge Rice filed an opinion in the case of W. P. Rend against the Venture Oil Co., refusing the injunction asked for, to stop the latter from drilling through certain coal land.

This decision is a very important one as it will affect many tracts of valuable coal land in Western Pennsylvania. Judge Reed bases his opinion on the erroneous idea that because the sinking of oil and gas wells in coal territory in the past has not resulted in accidents in the mines, that there is no danger for the future. This is one of the instances in which a lack of technical knowledge of coal mining, on the part of a Judge, has resulted in injury to the coal interests.

Because there have been no accidents in the past is no assurance that there will be none in the future. The sinking of oil and gas wells through coal is bound to cause more or less gas to flow through the hole in the coal seam, and even if there is a pillar left for the well, there is a likelihood of a leakage of gas through crevices in the rock or coal. This gas will find its way into the workings and accidents from this cause will not only be possible, but probable.

Again, even if the coal formation is solid enough to make it possible, by means of a large pillar, to protect the mines, the establishing of such an arbitrary pillar will be a serious matter. Pillars must always be so located as to not interfere with the profitable working of the mine, and the chances are that many wells will be so located as to require pillars in such localities as will materially interfere with the haulage roads, air courses, etc. But there is another side to the case. In many instances the mine owner has bought only the coal right, and other parties own the oil and gas rights, and, therefore, they are justly entitled to right of way to their property. But how and where this right of way shall be established is a question that requires careful consideration. It is not justice to give them right of way in such a manner as will jeopardize the property of the mine owner and the lives of his employes.

It is to be hoped that the mine owners of Western Pennsylvania, all of whom are more or less interested in this matter, will urge Col. Reed to carry the matter to a higher court than Judge Reed's and also assist him in the contest.

If the mine owners had been foresighted enough to secure the *mineral* right instead of only the *coal* right there would be no dispute, but, as things stand, the question is one that will require careful consideration, and the fact that oil or gas wells through coal territories jeopardize the lives of all inside employes as well as the property of the mine owner, should have great weight with the courts.

IT is announced that Gen. William Lilly, of Mauch Chunk, Pa., is a candidate for one of the Republican nominations for Congressman-at-Large from Pennsylvania—the State under the new census figures being entitled to two new congressmen. Gen. Lilly has been actively engaged in the coal business for many years, and is particularly fitted to represent the greatest industry of the state in the U. S. Congress. The coal interests have frequently suffered because the industry has not been represented in legislative bodies, and now that Gen. Lilly is a candidate, he should receive the unanimous support of all Republicans interested in coal mining. His Republicanism is of the stalwart order, and his time and money have for years been freely spent in the party's service, and if any one has earned honors at the hands of his party, he has.

THE Lehigh & Wilkes-Barre Coal Company's famous Nottingham Colliery has again broken the record. During the month of October, the colliery worked 24·15 days of ten hours each, and shipped 70,152·16 tons of coal, the average hoist per day being 1,318 mine cars.

The depth of hoist is 470 ft. and all the coal came from one opening. The engines are a pair of 22″ × 48″ first motion engines, with conical drums 4 ft. 1 in. long, 7 ft. diameter at small end, and 9 ft. diameter at large end.

This record has never been equalled in any coal field in the world, and Mr. E. H. Lawall, Supt. of the Wyoming Division is naturally very proud of it.

During the past year many important improvements and developments have been made at the company's collieries under Mr. Lawall's supervision, and their capacities have been greatly increased. The shipments from the Lehigh & Wilkes-Barre Collieries in the Wyoming division for the current year will approximate 1,900,000 tons, while the actual working time for the year will be something less than two hundred days. The prospects for the year 1892, are that these collieries will produce about 1,000,000 tons more than the output for 1891, and as the shipments are made over the Central Railroad of New Jersey, the railroad officials are making preparations to handle the coal by increasing their facilities in many directions.

GOVERNOR PATTISON, of Pennsylvania, has at last after an unnecessary delay of several months, issued commissions to Messrs. Edward Roderick and Patrick Blewitt as Inspectors of Mines for the First and Second Anthracite districts respectively. Mr. Roderick is a new man, but has a reputation as a careful, intelligent, and progressive miner. He is a nephew of ex-Inspector James Roderick, of Hazleton, who resigned the Inspectorship to accept the superintendency of the Linderman and Skeer Collieries in the Lehigh Region.

Mr. Blewitt is the former Inspector of the old First District, and will enter on his third consecutive term with this appointment. His new district is much smaller than the old, and he can therefore perform his duties even more efficiently than in the past.

WE have received a copy of the first number of *Cassier's Magazine*, an illustrated monthly engineering publication issued by the *Cassier Magazine Company*, Potter Building, New York, and welcome it to our list of exchanges. It is handsomely gotten up, and contains a number of valuable papers by such eminent writers as Prof. Thurston, of Sibley College, Cornell University; Prof. Alden, of Worcester Polytechnic School; Prof. John E. Sweet; C. H. J. Woodbury; Thomas Pray, Jr.; William Kent, M. E.; F. Merriam Wheeler, M. E., and others. Scattered through its pages are numerous short articles on engineering topics, and the whole make-up is not only interesting but pleasing to the eye as well, the illustrations being particularly good. As a magazine of general engineering literature it is a success.

AS an evidence of the encouragement THE COLLIERY ENGINEER SCHOOL OF MINES is meeting with from employers, we are permitted to state that a prominent superintendent will appoint as fire-boss the first intelligent miner gaining a School of Mines Diploma, and that his holding such diploma will be considered a strong point in his favor when promotions are made.

THE recent disaster at Nanticoke gave The United States Mine Signal Supply & Mfg. Co., an opportunity to rush into print in Philadelphia papers with misstatements calculated to influence the general public in favor of its machine, and thus make it easy to secure legislation to compel its use. This machine, or no other earthly contrivance, with the possible exception of the more improved types of safety-lamps, could have warned the Nanticoke miners of their danger in time to render escape possible. The communication of Joseph R. Wilson, in the Philadelphia *Inquirer* of the 10th ult., and the editorial entitled "Preventible Accidents" in the *Press* of the same date, were inspired by the same mind as is evidenced by the same statistical errors appearing in each. In both articles the number of collieries in Pennsylvania is given as over 8,000, when there are less than 1,000, and the number of inspectors is placed at seventeen, when there were but fifteen until a few days ago, when Governor Pattison commissioned Mr. Roderick, the sixteenth. Other statements contained in the articles are further from the facts, and are written to work up popular prejudice in favor of an impracticable contrivance. The object of such publications is, as we have stated before, to excite popular prejudice in favor of the apparatus. If the apparatus was practicable, it would not need legislation to introduce it. The operators and colliery managers will gladly purchase any contrivance that will give them even a reasonable amount of security from the explosions so destructive to life and property.

The Anthracite Trade.

The Anthracite trade is in fair condition. The enormous production of the past two months has been generally absorbed, but as stocks are fairly large, and purchasers are not so pressing in their demands, the sales agents, at their meeting in New York, on the 24th ult., decided that the production for December should be restricted to 3,250,000 tons.

The meeting was entirely harmonious and there was no evidence of the alleged strained relations between some of the companies out of which so much bear capital has been made in Wall Street. All of the companies were represented.

The prices were fixed at the same rate as in October, viz.: Broken, $3.75 per ton; egg, $4.15 per ton; stove, $4.40 per ton; and chestnut, $4.15 per ton; all f. o. b. The allotment of 3,250,000 tons is to include the shipments of the Pennsylvania and the New York, Ontario, & Western, which are estimated at 500,000 tons. The output in December, 1890, was 3,064,000 tons.

Navigation on the lakes is practically closed, and further shipments West must go by all rail routes.

The quantity of Anthracite shipped West this year was not much greater than that sent last year, but there were fair stocks of coal on hand at the Western distributing ports at the opening of this season. Some shippers, anticipating a severe winter, are of the opinion that the West will take a considerable quantity of coal in addition to that already forwarded, and that the heavy movement of grain East will provide the box-car facilities for return cargoes of Anthracite.

The prospects for the next four or five months, if we have a winter of ordinary severity, are brighter than they have been for several years.

There is no doubt that the Reading Co. will demand a larger percentage of the output next year, and that the Lehigh Valley, and Jersey Central, from whom the Reading takes the Coxe tonnage, will not yield tamely to a reduction of their percentages, as they can make up the Coxe loss from their own resources. This, however, is also true of the Reading's resources. The latter company has never worked its collieries to their full capacity, and has thousands of acres of undeveloped coal that could have been drawn on if the policy of restriction had not wisely been adopted, to keep the market in good shape. The arrangement of the quotas will, therefore, be watched with great interest by the trade, as there promises to be a lively time over it, but that an amicable arrangement will be finally arrived at is not doubted, for none of the companies are anxious for a coal war.

The Bituminous Trade.

The advent of cold weather has resulted in an increased demand, and the trade in general has largely increased. Not only are heavy shipments being made on old orders and contracts, but a large number of new orders have been booked. Owing to low water in the Ohio, there was a scarcity of coal in Cincinnati and lower river markets, dependent on river coal, during the greater portion of last month. There was not enough brought in by rail to supply the demand, and things began to have a serious aspect, until a storm on the 23d caused a rise, and the large fleets lying in the neighborhood of Pittsburgh were floated down. The prospects for the winter in the various Bituminous regions are good.

The Coke Trade.

The coke trade is in good shape, and the business being done is large. During the week ending Nov. 21st the Connellsville region made the heaviest shipments of any week in the year. Prices for Connellsville coke have not changed, and quotations are made as follows: Furnace coke, $1.90; foundry coke, $2.30; crushed coke, $2.65; all per ton of 2,000 lbs. f. o. b. at ovens.

LEGAL.

A contributor from Leechburg, Pa., writes us as follows: "Will you kindly state in your next issue, what the Bituminous Mine Law is in regard to the employment of a mining boss in two different and distinct mines at the same time. Can he lawfully hold both positions? This seems to be the judgment of our Mine Inspector, as we have a mine boss here who is holding the position of superintendent and mine boss of one mine working more than fifteen men, and mine boss of another mine, a half mile distant, owned and operated by another company, and employing some forty or fifty men." Section 5, of the Bituminous Mine Law, requires that the owner or agent of every coal mine shall employ a competent and practical inside overseer to be called mining boss, who shall be a citizen and an experienced coal miner, etc., etc. In no place does it prohibit the employment of one inside boss for two adjoining mines, provided he is able to fulfill the requirements of his position as set down in Section 5. That is, the law can not be construed, in its present shape, to make it unlawful, but it is evident that when the law was framed, such a state of affairs was not contemplated and that the idea was to have a mine boss for each mine. But, as the law does not so state, the Inspector can for no other judgment than the one stated by the contributor.

The *Moniteur Industrielle* recommends the use of a mixture of oil and graphite on all screws in machinery. It says it will effectually prevent them from becoming fixed, and protects them for years from rust, at the same time the mixture facilitates tightening up.

The Joseph Dixon Crucible Co., Jersey City, N. J., have for a number of years prepared graphite mixtures which have found great favor with machinists and steam fitters of this country.

Dixon's Graphite Pipe Joint mixture not only takes the place of red lead, but is infinitely better, while Dixon's Graphited oil is used where a thinner mixture is desired, and also for lubricating bearings. Graphite is the best natural lubricant known.

We have received from Messrs. H. Ward Leonard & Co., Electrical Engineers and Contractors, of 136 Liberty Street, New York, a neat little pamphlet containing testimonials and references regarding past work, indicating the experience and standing of Messrs. Leonard & Co. It will pay those of our readers using electric power, or contemplating its use, to write to Messrs. Leonard & Co., for a copy of this pamphlet.

Mr. John Hale, the inventor and manufacturer of Hale's patent surveying instrument, writes us under date of the 30th ult., that since he has advertised his instruments in THE COLLIERY ENGINEER, he has sold over 100 of them, and that they are now in use in every State and Territory of the Union, and in the British Provinces as well.

ANTHRACITE COAL STATISTICS.

Statement of Anthracite coal shipments, for month of Oct., 1891, compared with same period last year. Compiled from returns furnished by the Mine Operators, by John H. Jones, Chief of Bureau of Anthracite Coal Statistics.

	October. 1891.	October 1890.	Difference.		For Year 1891.	For Year 1890.	Difference.	
From Wyoming Region,	2,320,534·06	2,013,941·15	Inc.	306,592·11	17,340,626·07	15,165,666·02	Inc.	2,174,960·05
From Lehigh Region,	700,155·03	657,558·01	Inc.	42,597·02	5,214,512·14	5,284,876·10	Dec.	70,363·16
From Schuylkill Region,	1,475,845·03	1,221,217·05	Inc.	254,627·18	10,177,668·14	8,837,937·00	Inc.	1,339,731·14
Total	4,496,534·12	3,892,717·01	Inc.	603,817·11	32,732,807·15	29,288,479·12	Inc.	3,444,328·03

The stock of coal on hand at tide-water shipping points, October 31, 1891, was 635,446 tons; on September 30, 1891, 568,833 tons; increase, 66,613 tons.

THE NANTICOKE DISASTER.

On Sunday, the 8th ult., an explosion of gas at the Susquehanna Coal Co.'s No. 1 Shaft, at Nanticoke, Pa., resulted in the death of twelve men, and the serious injury of two others.

The accident was one that is hard to understand, as there are no witnesses alive to give a positive statement of the facts. The two survivors were working at a point that prevented their obtaining a knowledge of the causes, and to this fact they owe their lives.

From the meagre evidence before the Coroner's jury, and the deductions of Inspector Williams and the officials of the company, we are able to give the following explanation of the disaster:

The main shaft at No. 1 Colliery is sunk to the Lee or Red Ash seam, which corresponds to the Buck Mountain seam of the Lehigh and Schuylkill regions. From the workings in the Lee seam a tunnel 1,400 ft. long is driven South to the Ross seam, (corresponding to the Seven Foot seam of the Schuylkill region) overlying the Lee. About 110 yards East of the tunnel, in the Ross seam, an inside shaft was sunk to the Lee seam, and the coal was hoisted by an engine on the surface, the ropes passing from the drum through bore-holes to the head of the shaft.

In the Ross seam, parallel with and close to the East side of the tunnel, two openings were driven North to a point about 200 ft. South of the old workings in the Lee seam, with which they were connected by a rock plane.

The workings in the Ross seam were ventilated by a current of air from the Lee seam workings going up the rock plane, thence through one of these parallel roads to the Ross workings, returning to the upcast in the Lee seam by way of a brattice air course in the tunnel. From the bottom of the inside shaft an air course was driven in the Lee seam, on a general North course to the old workings in the same seam from No. 1 Shaft, the object being to make this the return air course instead of the bratticed way in the tunnel. Stoppings were erected when this hole was finished, and the ventilation was left in its original shape till Sunday, the 8th ult. To guard against accident it was determined to change the course of the air on Sunday, when there would be no men in the mine except those actually engaged in the work. Three of the most intelligent and experienced fire-bosses in the valley, Henry R. Jones, William Jonathan, and John Arnot were placed in charge of the work, and all the men employed were furnished with safety lamps of the Clanny or Davy type. All were specially instructed to use the utmost caution, and the possibility of accident due to carelessness was impressed upon them. The work of removing certain stoppings and erecting others, and clearing up the rubbish in the old workings in the Lee seam was started in the morning and progressed all right for several hours. The stoppings in the new air course were first removed and it was made a downcast, the air after flowing through it and the limited workings in the inside shaft level, ascending the shaft, and going out the Ross gangway to join the current entering by way of the rock plane and with it, flow out the bratticed airway in the tunnel, thence by way of old workings to the upcast. At about 4.00 P. M., when the work was approaching completion, the current flowing down the new Lee seam air course suddenly reversed and the explosion occurred. The two men who escaped with serious injuries were at work on the last stopping to be removed, between the foot of the rock plane and the mouth of the new air course, when they noticed their lamps fill with gas. They gave an alarm and started out toward the tunnel, and thus moved with the current carrying the gas. They are unable to state what the other twelve men did, or what direction they went. If any of them went towards the new air course they walked against the current which had unexpectedly reversed and flowed out the air course, and the flame of a lamp may have passed the gauze.

This reversion of the current in the new air course was one that no man, however experienced, would have expected, and is only to be accounted for on the following supposition:

The current flowing down the Lee seam air course was weakened by the work being done, assisted, no doubt, by a mine car of mortar standing in the air course, and by the gas accumulating in the downcast making the current lighter. This continued till the pressure on the current in the downcast combined with the friction therein, was less than the resistance offered by the return air course to the fan via the tunnel, and the air flowing up the rock plane and down the Ross air course, took the shorter and easier route out via the inside shaft and Lee seam aircourse, and swept a cloud of gas down on the workmen. This is the theory advanced by the officials of the company and other authorities on ventilation, and it is borne out by the fact that the three fire-bosses were experienced men, and would have followed an invariable precedent of removing all men from the course of the return air, had they taken any action, such as shutting a door, that would have effected such a reversion. The reversion was probably due to abnormal conditions existing at the instant of the explosion, and it is doubtful if the same conditions could ever be established again.

At this point, it would be well to explain that the stopping and rubbish being removed at the time of the explosion were at a point between the foot of the rock plane and the connection of the Lee seam air course and the old Lee seam workings, and in the natural order of things nothing but fresh air from either of the two intakes, that is the rock plane, and the air course being opened, should have reached the men.

The Coroner's jury, after hearing all available testimony at the inquest rendered a verdict in which they laid the cause of the reversion of the current to the action of the fire-bosses closing a door and reversing the current while men were working inside on the return airway. This verdict is not supported by any evidence and is not just to the memory of the three unfortunate men. They were men of experience and intelligence, and it is not at all likely that they would deliberately reverse the current without ordering the men to a place of safety, which is a rule invariably followed in such cases.

THE NELSONVILLE FOUNDRY AND MACHINE COMPANY.

Since the incorporation of the Nelsonville Foundry and Machine Company, of Nelsonville, Ohio, in 1882, it has by the excellency of its work, attention to details, and business energy of its officers, gradually risen among the prominent builders of mining machinery, till now it stands in the front rank.

The company owns and controls a number of important inventions, one of which is their patent mine car wheel, which has met with great success, and is now in use in every coal producing state in the Union. On this wheel, which is self-oiling and has a specially fine chill, made by secret process, the company challenges competition, both in quality and price. They sell the wheels either with or without axles and beds.

Another excellent invention, which has revolutionized the handling of coal at the mines is the Mitchell Coal Tipple, the manufacture and sale of which this company controls in the States of Virginia, West Virginia, Ohio, and Kentucky. The success of this excellent invention has been phenomenal. Every mine in the Hocking Valley, of any note, uses it, and we have seen it in successful practical operation in other localities. In reply to our inquiries as to its utility, we have been invariably informed that it fully sustains all claims made for it. In speaking of it some time ago, Mr. T. B. DeArmitt, Superintendent of the New York and Cleveland Gas Coal Company's Mines, at Turtle Creek, Pa., said, "We have adopted it and consider it a most excellent arrangement." With this tipple one man can handle two thousand tons of coal in ten hours.

A chain belting recently patented by the company, was invented by Supt. E. S. Jennings. It has also been very successful in gaining the favor of colliery managers, and is already in use in various parts of the country. Among other large mines using it are those of the Ellsworth and Morris Coal Company, at Brush Fork, Ohio.

This chain belting requires a very short amount of slack to couple or uncouple it. The total length or space being only 1½ inches. The links are slotted, and the couplings provided with shoulders so that they cannot be uncoupled until they are brought in the proper position for this operation. The making of the couplings and links separate results in so many more joints, thus adding to the pliability of the chain.

A friction clutch, also recently patented, possesses peculiar merits that put it far in advance of any other clutch on the market. The sales of this clutch have also been phenomenally large.

One of the most important branches of the business is the manufacture of fine rope haulage machinery. In the manufacture of this class of machinery alone, the company has won a national reputation. The striking features of their engines are in the style of friction and the method of handling them. The friction is very simple and has no complicated work about it to get out of gear. It is handled entirely by steam, the cylinders being placed on the bed-plate in front of the drums. These cylinders are so arranged that friction may be tightened or loosened, as may be necessary, or stopped and held in any position, the cylinders forming a steam cushion for the piston, thus relieving the yoke or lever from all strain. A steam reversing gear is also placed on the engine, thus making very light work for the engineer, and bringing his work in a close space where it is all very easily handled. Everywhere they have been placed these engines have given satisfaction.

They have recently placed in position for the Ellsworth & Morris Coal Company, the largest double engine they have ever produced. Its weight is forty-five tons. They have also put in large haulage plants for the Linton Coal Company, of Linton, Ind., and the Union Collieries Company, of Victoria, B. C. They also put up a large hoisting engine for the Nelsonville Coal and Coke Company, of Jacksonville, Ohio.

The company also manufactures all kinds of bar and revolving coal screens, gear-wheels, etc., etc. Besides their own patents, they also manufacture the Wallace and Brooks Compressed Air Pumps, an automatic machine for pumping water from mines. Before placing orders for mining machinery it will pay our readers to write to the Nelsonville Foundry and Machine Company, whose advertisement appears on another page, for estimates on the required machinery.

Get a "Cinch" on it.

We mean on your business. The only way you can do it is to keep posted on new machinery and appliances. You can't keep posted if you do not carefully watch all new inventions and improvements made in mining machinery and mining appliances. By sending for the catalogues, etc., of the following firms, you will get, free, a lot of valuable data:

Send for samples and prices of Mineralized Brattice Cloth, for doors, air stops, hanging cloths, etc., etc., a very necessary and useful article in all mines. Address, Mineralized Rubber Company, 18 Cliff St., New York.

Send for photographs and price lists of the improved mining machinery, mine cars, and mining appliances manufactured by J. A. Parker, Terre Haute, Ind.

Send for catalogue of steam engine specialties handled by Hine & Robertson, of 45 Cortlandt St., New York. It will pay you.

Send for catalogues and circulars of electric blasting apparatus, explosives, etc., to Ætna Powder Company, 95 Randolph St., Chicago, Ill.

Send for catalogue of Leviathan Belting issued by Main Belting Co., 1219 Carpenter St., Phila.

Send for catalogue of mining machinery, mine cars, etc., etc., manufactured by J. Herbertson's Sons, Brownsville, Fayette County, Pa.

Send for catalogue of Spiral Riveted Pipe for mine ventilation, blast pipe, water supply, exhaust, etc., to Abendroth and Root Mfg. Co., 28 Cliff St., New York.

Send for catalogue and circulars of practical mining machinery, to Robert Allison & Sons, Port Carbon, Pa.

Send for catalogues and circulars descriptive of improved mine cars, Bowden self-oiling mine car wheels, etc., to Bloomsburgh Car Co., Bloomsburgh, Pa.

Send for circulars and prices of mining powder and High Explosives to Henry Belin, Jr., No. 118 Wyoming Avenue, Scranton, Pa.

Send for description and prices of all kinds of steel and iron and mining hardware to Bittenbender & Co., 126 and 128 Franklin Avenue, Scranton, Pa.

Send for descriptive catalogue and samples of the celebrated Selden patent steam and water packing to Randolph Brandt, No. 38 Cortlandt St., New York.

In writing for the above use a postal card and state that you saw the advertisement in THE COLLIERY ENGINEER.

Electric Machinery.

Copy of a dispatch sent by one of the foremost engineering firms of the world in answer to an inquiry regarding the reliability and cost of maintenance of Thomson-Houston apparatus.

"After seven years with Thomson-Houston machinery, one hundred motors and about twenty dynamos, we have had the highest satisfaction and no difficulty whatever. In no single case have we had an armature to replace, and the cost of maintenance is practically nothing. You will make no mistake by adopting their system. We adopt ourselves because by comparison we have found them best."

The name of the sender will be gladly furnished on application to the Thomson-Van Depoele Electric Mining Company, 620 Atlantic Avenue, Boston.

BOOK REVIEW.

MINING DEPARTMENT OF VICTORIA; REPORTS AND STATISTICS FOR THE QUARTER ENDED JUNE 30, 1891. Compiled and arranged by A. W. Howitt, Secretary for Mines. This is a report issued by the government of the British colony of Victoria, and is uniform with the regular blue books issued by the British government. It is excellently arranged and is well illustrated with maps, sections, plans, and other illustrations. It contains a mass of valuable data concerning the mineral resources of the colony, and strange as it may seem, it is typographically a better publication than the blue books issued from London. The text is well edited. It is published by Robert S. Brain, Government Printer, Melbourne, and the price is two shillings.

THE QUARRYMAN AND CONTRACTOR'S GUIDE, or How to Remove Rock at Least Cost. By Arthur Kirk, Pittsburgh, Pa. Cloth, 4 Fo. pp. 147. Illustrated. Price $3.25.

While this volume is published by Arthur Kirk & Son, dealers in powder and high explosives, and thus comes under the head of trade publications, it contains much information very useful to both contractors and engineers. The bulk of the work relates to blasting operations and appliances, and the hints given as to the safe and proper handling of explosives and the prevention of accidents are evidently the outcome of intelligent practice and experience. The book is full of cuts illustrating the plant and methods advocated. Quarrying and blasting machinery take up the latter part of the volume, and the information here given is also very useful.

ROYAL GEOLOGICAL INSTITUTE OF HUNGARY. Vol. IX, Parts 1 to 5 of the Transactions of the above Institute, just to hand, contains papers descriptive of some artesian borings and an account of silver mining in Austro-Hungary.

We append a letter received from Mr. B. W. Cooper, Supt. Machine Dept. of the Litchfield Car & Machine Company, of Litchfield, Ill., which proves two important facts. First—It pays to manufacture first-class machinery, and second—It pays to advertise said machinery in THE COLLIERY ENGINEER.

"We are pleased to inform you that we have closed another contract with the Kansas & Texas Coal Company for a pair of hoisting engines 24" x 48" cylinder with 12' diameter drum. These engines are for their Riverside Mine at Leavenworth, and is the second pair which we have had the pleasure of building for them in the last six weeks.

"We are also repairing the engines for the Brighton Coal Company, at Harkness, Kan., whose machinery was destroyed by fire some two or three weeks ago.

"We have also closed a contract for a pair of our first motion hoisting engines for a new mine to be opened at New Douglas, Ill.

"We are also building cages and shaking screens for the Kansas & Texas Coal Company's No. 46 Mine, at Bevier, Mo., and are also building cages for their mine at Fleming.

"Inquiries are frequent and business generally satisfactory."

Since Mr. W. L. Bellis, of Cleveland, Ohio, introduced to the colliery managers of America, through the medium of THE COLLIERY ENGINEER, his new mining collar, it has met with phenomenal success. It is now in use in five different states and the demand for it is daily increasing. This is the strongest possible evidence of its merit and peculiar adaptation for mine use.

ENGINEERING ASSOCIATION OF THE SOUTH.

The annual meeting of the Engineering Association of the South was held in the Y. M. C. A. Building, Nashville, Tenn., on Thursday evening, Nov. 12, 1891, President John B. Atkinson, Earlington, Ky., presiding, with about thirty members and visitors present.

The President appointed as tellers to canvass the ballots for membership, and officers for the ensuing year, Messrs. W. L. Dudley and E. C. Lewis. A communication was received from Mr. C. H. Armistead, Secretary of the Nashville Commercial Club, extending the courtesies of the Commercial Club to the visiting members of the Association. On motion of Mr. MacLeod a vote of thanks was returned to the Commercial Club for the courtesies extended. A communication was received from the Canadian Society of Civil Engineers notifying the association that it had been placed on its list for exchange of publications.

A communication was received from the General Committee Engineering Societies notifying the Association that its assessment for the fund to meet the expenses of the Engineering headquarters at Chicago, during the Columbian Exposition, had been placed at $200; as this was in excess of the amount assessed at the time this Association voted to join the movement to establish Engineering Headquarters, the Association voted to ratify its previous action and to accept the assessment.

Treasurer W. R. Ross submitted the following report:

Received from former Treasurer	$377 07
Received from Secretary during past year	635 52
Total receipts	$1012 59
Bills paid on approval of Finance Committee	609 72
Leaving balance cash on hand	402 87

Secretary Olin H. Landreth submitted the following report:

MEMBERSHIP.

	At Beginning of Year.	Resigned.	Died.	Additions.	At Present.
Resident Members	21		1		20
Non Res. Members	70	5	1	11	75
Non Res. Associates	3	1		1	3
Resident Juniors	2			1	3
Non Res. Juniors	5			2	7
Total	101	6	2	15	108

DEATHS.

Eben Pardon, resident member; H. S. Butler, non-resident member, of Anniston, Ala.

Papers read, 12; Papers published, 10; Meetings at Nashville, 7; at Birmingham, 1; at Earlington, Ky., 1, total, 9.

ESTIMATED REVENUE FOR COMING YEAR.

Cash on hand	$402 87
Back membership dues to date	376 00
Estimated income on basis of present membership	593 00
Total	$1372 87

Mr. W. C. Smith announced to the Association that a chapter of the American Institute of Architects had recently been organized in Nashville and submitted an application from the chapter for the privilege of holding its regular meetings at the new headquarters of the Association at a rental price to be agreed upon. The matter was referred to the Executive Committee with power to grant the request.

The tellers appointed to canvass the ballots for election to membership, reported the election as member of Mr. Lucien S. Johnson, Engineer and Superintendent of Mines of the Great Western Mining Company, Peach Orchard, Ky., and as Junior, Mr. John K. Peebles, Draughtsman and Assistant Engineer with W. C. Smith, Architect, Nashville, Tenn.

The tellers also reported the election of the following Board of Officers for the ensuing year: President A. V. Gude, Atlanta, Ga.; First Vice-President, James Geddes, Nashville, Tenn.; Second Vice-President, F. P. Clute, South Pittsburgh, Tenn.

Directors from Tennessee—S. C. Lewis, W. L. Dudley, and W. F. Foster, of Nashville, Tenn.

Director from Georgia, Hunter McDonald, Atlanta, Ga.; Director from Kentucky, John MacLeod, Louisville, Ky.; Director from Alabama, Charles R. Percy, Montgomery, Ala.; Secretary, Olin H. Landreth, Nashville, Tenn.; Treasurer, W. R. Ross, Nashville, Tenn.

President John B. Atkinson then submitted the President's annual address, which comprised a very carefully prepared exhibit of the engineering features of productive and industrial development during the past year. The address also gave a brief resume of the most striking developments in engineering particularly in the Engineering of Transportation during the past year. The address will be published in full.

On motion the Association adjourned to the regular December meeting.

Profit Sharing in the Iron Trade.

Sir Alfred Hickman, proprietor of the Spring Vale Furnaces, Wolverhampton, who is the largest pig iron maker in South Staffordshire, has issued a circular to his workmen stating that he proposes to give them a direct interest in their labor by granting each man a substantial bonus out of the profits of his trade during the year ending next June. As soon as the result of the year's working is ascertained he will divide among them a certain share on their earnings. He wishes them to understand that they are not partners, and he reserves to himself the right to deal with them as to retaining their services or otherwise. An iron foundry at Gross-Ilsede, Hanover, employing from 600 to 700 men, has carried on the system of profit-sharing since 1869. All the employed who have deposits in the factory savings bank are participators in it. If the net profits of the firm exceed 5 per cent., a corresponding addition, up to 15 per cent. is made to the 5 per cent. interest given on the savings bank deposits. Hence, those deposits can bear up to 20 per cent. interest. The following table shows the percentage paid from 1869 to 1883: 1869, 8 per cent.; 1870, 9 per cent.; 1871, 10 per cent.; 1872, 18 per cent.; 1873-74, 20 per cent.; 1875, 6½ per cent.; 1876, 6 per cent.; 1877, 6½ per cent.; 1878-79, 10 per cent.; 1880-83, 20 per cent. In the year 1883 the number of depositors was 566, and the total savings amounted to £25,850, a proof that the system had a strong influence on the thrift of the people employed. The factory also has a "workmen's bank," which any of the men may join. It is supported by contributions equal to 6 per cent. of the wages, half of which are paid by the men and half by the firm. The accumulated capital of this bank amounted in 1883 to £15,000. There are also two widows' and orphans' funds—one for the lower class of workmen, and one for the foreman and employes.—*Colliery Guardian.*

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since our Last Issue.

Deep Vein Coal Co.,	Cedar Rapids, Iowa.
Union Coal & Mining Co.,	Des Moines, Iowa.
Oro Fino Mining & Milling Co.,	Louisville, Ky.
Lemhi Mining & Milling Co.,	Solomon City, Idaho.
Twin Falls Placer Mining Co.,	Hailey, Idaho.
The Sonora Development Co.,	New Orleans, La.
The Argyle Mining Co.,	Chicago, Ill.
Hermosa Mining Co.,	Camden, N. J.
The Aluminum Mining & Smelting Co.,	Chicago, Ill.
Anglo-Florida Phosphate Co.,	Ocala, Fla.
Star Gold and Silver Mining & Reduction Co.,	Moiden, Fergus Co., Mont.
Traymore Phosphate Rock Co.,	Camden, N. J.
Arlington Natural Gas Co.,	Anderson, Ind.
The Newport Mining Co.,	Milwaukee, Wis.
The St. John Mining Co.,	San Francisco, Cal.
Des Moines Coal Mining Co.,	Des Moines, Iowa.
New York and West Virginia Coal & Iron Co.,	Jersey City, N. J.
The Hornet Mining Co.,	Neihart, Mont.
Royal Fossil Flour Co.,	Portland, Me.
Florence Mining Co.,	San Francisco, Cal.
The Hobbs Natural Gas & Water Co.,	Hobbs, Tipton Co., Ind.
The Duke Mining Co.,	Denver, Colo.
The Arge Mining & Reduction Co.,	Denver, Colo.
The Wizard Mining Co.,	Denver, Colo.
American Aluminum Co.,	San Francisco, Cal.
Cleveland Consolidated Mining Co.,	Red Bluff, Cal.
Braybogle Mining & Milling Co., Consolidated,	San Francisco, Cal.

Mining in Missouri.

State Mine Inspector C. C. Woodson, has submitted the fifth annual report to Labor Commissioner Hall for the year ending June 30th, 1891.

The report shows a healthy condition of the coal, lead, and zinc industries of the State, but a depression in the iron product as compared with previous reports.

This report shows the total value of the State's mineral output to have been $8,896,995 against $8,165,865 for the preceding year—an increase of $731,730.

In producing this amount of wealth 30 lives were lost, 16 wives made widows, and 53 children made fatherless, or one life lost for every 413 persons employed—this is based only on the average number of men at work.

An interesting feature of the report is the number of employes at Missouri mines. The average number of which is 12,392, showing that a population of nearly 50,000 people is directly dependent on the mines for support—for a ratio of four to one in this instance is a very moderate one.

Notes on each industry are as follows:

The output of coal during the past year was 2,650,018 tons, the average value of which was $1.31¼ per ton, or a total value of $3,480,867 at the mines, as compared with 2,437,399 tons valued at $3,234,357 for the preceding year, showing an increase of 212,619 tons for the past year. This coal was produced by 385 mines or openings of all kinds, including strip-pits, 141 of which employ ten or more men. These 385 openings furnished employment for the year an average of 6,879 persons. There occurred during same time 18 fatal and 32 non-fatal accidents, showing one life lost for every 147,223 tons of coal produced.

Lead and zinc mines report 5,065 persons employed in and about the 610 shafts which are in operation, together with an output of 123,752 tons of zinc ore; 16,925 tons of lead, and 19,968 tons of pig lead valued at $5,084,462 at the mines, showing an increase of $728,943 over the past year. The value of lead ore has advanced from $45.40 per ton, in 1890, to $49.10, in 1891; while the value of the zinc ore has decreased from $22.51 per ton to $21.60 during the same time. The report also shows that 12 fatal accidents occurred, or one for every 422 persons employed.

St. Francois County continues to lead in the production of lead, while Jasper County produces 77 per cent. of the entire zinc output of the State.

The output of the iron ore during the past year was 138,356 tons against 232,835 tons for 1890, showing a decrease of 94,482 tons.

A Colliery Owned by Miners.

M. Jacques, liquidator of the Monthieux Collieries Company, has consented to a sale of the company's concession to a combination known as the Syndicate of Miners of the Loire, comprising about 10,000 workpeople. The concession, which comprises coke ovens, premises, and workshops, was offered for sale by auction in August at a reserve price of £4,400, but no purchaser was forthcoming. The concession also includes two collieries, the output of which has hitherto reached about 5,000 tons per month. The property is connected with the French railway system at St. Etienne by a branch about three-quarters of a mile in length.—*Colliery Guardian.*

It is sometimes convenient for an engineer to be able to approximate the amount of condensation that will take place in pipes during a certain length of time. From many experiments made on the condensation of steam in wrought-iron pipes when exposed to the open air it is found that 1 lb. and 6 oz. of steam per square foot of pipe's surface was condensed per hour when the difference in temperature between the steam and air amounted to 200°. As this is very nearly the difference of temperature usually found between the steam in the pipes and the air outside, this simple rule will give results sufficiently close for ordinary purposes.

PRIMARY EDUCATIONAL DEPARTMENT

FOR CANDIDATES FOR

MINE FOREMEN'S CERTIFICATES

AND FOR

STUDENTS OF MINING.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the sciences related to mining and to learn how to answer the questions in ventilation, surveying, and mechanics which are asked at the examinations for mine foremen's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine foremen and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and many calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

In this issue we wish to draw attention to the correct development of the capital letters I and J.

It will be found that the four laws of penmanship control the development, so far as symmetry, harmony, and beauty are concerned, of the whole of the letters of the alphabet.

The capital letter I on the left hand side of Fig. 26 is

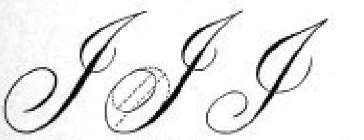

FIG. 26.

pleasant and satisfying.

The second letter from the left illustrates its development out of elliptical curves wherein the major axes are parallel.

The third letter from the left hand side has its parts so disproportionate that they are a violation of the

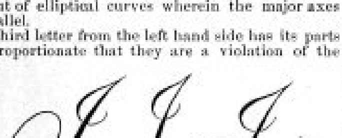

FIG. 27.

third law of penmanship, namely, all strokes should be proportionate in size. In this case the upper scroll is too large, and the bottom scroll is too small.

The first letter from the left hand side of Fig. 27 is also a violation of the third law of penmanship, and in

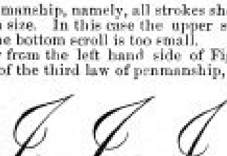

FIG. 28.

it it will be seen the upper scroll is too small and the bottom scroll is too large.

In the second letter from the left hand side it will be seen that the major axis of the ellipse that develops the

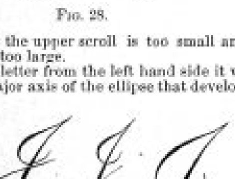

FIG. 29.

bottom scroll has the wrong inclination, and the main stem of the letter is not parallel to the former letters in the series.

In the third letter from the left hand side of the figure the scroll terminates in hair-lines that are neither parallel to the stem or proportionate in distance, according to the requirements of the second law of penmanship.

Figs. 28 and 29 illustrate the development of the capital letter J. The first letter on the left hand side of Fig. 28 has a normal development, and therefore it is pleasing.

The second letter from the left is intended to illustrate the development of the elliptical curves.

In the third letter from the left the bottom loop is too small, and, therefore, does not comply with the requirements of the third law of penmanship.

In the first letter of Fig. 29 the loop is too large, and, therefore, does not comply with the requirements of the third law.

In the second letter the loop is contracted, and, therefore, repulsive.

In the third letter the upper scroll is too large and the bottom loop too short.

From these illustrations, we repeat what we have said before, the elements of beauty are order and harmony, and these can only be secured by adherence to correct laws.

ARITHMETIC.

VULGAR FRACTIONS.

No difficulty would arise in the study of arithmetic and especially that branch of it called "Addition and Subtraction of Vulgar Fractions," if the student would first acquire correct ideas of fractional and concrete quantities. Our intelligence will be bright and sparkling, or dull and opaque, in proportion to the clearness with which we discover the relationships of things. For example, if we add 4 horses, 4 oxen, and 4 sheep, by relationship we cannot make them any other than 4 horses, 4 oxen, and 4 sheep, but we might add them together and speak of the sum as 12 beasts.

It is only then by making our knowledge sharp and incisive, and by clearly discovering the relationships of the subjects of our thoughts, that we can attain to true intelligence.

A fraction then is not a whole, neither is a whole a fraction, a whole is equal to the sum of all its parts, and a fraction is only a part of a whole. This is certainly presenting the matter in a simple way, but let us not forget that it is necessary to use simple illustrations to make difficult matters plain, a step is not a flight of stairs, and it is therefore impossible to describe what we call a flight of stairs without first defining what we mean by a step. A step is a member of a community of steps, the sum of which constitutes a flight of steps. So it is with our study of arithmetic, we first proceed from the simplest factor to discover its relationships with all the factors that go to make the great whole. Whole numbers can be added directly, for instance, 7 and 3 are 10, but a quarter cannot be added to a half until we have first discovered the relationship of a $\frac{1}{4}$ to a $\frac{1}{2}$; what then is the relationship of $\frac{1}{4}$ to $\frac{1}{2}$? The relationship then is that $\frac{1}{4}$ is the $\frac{1}{2}$ of a $\frac{1}{2}$, or that $\frac{1}{2}$ contains two quarters. Now, with this relationship before us we can add $\frac{1}{4}$ to $\frac{1}{2}$ by first noticing that a half consists of two quarters; now two quarters can be added to one quarter and the result is $\frac{3}{4}$.

Now, let us try to add $\frac{1}{3}$ to $\frac{1}{5}$, and we will soon discover that these fractions cannot be added as $\frac{1}{3}$ and $\frac{1}{5}$. Try to make a sum and say that $\frac{1}{3}$ added to $\frac{1}{5}$ would be two somethings. Now, what is the something? Call it $\frac{2}{5}$? But it cannot be $\frac{2}{5}$ because it is a fifth added to a third. Then call it $\frac{2}{3}$; but it cannot be two-thirds because it is a fifth added to one-third. We can, however, add these fractions together by multiplying their denominators into each other, then five three's are fifteen, now, there are three fives in fifteen, therefore, $\frac{5}{15}$ has the same value as $\frac{1}{3}$ because 5 is contained in 15 three times; and $\frac{3}{15}$ will be equal to $\frac{1}{5}$ because three is contained in 15 five times. Again, $\frac{3}{15}$ can be added to $\frac{5}{15}$ and the sum will be $\frac{8}{15}$.

From this reasoning it is clear that two fractions cannot be added together until they are expressed with denominators of equal values, that is, fifteenths can be added to fifteenths, but fifths cannot be added to thirds, although it does seem somewhat paradoxical that we can add fifths to thirds by expressing both as fifteenths. Now the discussion of this matter in this simple way ought to excite in the mind of the student an interest in the relationships of values, and in the relationships of things, because it is only by these means he can become intelligent.

In the same way $\frac{2}{9}$ might be added to $\frac{3}{5}$ by establishing in each a relationship of such a character that a whole is conceived to be broken into equal parts. For instance, suppose we were to chop up an apple, regardless of measurement or volume, no two of the pieces being equal in size; but to make the matter clear let us still further suppose that this apple was approximately broken into nine parts, now if we pick up two of these unequal parts it would be foolish to say that the two unequal parts constitute $\frac{2}{9}$ of the apple. We cannot tell what fraction two parts constitute until we have discovered their relative measure in relation to the volume of the apple itself. The same reasoning applies to the two fractions before us, and the addition of them must be proceeded with on the same lines as those on which we succeeded in adding a third to a fifth.

The same principles are involved in the subtraction of fractions.

You cannot take $\frac{3}{7}$ from $\frac{7}{9}$ because the values are expressed as sevenths and ninths, 3 from 7 leaves 4, but the remainder cannot be designated either sevenths or ninths, so that the 4 in this case has no measurable value, but if we convert both the fractions into sixty-thirds by multiplying the denominators into each other, we can express the same fractional values as sixty thirds as we can express in sevenths on the one hand and ninths on the other; $\frac{3}{7}$ then may be expressed as $\frac{27}{63}$, and $\frac{7}{9}$ may be expressed as $\frac{49}{63}$. Now in each case the same values are expressed in different numbers. $\frac{27}{63}$ is the same in value as $\frac{3}{7}$, and $\frac{49}{63}$ is the same in value as $\frac{7}{9}$; for example, $\frac{1}{2}$ is the same in value as $\frac{2}{4}$, and $\frac{5}{10}$ is the same in value as $\frac{1}{2}$, and $\frac{500}{1000}$ is the same in value as $\frac{1}{2}$.

All these arrangements represent $\frac{1}{2}$; therefore, we can subtract $\frac{27}{63}$ from $\frac{49}{63}$ and the remainder must be $\frac{22}{63}$. Understanding clearly the explanation given, all additions and subtractions of vulgar fractions may be performed intelligently, because the reason for the rule has been made sharp and clear to the understanding.

Then we may now safely enunciate the rule that all vulgar fractions to be added or subtracted must first be converted into fractions having their original value and expressed with the same denominator.

EXAMINATION QUESTIONS ANSWERED.

QUESTION 26.

(This question was incorrectly answered in our last issue, and the error was not only detected by the editor, but by several readers as well.)

Supposing a gangway has been driven due East to the land line running South 40° East; it is proposed to open a breast 40 feet from the face of the gangway, how far would the breast go to reach the land line, when the pitch is 25°?

ANSWER.—It will depend on the direction in which the breast is driven. If it is driven South it will never reach the land line. If it is driven North it will reach the land line at a distance of 52·6 ft.

In the first place we have the land line running S. 40° E., or 40° East of South, which forms an angle of 50° on the North side of the gangway. Then, if the seam were flat we would have a right-angled triangle with a base of 40 ft. and an angle of inclination of 50°, and we want to find the altitude. Then to find this we multiply 40 by the tangent of 50°, which gives us 40 $\times$ 1·191754 or 47·670160 ft. This would be the distance to the land line if the seam were flat, but as it pitches 25°, we have a right-angled triangle with a base of 47·670160 ft. and an angle of inclination of 25°, and we want to find the hypothenuse or pitch distance. We therefore divide 47·670160 with the cosine of 25°, or 47·670160 ÷ ·906308 = 52·6 ft.

CHEMISTRY RELATING TO MINE VENTILATION.

Will coal dust in air make an explosive mixture? To this inquiry we decidedly say yes! Any substance in air that will suddenly, on combining with the oxygen of the air produce a volume of flame equal to the volume of the mixture, cannot do otherwise than produce an explosion, because the force developed by the intense heat is an explosive force. From experiments we learn that coal dust does not ignite and instantly set up an explosion; its behavior is as follows: Take a space whose contents are equal to 1000 cubic feet, cause very fine coal-dust of a flocculent character to be suspended in the air of the chamber; if a strong light be introduced a sheet of flame is set up in the neighborhood of the light. Now let fresh air have access, the first sheet would be succeeded by a second one a little larger, and the second sheet is succeeded by a true explosion. If a continual supply of coal-dust be poured into the air as in the neighborhood of a coal crusher, a great tongue of flame is at once produced.

Will sparks ignite fire-damp in air? If the temperature of the spark be equal to the temperature of the lowest point of ignition of fire-damp, it must produce flame. If a piece of iron pyrites be chipped with a hammer in the neighborhood of an unlighted gas jet, it will light it. Sparks from the points of tools, and sparks set up by the stones rending and breaking in a goaf, are all sufficient to ignite an explosive mixture.

Important relationships of gases. Fire-damp, nitrogen, and carbonic acid, if breathed alone, or in an atmosphere undercharged with oxygen, produce suffocation, but carbon monoxide and sulphureted hydrogen cause death by poisoning. To make the distinction very clear, fire-damp, nitrogen, and carbonic acid, when breathed, bring about no chemical change in the blood, hence the sufferer dies through lack of oxygen. When carbon monoxide and sulphureted hydrogen are breathed they each act chemically on the blood and destroy it, hence the victim is poisoned. A healthy man inhales into his lungs ·35 of a cubic foot of air per minute. Ten per cent. of carbonic acid gas in air extinguishes lights. Ten per cent. of carbonic acid gas is not immediately fatal to life, but by continuing in such an atmosphere death certainly ensues. As has been previously shown, carbonic oxide is always one of the constituents of after-damp when the supply of oxygen is not sufficient for complete combustion, and, we should say, carbonic oxide would be one of the constituents of every after-damp, for the following reason: The air of the mine is not highly charged with coal-dust at the moment of explosion; but the sudden rush of air will lift up clouds of dust, and these being ignited by the great tongue of flame, will undergo partial combustion, and any vital air that may exist will be diluted with the blast of after-damp, and certainly render the succeeding combustion imperfect, thus generating carbon monoxide. Only one half per cent. of this gas is dangerous to breathe, and the unhappy victim seems to be relieved of mental excitement, and has a desire to sit and take things easy. It seems to paralyze muscular action, the poor fellows die standing, sitting, and lying with comparatively pleasant expressions on their faces, and so singular is the chemical action set up in the bodies of the victims, that their flesh does not stiffen when they are dead.

The carbonic acid of our shallow seams is chiefly carried into the mines in solution in water. We do not doubt a little is given off by the coal, but the student who has studied the great subject of the solubility of gas, will quite understand the large quantities carried into the mine by the agency of water. The quantity of carbonic acid produced by the exhalation of men and animals, and the burning of lights is relatively very small to the quantity given off by water. In the deeper seams overlaid with compact strata, through which much water does not find its way into the mine, we find comparatively little carbonic acid or stythe.

It is often a practical question with the miner how much air should be allowed for the efficient ventilating of a given seam. To satisfy this query it is often said that from one to four hundred cubic feet per minute is an adequate supply. Such statements are, however, in the absence of certain important considerations, vague and untrustworthy. It will appear clear that portions of the mine not at present working require ventilating, but the far weightier consideration is that of the height of the seam; a quantity equal to 600 cubic feet per minute per man could be easily supplied in a six-foot seam, but the pressure required to supply the same quantity per man in a three-foot seam would be such that the hap-hazard statement on the face of it appears ridiculous. Quantities can only be approximately calculated, but even then the dimensions of the roads should receive first attention.

Suppose we allow 300 cubic feet per minute per man in the three-foot seam, that quantity would be totally inadequate for a six-foot seam, the velocity not being sufficient to remove fire-damp. It is not so much a question of supplying oxygen for the breathing of men and animals, and the burning of lights, as it is a question of getting sufficient velocity to remove the gas. Perhaps a convenient approximate rule would be the following: For a seam giving off gas in the working places, allow 100 cubic feet per minute per man for every foot the seam is high, so that for a 1, 2, 3, 4, 5 or 6 foot seam the quantities would be respectively 100, 200, 300, 400, 500, or 600 cubic feet per man per minute.

Coal-dust and fire-damp mixed with air. It has been found that an atmosphere heavily charged with particles of fine coal-dust and about two per cent. of fire-damp is in a dangerous and explosive condition. It is sometimes suggested that there can never be sufficient oxygen in the air to burn up a cloud of fine particles that are suspended in it, but this is a serious mistake; an average cubic foot of air contains rather more than a quarter of an ounce of oxygen, and however dense may be the cloud of fine coal-dust that is found in one cubic foot of air, it is very unlikely that it ever will even approximate half the weight of the oxygen. From this circumstance we are convinced that the experiments of Professor Abel are perfectly satisfactory.

A Safety-Lamp may be defined as one that cannot, under ordinary working conditions, ignite an explosive mixture outside of itself, and the principle of its action may be further defined by saying, the gauze cylinder isolates the flame of the lamp from the outside air in the following manner:

The wire of the gauze always being at a temperature below that of flame, chills it. Now, as flame consists of gas at a white heat, and the gauze being much below the temperature of flame, we can see at once why flame does not pass through the meshes of the gauze, but gas moving at a high velocity, when its temperature is equal to that of flame, passes easily through the meshes of red-hot gauze, hence the dangers attending the use of the ordinary Davy and Clanny lamps in the event of an explosion inside of the lamp.—*Tate's Chemistry.*

SCIENCE RELATED TO MINING.

WATER.

The most marvelous story that human language could tell, would be that of a drop of water. Water extinguishes fire, and yet it is composed of the most fiery elements in nature, viz., oxygen and hydrogen. To the unthinking, it would appear that three-fourths of the earth's surface is comparatively lost, as the result of being covered with water; nevertheless, had the extent of the great water sheet been less than it is, very little of the dry land would have been habitable, because it would have been a dry, barren waste. The ocean supplies a large proportion of the food of man, which is both healthful and nourishing. If the British Isles were to lose their fish supplies the flesh of animals could not be found, in sufficient abundance, to compensate for it.

Water is found in three forms, solid as snow and ice, liquid as water, and gaseous as vapor; as the temperature of the air, overlying damp earth, or sheets of water, increases, its power of converting water into gas increases. Air is said to absorb water as vapor; the natural law by which absorption takes place is not at present understood; our knowledge, therefore, extends no further than the fact.

All the water of the clouds is the result of this absorption; the heat of the sun warms the air, the air absorbs vapor, which is carried to the higher regions of the atmosphere, where the temperature of the air is at once lowered, when it parts with its vapor, which now contains in it little particles of water, so small that their surface is enormous when contrasted with their volume, the result is they remain in a state of suspension, countless millions of them forming clouds, which sail along on the wings of the wind, and if this current should meet with counter or cross-currents, the miniature particles collide and coalesce into rain drops, which being too heavy for suspension, at once fall as rain, hail, or snow. These water the land, and act as a solvent of the plant food in the soil.

A portion of the rain constitutes the life-blood or sap of plants, which cannot live without the aid of water. The excess of water goes to form torrents, streams, and rivers, which carry off effete matter, which nourishes the germs of disease that destroy living organisms.

THE AIR WE BREATHE.

The air we breathe is an elastic fluid, that is to say a cubic foot of air might be pressed into the volume of a cubic inch, or a cubic foot of air might expand into the volume of a cubic yard or more. There is a known limit to which air can be compressed or contracted in volume, but we have not yet ascertained any limit to its expansion. It has been said that if a cubic inch of air, at atmospheric pressure, was admitted into the vacuum of a large sphere, whose radius was equal to the mean distance of the planet Neptune from the Sun, the little volume of a cubic inch would expand and fill the whole sphere; if it is so the conclusion is a very startling one. Air in common with all other bodies expands when heated, and contracts when cooled, by a well defined law. It is composed of oxygen and nitrogen, and some other compound gases in very small proportions; by volume it is about 21 per cent. oxygen, and 79 per cent. nitrogen, with small percentages of watery vapor, carbonic acid, etc. Now the presence of carbonic acid in the atmosphere is immediately important to all living beings, although this gas destroys life by suffocation when breathed in sufficient quantities, it is nevertheless necessary to the life of plants, supplying the necessary carbon for the tissues. We exhale carbonic acid to-day, and the carbon in that acid we may eat some days hence in butter, in the flesh of animals, and in the nutritious parts of plants. The composition is invariable; it is anywhere and everywhere the same, excepting where it is locally polluted, or in the neighborhood of the dwellings of men, where it is vitiated by the putrefaction of matter in a state of decay.

THE THERMOMETER.

The thermometer is an instrument for measuring the temperature of bodies, and especially in mining to indicate the temperature of air columns and air currents. The instrument is constructed with a scale of parts and a glass tube, having at one end a bulb. The tube and bulb either contain mercury or spirits of wine. Its mode of action is as follows: First, the ratio of temperature is shown by the expansion or contraction of the mercury or spirits of wine. In the event of their temperature being raised or lowered the column in the small tube is lengthened or shortened.

The expansion of either mercury or spirit is too small, or, in other words, the co-efficient of expansion is too small to admit of being measured by a tube of uniform bore without a bulb; therefore, the cubical contents of of the bulb are at least fifty times that of the tube. Consequently, by the arrangement of a bulb, the expansion of the mercury or spirit is read off by a magnified range of column. The tube is sealed at the top end in such a way that it contains no air to affect the expansion by its varying pressure. Nature has furnished the unit basis of the scale of temperatures.

The French make the zero of their scale freezing point, because water becomes solid as ice at that point of temperature. The other limit of the unit is boiling point at a pressure of 760 m. m., or 30 inches of barometer column. Now, the column or range between the freezing and boiling points is divided by the French into 100 equal parts. Unfortunately, the English divide the range between the freezing and boiling points into 180 equal parts. Still different, the English, instead of accepting nature's gift of a fixed point, an artificial point is set up for the zero, and this is found by mixing salt and pounded ice or snow together, producing a temperature of 32° below the freezing point of water. Then 180 + 32 = 212° F., the boiling point of water. Observe, the French make freezing point 0°C and the English make the same point 32° F.

THE SIPHON.

The siphon is a useful and economical hydraulic appliance of great value in mining, and to understand it you must first study it from the standpoint of a balance. Really in a siphon the resultant action is that of a waterfall; this will appear plain when we state that the level of the intake is always above the level of the delivery, otherwise the siphon would not act. The amount of fall will afterwards be called the motive column. The balance occurs where the bend of the siphon rises above the level of intake and afterwards falls to the same level. This balancing of the rising and falling columns of the siphon is the result of atmospheric pressure. If the pressure of the atmosphere was double what it is, then water could be carried over an elevated point double that of what we ordinarily accomplish. Then let a vertical column of 34 feet balance the atmosphere, and call this balance A, and let the greatest vertical height of the siphon above the level of intake be called S, and let the motive column overcoming the friction of the water in the siphon be called F, then A = S + F; that is to say, the pressure of the atmosphere A is equal to the pressure due to the vertical rise of the water column above the level of intake plus the friction due to the water moving through the siphon, which is equal to the pressure due to the motive column. There is a limit to the successful working of all siphons, and that limit is reached when the friction of the water through a long range of pipes begins to approach the full pressure of the atmosphere. The fact is, although this instrument has been for many years employed in mining, it is very little understood. Ignorance of the laws that govern the action of the siphon has led to great disappointment and often waste of money; the student is therefore desired to give close attention to the operation of the laws affecting the action of it.

The five laws to be especially noticed are as follows:

(1). A 34-feet vertical column of water balances the pressure of the atmosphere.

(2). The motive column must be sufficient to overcome the resistance of the intake valve and the friction of the water passing through the pipes at a required velocity.

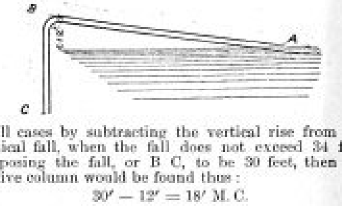
(3). The greatest altitude at which a siphon will act to run off a given quantity of water must be so much less than 34 feet that a sufficient motive column may be obtained.

(4). The delivery end of the siphon must be either bent upwards or dip into water to hinder air from gurgling up the delivery limb.

(5). No advantage is gained when the vertical depth of the delivery end from the highest point exceeds 34 feet.

The student must bear in mind that after the vertical fall reaches 34 feet no advantage whatever can be gained by making the fall any greater. Suppose the rising column to be 20 vertical feet and the falling column to be 34 vertical feet, the siphon must act, because 34 — 20 = 14. Now we have a motive column of 14 feet to overcome the friction due to the intake valve and the friction due to the velocity of water through the pipes. It is true a siphon might act with a vertical rise of 28 feet, a vertical fall of 34 feet, and a motive column of six feet; but if the lead of the siphon was say, half a mile, then the friction through the pipes would exceed in amount this small motive column; nay the six feet might not be sufficient to overcome the friction due to the intake valve alone, and the result would be the siphon would not act. On the other hand, a motive column of six feet might be ample for a short lead.

By referring to the figure it will be noticed that the intake is at A, the highest point, or altitude at B, and the delivery at C. The motive column is found



in all cases by subtracting the vertical rise from the vertical fall, when the fall does not exceed 34 feet. Supposing the fall, or B C, to be 30 feet, then the motive column would be found thus:

$$30' - 12' = 18' \text{ M. C.}$$

MECHANICS IN MINING.

ENDLESS ROPE HAULAGE.

When endless rope haulage is to be calculated in H. P. the following important particulars must be understood:

First, whatever the gradient of the road, the empty cars balance each other; second, any rise in the road only affects the engine so far as the weight of coal is concerned. The traction due to the friction of the road must be reckoned on the coal and the weight of cars equal to the weight of coal, for example: Suppose the weight of a car to carry 8 cwts. (a cwt. equals 112 lbs.) of coal is 4 cwts., and in addition to the car carrying the coal, there is an empty car; from this it will be seen there are two cars for one load. Therefore the coal to be hauled in a given time must be doubled in weight to make a correct allowance for the cars, each being half the weight of the coal, that is, if 500 tons are delivered at the shaft bottom in ten hours; for traction you must double this, or the traction will be due to 1,000 tons. Gravitation due to the gradient must be calculated on the coal only.

Q. What horse power of an engine will be required to haul 500 tons in 10 hours by an endless rope towards the pit bottom, the length of road being 3,000 yards, and the average gradient being 2 inches to the yard outbye?

A. Here the traction will be 1,000 × 28 (the co-efficient of traction being taken at 28 lbs.) = 28,000 lbs. Traction due to gravitation will be found thus: Multiply the pounds in one ton by the ratio of the rise, viz., 2 inches to the yard, and as there are 36 inches in a yard, it would be $\frac{2}{36}$, or $\frac{1}{18}$ for each lb., then for 500 tons it would be found thus:

$\frac{1}{18} \times 2240 \times 500 = 62{,}222$ lbs., and 28,000 × 62,222 = 90,222 lbs. Now if the pounds of force required to do the work of hauling 500 tons up this incline be multiplied by the distance in feet through which the load has to be moved, the result will be the units of work. Now 3,000 yards are equal to 9,000 feet, then 90,222 × 9,000 = 811,998,000 units of work to be done. Then, 811,998,000 divided by the time in minutes gives the units of work done in one minute, thus: 811,998,000 ÷ 600 (600 minutes in ten hours) = 1,353,330. Now as there are 33,000 units of work in a horse power the total horse power would be found by dividing by 33,000. But this amount of work is too large practically and it will be necessary to use the modulus ·7, which represents the amount of useful work done, therefore

$$\frac{1{,}353{,}330}{33{,}000 \times \cdot 7} = 58 \cdot 58, \text{ H. P.}$$

Q. What H. P. of an engine will be required to haul outbye 1,000 tons per day of 10 hours by an endless rope, the lengths of the roads being 1,500 yards, and the average gradient being ¼ of an inch to the yard rise inbye?

A. Here tractions equals

$$28 \times 2{,}000 = 56{,}000$$

therefore

$$56{,}000 - \frac{1{,}000 \times 2{,}240 \times 1}{144} = 40{,}445 \text{ total traction.}$$

Then

$$\frac{40{,}445 \times 1{,}500 \times 3}{600 \times \cdot 7 \times 33{,}000} = 13 \cdot 13 \text{ h. p.}$$

WINDING IN SHAFTS.

When winding in shafts is carried on with cylindrical drums and round ropes, the balance of the rope and the load is disturbed by this cause, but when winding is done with flat ropes coiling on reels, the balance of the ropes and the load is less affected.

The pass-by or meeting of the cages wound with flat ropes does not occur at half the depth, or midway in the shaft in this case however. The best rule for determining the point in the shaft where the meeting of the cages occurs is as follows:

Suppose the shaft to be 1,680 feet deep, the thickness of the winding ropes to be $\frac{3}{4}$ of an inch, and the diameter of the reel when the cage is at the bottom to be ten feet. We may proceed as follows: First find the circular feet in the edge measure of the rope which is 1680 feet long. Now the square feet in the edge measure will be as follows:

$$1680 \times \tfrac{3}{4} = 1260 \div 12 = 105.$$

As the reels are circular, next convert the square into circular measure as $\frac{105}{\cdot7854} = 133{\cdot}69$ nearly circular feet.

Next proceed to find the diameter of the reel when the cage is raised. The empty reel being 10 feet in diameter, the surface area of the end of the reel will be $10 \times 10 = 100$ circular feet, now $100 + 133{\cdot}69 = 233{\cdot}69$ circular feet. The area of the end of the full reel will be 15·28 feet.

$$(\sqrt{233{\cdot}69} = 15{\cdot}28 \text{ feet.})$$

Now to find the diameter of the reel at the moment when the cages meet, add to 10 half of the difference of the two diameters already found, as

$$\frac{5{\cdot}28}{2} = 2{\cdot}64,$$

then 12·64 is the diameter required.

Next call the diameter of the full reel D, and the diameter of the empty reel d, and the diameter at the meeting M, it follows then the cages will meet in the shaft at a distance from top X, and at a distance from bottom, x.

X may therefore be found by the following equation:

$$\frac{(D^2 - M^2) \times L}{(D^2 - d^2)} = X.$$

Let L be the depth of the shaft in fathoms, yards, or feet, and the meeting will be given in fathoms, yards, or feet.

The D^2 in this case equals 233·69, and M^2 will be equal to 159·7696, and d^2 will be equal to 100.

Then,

$$\frac{(233{\cdot}69 - 159{\cdot}7696) \times 1680}{(233{\cdot}69 - 100)} = 928{\cdot}92 \text{ feet from}$$

top, or 751·08 feet from the bottom of the shaft or

$$\frac{(M^2 - d^2) \times L}{(D^2 - d^2)} = x.$$

NOTE.—The following problem employs some principles not yet explained in this department, but is given for the benefit of some of the more advanced students:

TO FIND THE NUMBER OF TONS IN A PILE OF COAL.

Q. How many tons of coal are there in a pile 50 yards 2 feet long, and 30 yards 1 foot broad; the height of the pile from the floor being 10 yards, and the angle of the slope of the pile 45°?

A. There are several methods of determining the weight of such a mass of coal, but as many of them are only approximate solutions, and not correct to hundreds or thousands of cubic feet, we will give the two best and accurate solutions. Before proceeding, however, let us notice that if the slope of the pile makes an angle of 45° with the plane of the horizon, this means that the angle of repose for broken coal on the side of a pile is 45°. By the first solution we proceed to find the contents of a rectangular block situated within the slope of the pile. Finally the contents of four pyramids coinciding with the four corners.

Now the pile is 152 feet long at the bottom, and as the base and perpendicular, or the sine and cosine of an angle of 45° are equal, it follows that if twice the height of the pile in feet be subtracted from 152 the remainder is 92, the greatest length of the top of the pile. The breadth at the bottom of the pile is 91 feet, and if 60 be subtracted from this, the remainder is 31 feet, the greatest breadth across the top. Now as the height of the heap is 10 yards or 30 feet

$$92 \times 31 \times 30 = 85{,}560 \text{ cubic feet.}$$

Now each of the long prisms measure 92 feet, and their contents will be found by multiplying.

$$\frac{92 \times 30 \times 30}{2} = 41{,}400 \text{ cubic feet.}$$

Now the contents of the short prisms will be found by

$$\frac{31 \times 30 \times 30}{2} = 13{,}950 \text{ cubic feet.}$$

There are four pyramids, and the area of each may be found as follows:

$$\frac{30 \times 30 \times 30}{3} = 9{,}000 \text{ cubic feet.}$$

The sum of the contents of the figures, namely, one rectangular solid, four prisms, and four pyramids, is equal to 232,260 cubic feet.

The second solution is as follows: Let the slope of the two ends of the pile be supposed to be cut off, now we can solve the problem by two operations. First, find the mean breadth of the pile which is 61 feet, now 61×30 = the area of section, or 1830 square feet, then $1830 \times 92 = 168{,}360$ cubic feet. Each of the ends will be left in the form of a wedge, having a short edge and two long ones, the sum of the three edges will be $(31 + 91 + 91) = 213$, which divided by 3 gives 71, the mean length. The section may be considered as square, having one wedge resting on the other; the area of the section will be

$$30 \times 30 = 900, \text{ and } 900 \times 71 = 63{,}900$$

cubic feet, now the sum of the two solids will give the same as before:

$$63{,}900 + 168{,}360 = 232{,}260 \text{ cubic feet.}$$

A cubic foot of broken coal weighs 50 lbs., and as there are 2,240 lbs. in a ton, the weight of the coal pile will be

$$\frac{232{,}260 \times 50}{2{,}240} = 5184{\cdot}3 \text{ tons.}$$

MINE VENTILATION.

[From the Report of the Prussian Firedamp Commission, as published by The Colliery Guardian, England.]

Conveying the Air Current to the Working Face.—In order to obtain satisfactory results in ventilation it is not enough to force a great quantity of fresh air into the mine, but this air must be brought in as close proximity as possible to the face of the workings. The solution of this problem is all the more difficult because it varies with circumstances, and also for the reason that it depends on the attention, good will, and intelligence, not only of those who have the supervision of affairs, but also of the men themselves. This explains why it is the relatively short passages through which the current is conveyed to the working faces which are precisely the most dangerous parts of the mine.

The special arrangements for ventilating the working faces consist of air-pipes, partitions, compartments, parallel roads, and borings. The use of air-pipes supposes the mouth of the pipe which reaches the working face, to be received by the air-door, which can either be set up in the gallery which first receives the air current, or in the return airway. But, as a general rule, the use of air pipes is only advisable in large-sized galleries and for short distances.

Ventilating partitions offer much greater security, for by their means two independent currents of air of almost equal section, and reaching the working face, can be obtained. They are made of brickwork, boarding, and sail-cloth, either stretched on frames or hung loosely. Brickwork partitions are specially suited for long cross-cuts, and the sail-cloth arrangements for the working properly so called. The partition should naturally be kept air-tight, and approach as closely as possible to the working face.

In the deep levels and broad roads, the embankment, if sufficient, may serve for partition purposes, but an airway must be maintained in the lower part, to permit of the passage of fresh air, and the gallery proper must be intercepted by a door which will expel the foul air issuing from the working face, in the direction of the nearest heading. But in this case it is absolutely necessary that the embankments should be carefully made, and especially that a facing as smooth and impermeable as possible be made the length of the airway and also of the gallery. But in the event of a violent explosion this arrangement presents the great inconvenience of its being easily destroyed, which might result in the entire suspension of the ventilation of a portion of the mine.

When winning in fiery beds where there is an abundance of gas, it is better to proceed with the deep levels, self-acting planes, and other main galleries, and at the same time also to drive a secondary parallel gallery in the seam or rock, which should connect with the principal gallery by means of shafts which ought not to approach each other too closely. In this case it is best to forward the working face of the parallel gallery (upper) with respect to that of the main gallery (lower), but the air current ought to arrive there in the last place, in order that the gases which are liberated from it may be carried away immediately. Under some circumstances it would be necessary not to drive the two galleries simultaneously, but one after the other, and in portions. In fiery seams it is also strictly necessary to set up a ventilating partition in each of the two galleries from the last cross-cut to the face of the working. Lately, particularly in the coal mines of Westphalia, ventilating cross-cuts have been replaced by bored air-holes, which have this great advantage—that they do away with the always dangerous necessity of driving ascending galleries. But, on account of their small size, it is not usually possible to circulate the air current through them, which, in the event of an explosion, might be the cause of serious danger. Nevertheless, if by boring holes of greater diameter this defect were remedied, they would then answer all requirements.

With respect to the use, according to the different methods of working, of the various means of ventilation enumerated above, the preference is usually given to parallel roads for such operations as shafts, cross-cuts and isolated galleries; but even for these partitions, embankments, air-pipes, provided the latter were of adequate size, might suffice. In any case in fiery mines these works cannot be executed without the help of one of these means of ventilation. All airways which have become useless should be stopped up as completely and in as durable a manner as possible.

Independent Ventilation.—In spite of the attention given to the subject of ventilation, it is not always possible to efficiently circulate either the main or partial current through all the working places, without its becoming either dangerously enfeebled or else receiving a downward direction. Therefore, in narrow mines especially, it becomes necessary to supply badly-ventilated and isolated parts of the mine with independent means of ventilation. The most simple means of effecting this is the method which is adopted in fiery parts of Prussian mines—namely, that of setting up armed fans combined with pipes; but generally speaking it is the Schiele and Kittinger fans which are used for the purpose, and of late years the Pelzer fan, and in some regions the Roots fan, are also being employed.

In each particular case it is necessary to ascertain whether the fans are exhausting or blowing. As a general rule the latter are preferable, because the mechanical effect of the air-current is better able to keep the workings free from gas, and to continually convey fresh air to the miner, whilst with an exhausting fan the air, before its arrival at the working-face, has already absorbed the gases which have been liberated from previous portions of the gallery. On the other hand, it is true that the gallery itself is better ventilated by an exhausting fan. In all cases it is strictly necessary that armed fans shall only be placed in currents of pure air (Art. 20 of *Principles*). When they exhaust there must also be an air return pipe which will lead the foul air as directly as possible into the issuing current—that is to say, into the nearest channel of ventilation.

If a fan of this kind is intended to work for a prolonged period, or if it simultaneously supplies air to several workings, a mechanical motor is preferable but if steam is not to hand, recourse may be had to hydraulic turbines, aeromotors, or to electric transmissions. The numerous accidents which may result from the unsuitable position of armed ventilators, or negligence in their management, combined with their lack of usefulness for long distances, have led, since 1875, to the use, in a great number of fiery mines, of compressed air as a local means of ventilating those portions of a mine which are removed from the general current. This method possesses the great advantage of being independent of the current properly so-called, and of conveying the fresh air, without loss of time, to the working place. Also, when expanding at ordinary pressure it diffuses a refreshing coolness in the mine. It is unfortunate that this method involves great expense.

The method, formerly almost exclusively in use, which consists of simply allowing the compressed air to escape from pipes placed at the working face, may serve perfectly to dissipate the liberated gases, but from an economical point of view, it constitutes a waste of motive power, and consequently should only be employed in workings where a small amount of air only is necessary and which are situated at the end of very long galleries, or where there is a great pressure of earth.

A better use is made of compressed air by allowing it to escape by means of a narrow adjutage or pipe, and then by virtue of its great force exhaust through an open pipe, in the manner of the Giffard injector, a considerable volume of air (at least twelve times that of the compressed air). The Kœrting apparatus, where the air is introduced through several concentric adjutages is the most suitable for this purpose, but a simple and single adjutage will also suffice.

Apparatus of this sort may be used both for blowing or exhausting; for the former, the mouth of the pipe well extended should be in the current of fresh air. Of late years their use has greatly increased, particularly in the Maria Colliery, near Hoengen, Aix-la-Chapelle, and also in several collieries of Westphalia and Saxony. In connection with these an excellent arrangement (differential blowers) has been arrived at, which regulates the escape of the compressed air in such a way that the afflux of air in any working may be increased at all times according to need.

The Commission strongly recommends the use of compressed air and blast pipes as an independent means of ventilation, and also the Kœrting and other apparatus for workings which are difficult to ventilate (Art. 10 of *Principles*). Water under pressure may also in the same manner as compressed air be used to advantage in the Kœrting apparatus. At the Friedenshoffnung and Karl-George Victor Mines, near Waldenburg (Lower Silesia) an independent method of ventilation has been realized in very fiery coal-seams by means of wide blast pipes, and by artificially retaining the fresh air current, and strongly depressing the outgoing current. The fresh air current kept back by the air-doors is conducted to each working-place through wooden pipes (water level and parallel gallery), or by ordinary zinc pipes (winning). After becoming charged with the gases freed from the working, and without passing any other working-face, it is allowed to make its escape without restraint by erections superposed in the upper return airway. These air-gates are placed immediately before the last erections, so that the pipes which commence there are never very long. The erections at the back and also the self-acting plane are carefully intercepted. In order to prevent loss of air, the surplus of depression necessary for the fan to circulate the air in three self-acting planes amounts, in the Friedenshoffnung Mine, to about 12 mm. of water (37 mm. instead of 25 mm.). Although this method of independent ventilation, as compared with others in use, undoubtedly requires a great expenditure of motive power, yet the Commission recommends it on account of its excellent results in all cases where considerable volumes of air may be disposed of with adequate depression.

Explosions of Fire-Damp in Prussian Collieries in 1890.

According to official statistics concerning the coal mines of Prussia during 1890, 116 accidents occurred in consequence of the ignition of coal gas, and of these 32 were fatal and 84 non-fatal. As compared with 1889, the number of explosions with fatal results in 1890 increased by 6, and was greater than in any one of the previous five years. The number of persons killed also showed an increase over the years 1888 and 1889, but was more favorable than the average of the years from 1881 to 1890. On an average 2·44 deaths were caused by each fatal explosion; this compares with 2·62 in 1889, 3·74 in 1888, and 4·89 deaths in 1887. Moreover, the 32 mortal accidents also caused severe injuries to 8 and light wounds to 17 miners. The injuries in 69 of the non-fatal accidents were light, in 8 they were very serious, and in the remaining 7 cases they were both light and serious. Explosions took place in 79 steam coal pits out of the total of 354 operated in Prussia last year.—*Engineering and Mining Journal.*

Mr. Arthur Winslow, State Geologist of Missouri, reports that during the month of October inspections of iron ore deposits, lead, and zinc deposits and of coal beds have been made in the several districts of the State. Detail mapping has been prosecuted and over 230 sq. miles covered in Henry, Benton, and St. Francois Counties. Examinations, covering a large section, have been made for outlining the areas of the crystalline rocks, also the examinations of important clays of the State have been continued. In the office work has progressed rapidly in all the departments.

BORING MACHINE FOR TAPPING WASTES.

BY ROBERT M'LAREN.

(Transactions of the Mining Institute of Scotland).

In a working approaching an old waste known to contain water, bores must of necessity be kept in advance, and in practice it has been found that, with the ordinary method of drill or jumper, the boring of holes of over 20 ft. becomes difficult, owing to their getting stopped up with the *débris* made by the tool, and this difficulty is increased when it is necessary to have a large barrier sufficient to withstand the pressure of water behind, in order to protect the workings to the dip from being drowned. Such a difficulty presented itself at Alloa and Devon Collieries, where there are large areas of waste with water, and to tap these wastes, and leave a sufficiently strong barrier of coal, the machine about to be described was introduced by Mr. Andrew Hunter, manager of Alloa Colliery.

The machine consists of a cylinder C, 1½ inches diameter inside, with packing glands *a a*. At *b* is an opening, to which is attached an india-rubber pipe ⅜ in. diameter, fixed to pump-chest D. Two plunger-pumps *d d*, 1 in. diameter, with 1 in. stroke, are fixed to crank-spindle E, and from *c* is led an india-rubber pipe to a cistern containing water for suction. On the one end of the crank-spindle is a handle 9 inches long, with which to turn the machine, and on the other end F is the part to which the rods are attached. The whole is fixed on to a bogie G (Fig. 3), 3 ft. 6 ins. long × 2 ft. 6 ins. broad × 4 ins. deep, and running on ordinary

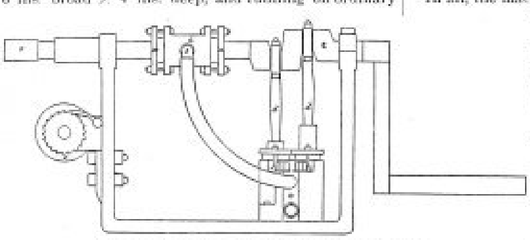


FIG. 1. ELEVATION—SCALE 1½ INS. = 1 FOOT.

cast-iron rails, and set at the inclination of the seam. In order to keep the machine moving forward while the drill is cutting, a chain ¼ in. diameter is fixed to a barrel *e* (Fig. 1), with ratched wheel, and passes round two pulleys *f g* (Fig. 3), 6 ins. and 10 ins. respectively, fixed to prop *h*, and a weight *j* is hung upon a hook at the other end of chain. This hook is so made that a number of similar weights can be placed upon it.

Rods. The rods, which are hollow, are ¾ in. diameter outside, with ¼ in. diameter hole inside, and in 6 ft. lengths. A box F (Fig. 1) is put on the crank-spindle, into which the first rod is screwed with ⅞ in. diameter screw. The other rods are screwed into each other, as is done in the ordinary method of boring. The drill K (Fig. 3), which is also hollow, is 1½ in. outside diameter,

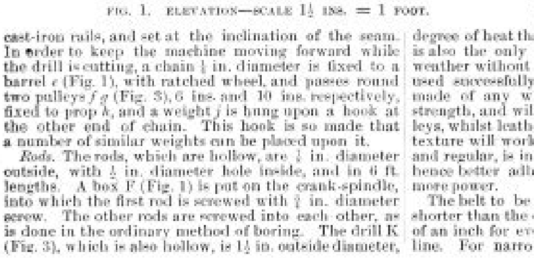

FIG. 2. PLAN—SCALE 1½ INCHES = 1 FOOT.

and of the ordinary description, as used by miners for drilling holes, except that 1½ in. from the point is the hole to allow the water to escape.

Where water enters from pumps at *b* are four small holes drilled through crank-spindle into the hollow—the hollow being continued right out to F. A groove *b b* (Fig. 4) is also cut, into which a set pin *m* (Fig. 2) is screwed to keep cylinder C in its place.

Mode of Application. In applying the machine, the handle is turned, which works the cranks, and water is pumped into cylinder C and forced into hollow rods

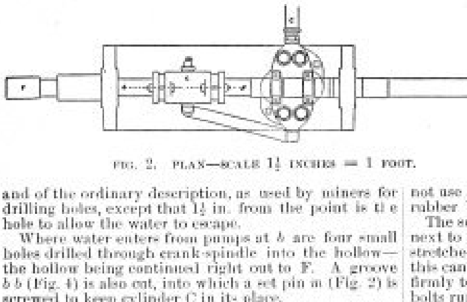

FIG 3. SCALE ½ INCH = 1 FOOT.

to drill-point, and is discharged at the circumference of rods, carrying the *débris* which has been made with it. As the drill cuts, the machine moves forward, and is kept from going back by ratched wheel. When 6 ft. has been cut, the machine is unscrewed from rods, and run back, and another rod fixed. Care must be taken in cutting the rods not to allow them to become empty of water, as, if this is not guarded against, they get filled with small coal and *débris*, and have to be drawn. To prevent this, a small plug is inserted at part where rods are cut. Should the weight *j* reach the floor before the machine is up distance, it is taken up by turning the ratchet handle.

Work performed by the machine. Holes have been bored at Devon and Alloa Collieries. At the former there is a large area of waste in the lower 5 ft. coal, with a pressure of 135 lbs. per square inch, and waste has been tapped at several places—the greatest distance bored for one hole being 168 ft., 50 ft. of which passed through a hard sandstone. Up to 20 ft. or so, two men can easily

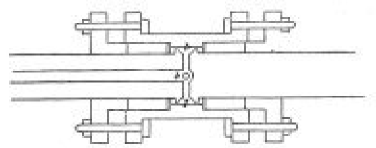

FIG. 4. SECTION THROUGH LINE A B ENLARGED.

bore one foot per minute, while 30 yards, on an average, can be bored in a shift of eight hours by two men. The following is section of seam bored :

Sandstone.	
Blaes	1′ 8″ to 6′ 0″
Cherry coal	0′ 7″
Splint coal	1′ 1″
Cherry coal	0′ 7″
Daugh	0′ 1″
Cherry coal	2′ 0″
Fire-clay.	

In all, the machine has bored in this seam holes to an aggregate distance of 900 yards.

At the latter colliery, three holes were put in, at different angles, a total distance of 46 yards in lower 5 ft. coal in eight hours by four men, which included the shifting and fixing of the machine.

THE USE AND CARE OF RUBBER BELTING.

BY C. A. DANIEL.

Rubber belting properly-made is more uniform in thickness, will endure without injury a greater degree of heat than belting made of other material, and is also the only belting that can be exposed to the weather without injury, and can at the same time be used successfully in damp or wet places. It can be made of any width and thickness, and of uniform strength, and will always run true and smooth on pulleys, whilst leather belting of different thicknesses and texture will work unevenly. Its surface, being smooth and regular, is in more perfect contact with the pulley, hence better adhesion, resulting in the transmitting of more power.

The belt to be adjusted to the pulley should be cut shorter than the distance around the pulleys by ½ to ¾ of an inch for every foot, when measured by a tape line. For narrow belts, butt the two ends together, making two rows of holes in each end (thus obtaining a double hole), and lace with lacing leather. For wide belts in addition, put a thin piece of leather or rubber on the back to strengthen the joint, equal in length to the width of the belt, and sew or rivet it to the belt.

If the belt should slip, from dust or other causes—which seldom happens—moisten it lightly on the side next the pulley with boiled linseed oil. If one application does not produce the desired effect, repeat it. Do not use animal oils or grease, as they are injurious to rubber belts.

The seam side of the belt should never be placed next to the pulley. In putting on belting it should be stretched as tightly as possible; and with wide belts this can be done best by the use of clamps secured firmly to each end of the belt, and drawn together by bolts running parallel with, and outside the edges of the belt.

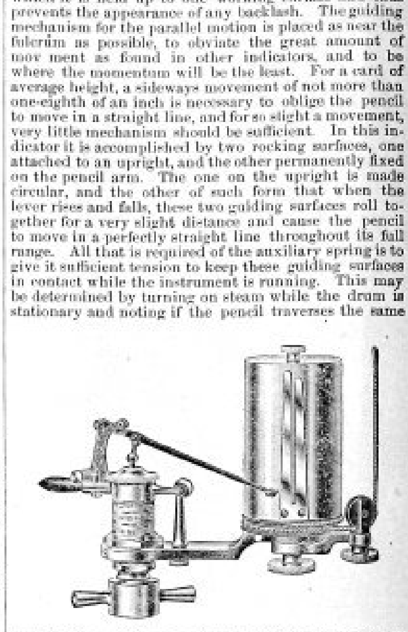
The belts will be greatly improved and their durability increased by putting on with a painter's brush, and letting it dry, a composition made with equal part of red lead, black lead, French yellow and litharge mixed with boiled linseed oil and japan enough to make it dry quickly. This will produce a finely polished surface. A coat of the same composition may be applied, should the rubber get peeled from the surface of the belt.

If the belt is to be shifted from one pulley to another, rollers should be placed on the shipper on each side of the belt in a diagonal position, bringing the upper ends of the rollers as near together as possible to clear the belt, and diverging from each other as far as may be; this plan slips the belt much easier than the old method and entirely prevents the liability of injuring the edge.

The "Quaker City" and "Crown Brands" of rubber belting, furnished by the Quaker City Rubber Co., of Philadelphia, are both high grades and are thoroughly warranted. They are made with a special view to the requirements of mine work and they are now in use at many collieries at all of which they are giving satisfaction, as they are thoroughly warranted and the user takes no risk. Price-list and discounts will be cheerfully furnished by the Quaker City Rubber Co., of 313 Market Street, Philadelphia, whose advertisement appears on another page.

The Straight Line Indicator.

The peculiarity of this indicator lies in the simplicity of its parallel motion and in the auxiliary spring by which it is held up to one working surface and thus prevents the appearance of any backlash. The guiding mechanism for the parallel motion is placed as near the fulcrum as possible, to obviate the great amount of movement as found in other indicators, and to be where the momentum will be the least. For a card of average height, a sideways movement of not more than one-eighth of an inch is necessary to oblige the pencil to move in a straight line, and for so slight a movement, very little mechanism should be sufficient. In this indicator it is accomplished by two rocking surfaces, one attached to an upright, and the other permanently fixed on the pencil arm. The one on the upright is made circular, and the other of such form that when the lever rises and falls, these two guiding surfaces roll together for a very slight distance and cause the pencil to move in a perfectly straight line throughout its full range. All that is required of the auxiliary spring is to give it sufficient tension to keep these guiding surfaces in contact while the instrument is running. This may be determined by turning on steam while the drum is stationary and noting if the pencil traverses the same



vertical line. This spring is intended also to take up all play that may ever appear in the joints and oblige the pencil to always follow in the same path. The first indicator made was subjected to the test of being run continuously, nine hours a day on a high speed engine, for over a month, and showed no appreciable wear, as what there may have been was taken out by the auxiliary spring, and the instrument improved if anything by this hard usage.

The effect of the auxiliary spring on the main spring is to weaken it. This allowance is made in numbering the spring, and the scale of spring, therefore, is the net resistance of the two springs.

The moving parts of the instrument are the lightest weight of any straight line indicator, and that weight is disposed so near the fulcrum that its little movement makes the momentum very little, and specially adapts it for the highest speeds.

Any one wishing any further information relative to the Indicator can obtain it by addressing Messrs. Hine and Robertson, 45 Cortlandt St., New York, who are introducing it.

Mine Pumps.

Not every steam pump, even if its capacity and power are fully up to the requirements, is adapted to mine work. To be durable and efficient, mine pumps must be specially constructed to meet the conditions existing in mines. The celebrated "Yough" pump, manufactured by Messrs. Boyts, Porter & Co., of Connellsville, Pa., is specially constructed for this work, and the result has been that the "Yough" pump is rightfully regarded a great success.

Hundreds of them are now in use in all parts of the country, and as the mine workings of the purchasers are extended and greater pumping facilities are required, they invariably duplicate their orders, if they do not order the same type or pump of larger size.

They are constructed with large ports, and they thus permit solid substances that may be in the water, to pass through without injury to the working parts.

Where the mine water is acidulated special provisions are made to counteract its deleterious action on the metal. As an evidence of the superiority of the pump, Capt. Boyts informs us that they have just shipped the following large pumps to companies that have used the "Yough" pump for years:

One to the Lemont Mine of the McClure Coke Co., which has a 24″ steam cylinder, a 10″ water cylinder and 30″ stroke.

One to the Hecla Coke Company's, new plant, at Hecla, 26″ steam cylinder, 16″ water cylinder, and 48″ stroke. This is one of the two largest pumps in the Connellsville region and is a duplicate of one furnished the same company nearly two years ago, for the Trauger Mine.

One to the H. C. Frick Coke Company's Standard Mine at Mount Pleasant, with 26″ steam cylinder, 14″ water cylinder and 48″ stroke. This is the third of the same type and size furnished for this mine.

They have also just completed a large pump, for the Cambria Iron Company's Morell Mine, of the following dimensions: 32″ steam cylinder, 14″ water cylinder and 48″ stroke. They have also just secured an order from the Tennessee Coal, Iron & R. R. Co., for a Yough pump with 26″ steam cylinder, 12″ water cylinder, and 48″ stroke, for Pratt Mines, Tennessee. The constant duplication of orders on the part of old customers, Capt. Boyts considers the best proof of the efficiency, durability, and economy of the Yough pump.

USEFUL INFORMATION

Birds and the Statue of Liberty Light.

A few evenings ago I took the steamer, with a party of naturalists, to Bedloe's Island, as the electric lights at the top of the statue are known to attract multitudes of birds every Spring and Fall. There had been cold weather for a few days before, and millions of birds were hastening South. We obtained a permit, and went up to the topmost gallery of the statue, and waited. The night had not far advanced when all the heavens seemed to become full of wings, which produced a tempest of whirring sound. Then came the calls of the leaders, and they rang out so clearly that they could be heard for half a mile through the storm. The responses were fainter than the signaling cries, but they were quite definite. The object of the calls, of course, was to keep the flocks together, for, as could be seen through strong glasses, birds of a hundred species were driving along on the breast of the storm. All that came near the statue hovered around the light in large circles, but some of them struck against the bronze or stone. There were sand-pipers of every kind, "peeting, peeting," as they went; golden wings and other wood-peckers, with their loud and rather hoarse cries; warblers of every kind—and their signaling ran through a wide gamut of sounds—thrushes, robins, meadow-larks, nuthatchers, and congregations of bobolinks that filled the air with hurricanes of lovely music as they swept by. Sometimes a huge black cloud passed along, and the glasses showed that they were blackbirds, but they did not chatter as they do on the edge of the forest. The leaders made all the noise and preserved order. I know not how many flocks went by of teal, wood-duck, black duck, mergansers, curlew, snipe, plover, pewees, phœbebirds, and what not; but none could mistake the kingfishers as they went, with their scolding laughter, through the dark.

We caught a score or so of the birds in nets and in our hats, and kept them till the morning, after which we released them. And all through the night bats chased and feasted upon the silly moths that gathered around the spikes of electric flame.

A large number of birds lay dead upon the grass in the morning, having struck the statue. One morning, shortly after the statue was put up, over a thousand birds were picked up; but latterly they seem to be aware of the danger, and not nearly so many are killed against this tall obstruction.—*Edmund Collins, in Harper's Weekly.*

Result of a Superstition.

In China, dead ancestors are held in peculiar and profound reverence. This feeling is sometimes manifested in ways which excite ridicule in more enlightened people. For instance, to cast a shadow upon the grave of an ancestor is considered an insult of so heinous a character that it cannot be permitted to pass unresented. The occupant of the grave is supposed to be disturbed and made uncomfortable by the shadow, and it is superstitiously believed that unless his living descendants protect him against such an indignity, he will make it hot for them both in this life and in the life to come.

This superstition leads to practical difficulties. There being no cemeteries or public burial grounds in China, the dead are buried on the family premises, hence every yard or garden is a receptacle of ancestral remains. When it is remembered how populous China is, and how long the processes of burial have been going on within its domain, it is easy to imagine that the remains of ancestors are sown so thickly that it is difficult to avoid casting a shadow on some carefully-watched grave.

This state of things led, in one instance, to results which were both amusing and beneficial. When the first electric telegraph company in China began to establish its lines, the linemen planted the poles as they had been accustomed to do in other countries. To their surprise, bands of infuriated Chinamen would rush upon certain poles, cut them down, and menace the linemen with bodily harm in case they should set the poles up again. The cutting down of poles was so frequent that it was impossible to establish the line. At first the telegraph men did not know why the Chinamen cut down the poles. But, on investigation, it was found that it was because the doomed poles, at some time in the day, cast shadows on the graves of revered ancestors of the indignant pole cutters.

The telegraph company sought to overcome the opposition of the superstitious Chinamen by persuasion and argument, but their efforts were in vain. They then tried bribery, which was equally futile. The superstition was found to be so deep-seated and so sacred that nothing could overcome it. The result was that the telegraph wires had to be laid under ground, and the Chinese escaped the nuisance of having the streets of their cities and the country at large stuck over with unsightly telegraph poles. Thus did superstition in heathen China effect what public indignation and the power of the courts have not been able to accomplish in this Christian land.—*New York Ledger.*

Four Hundred Millions of Silver.

The Treasury of the United States had in store on the 1st of October, 1891, 348,341,193 silver dollars; $15,848,620 in the form of subsidiary silver; silver bars to the value of $41,579,253; trade dollars (bars), $2,394,260—total $409,161,326, or, in round numbers, $400,000,000. The government, furthermore, is increasing this immense store by buying seven additional tons of silver every working day in the year.

Now what does $400,000,000 worth of silver mean? Stated in figures, or expressed in words, it conveys to minds as ordinarily constituted no definite idea other than that of an incomprehensible something, endowed with certain potentialities—possibly for good, possibly for evil. Yet silver is a physical entity, possessing the properties of length, breadth, thickness, capacity to occupy or fill space, and weight. Let us apply these properties to the $400,000,000, and note some of the results of such application.

Coined into dollars, the product will weigh over 22,000,000 pounds avoirdupois, or 11,000 net tons; and if its movement is desirable, will necessitate for so doing the use of 1,000 railroad freight cars carrying eleven tons each, or 2,200 cars carrying five tons each, or 5,500 two-horse wagons carrying each two tons.

A cubic inch of pure silver weighs about 0·28 pounds, and a cubic foot about 637 pounds. Hence the $400,000,000, if melted into a solid mass, would occupy some 33,590 cubic feet, which in turn would make a solid column of pure silver a foot square and about 6½ miles high—the Washington Monument being 550 feet. Assuming a load of 100 pounds per man, an army of 220 000 men would be required to carry the mass, and would make a file, in close order, 80 miles long, occupying 30 hours in "passing a given point," allowing nothing for halts or "rests."

The Treasury counts its silver by weighing it, which is the part of wisdom, in view of the fact that a man counting at the rate of 200 dollar pieces per minute, steadily for eight hours a day, Sunday included, would be kept busy for considerably over eleven years.

Piled upon one another, the $400 000,000 would attain a height of 675 miles; and placed side by side, they would carpet a room 50 feet wide and nearly 24 miles long.

Great, however, as is the mass of silver at present in the "treasure-houses" of the government, it is being steadily increased by the purchase of 54,000,000 additional ounces every year, or at the rate—as before stated—of seven tons for every working day of the year.—*David A. Wells, in Harper's Weekly.*

How Playing Marbles are Made.

Nearly all the common marbles which drag down the pockets of our boys are made in Oberstein, Germany. They are made from the refuse of the agate and stone quarries in that neighborhood. The stone is broken into small cubes by blows of a light hammer. These small blocks of stone are thrown by the shovelful into the "hopper" of a small mill formed of a bed of stone having its surface grooved with concentrated furrows; above these is the "runner," which is made of hard wood having a level face on its lower surface. The upper block is made to revolve rapidly, water being delivered upon the grooves of the bed-stone where the marbles are being rounded. It takes about fifteen minutes to finish a bushel of good marbles ready for "snapping." One mill will turn out 170,000 marbles per week. The very hardest "crackers," as the boys call them, are made by a somewhat slower process, somewhat analagous, however, to the other.

How Congress Carries on its Work.

In the days of the famous statesmen sketched and delineated by Oliver Dyer in his "Great Senators of the United States," transcendent ability and personal greatness exercised a controlling influence in the halls of Congress. When Calhoun, Benton, Clay, or Webster supported a measure, it was understood that he had made himself familiar with all its bearings and was advocating it because he believed its passage would conduce to the welfare of the country. Moreover, he was acknowledged as a leader; his followers had faith in him, and his eloquence and his arguments had a powerful influence upon the minds of his colleagues.

In those days the bills which came before Congress were so few that whenever a measure of vital interest was introduced it was possible for a great party leader to examine it critically and give ample time to its consideration. Now it is different. The calendars of the Senate and the House of Representatives are so loaded down with important bills that it is physically impossible for anybody to master the details of even a moiety of them. Hence, as a matter of necessity, the work of examining them is divided up between the committees of either House. Every measure is referred to the appropriate committee; the committee examines and reports upon it, and if the report be unanimous, it is usually accepted as conclusive, and the bill is passed or rejected in accordance with the report. The influence of the committees has become so controlling that the constitution of them is of vital importance. They are appointed by the presiding officer of either House—the President of the Senate or the Speaker of the House of Representatives.—*New York Ledger.*

The Story of the Obelisk.

At Heliopolis was the Temple of the Sun, and the schools which Herodotus visited "because the teachers are considered the most accomplished men in Egypt." When Strabo came hither, four hundred years later, he saw the house which Plato had occupied; Moses here learned "all the wisdom of the Egyptians." Papyri describes Heliopolis as "full of obelisks." Two of these columns were carried to Alexandria 1937 years ago, and set up before the Temple of Cæsar. According to one authority, this temple was built by Cleopatra; in any case, the two obelisks acquired the name of Cleopatra's Needles, and though the temple itself in time disappeared, they remained where they had been placed—one erect, one prostrate—until in recent years, one was given to London and the other to New York. One recites all this in a breath in order to bring up, if possible, the associations which rush confusedly through the mind as one stands beside this red granite column rising alone in the green fields of Heliopolis. No myth itself, it was erected in days which are to us mythical—days which are the jumping off place of our human history; yet they were not savages who polished this granite, who sculptured this inscription; ages of civilization of a certain sort must have preceded them. Beginning with the Central Park, we force our minds backward in an endeavor to make these dates real. "Homer was a modern compared with the designers of this pillar," we say to ourselves. "The Mycenæ relics were *articles de Paris* of centuries and centuries later." But repeating the words (and even rolling the r's) are useless efforts; the imagination will not rise; it is crushed into stupidity by such a vista of years. As reaction, perhaps as revenge, we flee to geology and Darwin; here, at least, one can take breath.—From "Cairo in 1890," by Constance Fenimore Woolson, in *Harper's Magazine* for November.

European Industrial Schools.

In almost all the manufacturing towns of Europe during the last half century schools have been opened for apprentices in the industrial arts. In Russia there are no less than 1,200 of these schools, with 20,000 pupils. Among justly celebrated preparatory schools are found the Ambats school at Amsterdam, the technical school at Birmingham, Heriot's Hospital of Edinburgh and the St. Luc schools at Belgium. All agree that industrial education can only be really given in a workshop, where teachers will be able to instruct pupils by means of practical demonstration and by sketches of designs. At Birmingham and Edinburgh pupils are admitted to technical schools, which are considered merely as a sort of primary industrial schools, where very fine chemical and physical laboratories are at their disposal, and in which they acquire a certain practice in preparation for industrial work. Belgium has founded thirty-six industrial schools, in which are given every evening, and on Sundays, the elements of scientific and artistic knowledge corresponding to the profession of those who frequent them. The number attending exceeds 25,000. In both England and Belgium the number of pupils in proportion to the population is about the same, that is, 42 to each 1,000. In Holland there are thirty-two industrial and twenty-five professional schools, attended by about 7,000 pupils. Switzerland has no less than eighty-seven schools, giving to apprentices and workmen professional instruction. The pupils number 8,000. In Denmark, a country of 2,000,467 inhabitants, there are seventy-seven schools for professional instruction of workmen, with more than 6,000 pupils. The technical school of Copenhagen alone numbers no less than 2,000. In Sweden there are twenty-eight industrial schools; that of Stockholm has 800 pupils, more than one half per cent. of the population of the town. Italy, which in 1885 had 136 industrial and art schools, with 16,274 pupils, has since then made great progress; but she is suffering, as England sometimes suffers, from an excess of manufactured articles, and these must be disposed of at any price in order to avoid a ruinous embarrassment. Hamburg, under the direction of Marius Vachou, has the best institution in Germany, both on account of the principles which inspired its creation and the methods of instruction. In entering there, if the pupil is neither an apprentice nor workman, he must choose a trade. A law of the Hamburg senate imposes on all industrial superintendents the duty of sending their apprentices to this school for six hours every week. The first part of the first year is exclusively devoted to the study of the primary elements of drawing. All drawings must be made from nature. After that comes instruction from professional designs. Each pupil receives instruction, personal, varied, and rapid, according to his temperament and taste. The discipline is very severe, so that the pupil becomes accustomed to conduct himself as a serious man, and to consider work as a social duty. The Hamburg school has served as a model to the schools of designs in various parts of Europe.—*Translated for Public Opinion, from the French of Edmond Planchut, in the Revue des Deux Mondes.*

MECHANICAL NOTES

Iron Buildings.

Notwithstanding the great value of iron as a material of construction for certain purposes, we think that in this country, where more iron buildings, perhaps, have been erected than in all other countries put together, there is a strong feeling among architects that they have had their day; and that a better, safer, and more durable structure can be made by combining masonry with iron than by using the metal as the only, or even the principal constructive material. In other countries, and especially in France, where iron construction is now applied to all sorts of new uses, it has the charm of novelty, and is often spoken of as the universal material of the future; but most experienced American architects have seen too many iron columns honeycombed with rust, and girders with half the thickness of the webs separating in flakes, to wish to entrust their reputation to such perishable material, while our fire engineers have thoroughly satisfied themselves that an iron building of the ordinary sort is less capable of resisting a severe fire than one of almost any other material. Among the engineers, a similar distrust of iron for construction exposed to the weather has become very general. Two serious accidents have shown that the life of a suspension bridge, with either wire or chain cables, is only about 40 years, and some recent examinations of plate-girder bridges have shown that, in about the same length of time, the web plates, notwithstanding careful and often-repeated painting, are eaten nearly or quite through, by corrosion, which works unobserved beneath the paint. The contrast between bridges which perish in a generation, and those which, like several of the masonry bridges built by the Romans, have been in use for nearly 2,000 years, and are still in excellent condition, is too striking not to attract the attention of intelligent engineers, and the next decade is likely to see brick and stone extensively used for railway bridges, to the great advantage of the landscape in the neighborhood. Already, it is said that the officials of the Pennsylvania Railroad, which has always led in scientific engineering, have given orders that no more iron bridges shall be built on the road, and the children of the present stockholders will probably have reason to rejoice at the decision.—*American Architect.*

Rolling Hollow Staybolts.

The rolling of hollow staybolts is an industry recently introduced, and claimed to possess special advantages. In this process, two pieces of iron rolled in U-shaped section, are laid together and wired in that position, these parts being then heated to a welding heat and run through rolls, and, as the welded tube comes from the rolls it passes over a mandrel, which fills the interior; before reaching the second pair of rolls it cools slightly and shrinks upon the mandrel, and in this pair of rolls it is drawn from the mandrel and the interior cleared. In this way, by five repeated operations, a hollow staybolt is obtained, which has a uniform interior diameter. The material must necessarily be the very best quality of charcoal iron; the bolts are made in lengths of six feet, and it is alleged that a considerable saving in expense is made by using hollow staybolt iron, instead of drilling the ends of the bolts after they are in position.

Action of Oils on Metals.

A series of tests, lasting some twelve months, on the action of various oils on metals in contact with them, recently carried out, gave the following results: In the case of iron, seal oil acted the least on it and tallow the most. Bronze was not attacked at all by colza oil, and but very slightly by olive oil. It was, on the other hand, vigorously eroded by linseed oil. In the case of lead, the most deleterious lubricant was whale oil, the best, olive oil. Whale, lard, and sperm oils were about equally erosive. Zinc seemed to be little attacked by mineral lubricant oils. The best oil was lard, and the worst, sperm. Copper was not attacked by any of the mineral oils. Sperm oil had the least and tallow the most action on it. Generally speaking, mineral oil attacked the metals under test, the least, and sperm oil attacked them the most. In conducting the experiments, the metals were first thoroughly cleaned in ether and then dried. They were next carefully weighed and placed in closed vessels filled with oil, which were kept for a year at a uniform temperature in summer, of 80° F. and in winter, of about 50° F.—*Metal and Iron Journal.*

Wolfram Mining.

Wolfram, or tungsten, belongs to a group of rare metals, and, until a comparatively recent time, was known only to the chemist, and its value was known only in the laboratory. With the invention of 100-ton guns the demand for tungsten soon made the previously obscure metal well known throughout the mining world. It was soon found that the steel tube lining the bore of these enormous guns could not resist the shock entailed by discharging many shots without becoming fractured. Experiment proved that the addition of a small quantity of tungsten to the fine steel employed in gun-making rendered the latter metal wonderfully elastic, so that the steel tube will expand under the tension of firing and contract again to its normal size a great many times before the quality of the metal is in any way impaired. The German gun factories absorb most of the tungsten found in the world, and from being a mere curiosity seen only in the laboratory of the chemist, this rare metal has acquired considerable value. Wolfram generally occurs in combination with iron in Europe, but it is also found in Scheelite, or tungstate of lime. It is in the latter form that it occurs in Otago. The metal itself is of a white color, extremely brittle and heavy, the specific gravity being 19·1, that of gold being 19·3. It will thus be seen than tungsten is a very heavy metal, being only very slightly lighter than gold.—*New York Ledger.*

Nuts.

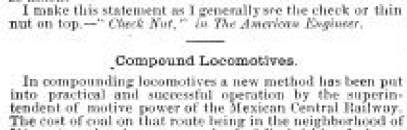
In looking over your correspondence column I am reminded of a problem that I think is generally misunderstood by mechanics. The problem is the use of double nuts on a bolt. One of the nuts is used as a check or jam nut and need be only ¼" or less in thickness except for convenience in not requiring a special wrench too thin for any other use. In theory the number of threads in the check or jam nut need only be sufficient to stand the strain that would usually be applied to the wrench in setting the nut as a check or jam.

The top nut is usually called the check nut whereas the bottom one is the check nut, and when set, prevents the top one from unscrewing. There is no weight or strain on the thread of the bottom nut due to the weight that is being held up, the thread of top nut holds the entire weight. The material in the bottom nut outside of the thread supports the top one and is of use only as a check or jam nut. When double nuts are used on large bolts it is more important to understand the problem as the cost is increased so much.

I make this statement as I generally see the check or thin nut on top.—"*Check Nut,*" *in The American Engineer.*

Compound Locomotives.

In compounding locomotives a new method has been put into practical and successful operation by the superintendent of motive power of the Mexican Central Railway. The cost of coal on that route being in the neighborhood of $11 per ton, the plan was conceived of diminishing fuel consumption by the introduction of a compound system, in which the high pressure cylinder is encircled by the low pressure cylinder. In this arrangement the high pressure cylinder is fourteen inches in diameter, and the low pressure a diameter of thirty and three-fourths inches, which is equal to a cylinder twenty-four and one-fourth inches in diameter. The stroke is twenty-four inches, and the two rods of the low-pressure piston are coupled with the single high-pressure rod to one crosshead. It appears that in a competitive test of twelve trips with a single engine the compound locomotive showed economy in fuel of about twenty-five per cent.—an important economy on a road where the fuel account is the largest item of operating expenses, being twenty-two per cent. of the total.—*New York Sun.*



Insomnia and Its Therapeutics.

Dr. Macfarlane, Fellow of the Royal College of Physicians, Edinburgh, has written a monograph upon the causes and remedies for insomnia. He outlines the hypotheses of many students who have made a specialty of investigating the phenomena of sleep, and a great part of the discussion is devoted to describing and differentiating the symptoms of sleeplessness. This he pronounces not a disease, but a symptom of many diseases differing widely in complexity and gravity. The paradoxical statement is made that women require more rest than men, and yet at the same time they "bear loss of sleep better—for a time—than do men." In reference to the habit of sleep, the writer quotes the example of the Iron Duke, who could induce sleep at will and preferred to rest in a narrow bed, believing that when it was time to turn over it was time to turn out.

Insomnia from over-cerebration is discussed in a chapter upon sleeplessness from disorders of the nervous system. Sea bathing, change of scene and of occupation, instantaneous stopping of work, are the remedies proposed, for in such cases medicine does little for the tired mind. Dr. Macfarlane does not lay claim to any new suggestion as a cure for sleeplessness, but he gives a careful resume of the therapeutics of the subject.

To Promote Sleep.

How to get to sleep is a matter of high importance to many persons besides yourself. Nervous persons who are troubled with wakefulness and excitablity usually have a strong tendency of blood to the brain, with cold extremities. The pressure of blood on the brain keeps it in a stimulated or wakeful state, and the pulsations in the head are often painful. Let such rise and chafe the body and extremities with a brush or towl, or rub smartly with the hands to promote a circulation and withdraw the excessive quantity of blood from the brain, and they will fall asleep in a short time. A cold bath, or a rapid walk in the open air, or going up and down stairs a few times, just before retiring, will aid in equalizing circulation and promote sleep. These rules are simple and easy of application in castle or cabin, and may minister to the comfort of thousands who would freely expend money for an anodyne to promote "Nature's sweet restorer, balmy sleep."

To Prevent Consumption.

At a time when so much is said about Koch's cure for tuberculosis, it may be worth while to call attention to the remarks of Mr. G. W. Hambleton, at the meeting of the British Association. He pointed out that consumption was a disease of civilization, produced by causes which reduced the standard breathing capacity below a certain level. To prevent this disease it is necessary to use the body to the extent its strength demanded, and to see that the work it had to perform was carried on under conditions favorable to the body. It was also desirable so to arrange habits and surroundings that their tendency as a whole should be to develop the lungs. Close and badly ventilated or heated rooms, occupations which involve stooping and cramped positions, corsets, tight-fitting clothes, should be avoided; "nipping" should also be prohibited; as much time as possible should be spent in active exercise in the open air; bedrooms should be well ventilated; wool should be worn next the skin; the body should be held erect; deep inspirations in breathing should be taken through the nose, and the cultivation of all kinds of athletic exercise should be encouraged. But above all, he considered a great deal depended on prompt and early treatment of the victims of consumption.—*New York Ledger.*

A Sea Trip for Health.

When exhaustion has gone so far as to produce a condition of positive breakdown without any special organic lesion a sea trip is in most cases to be preferred to any alternative. The patient has the advantage of perpetual carriage, exercise without the irksomeness of restrained posture and without its limitation to a few hours of sunshine. The chilling effects of night air and alternations of dryness and dampness of atmosphere are almost unknown at sea, and a recovery may in such cases usually be predicted as following almost certainly a few weeks on shipboard. But it is to the middle-aged man more than all others that a holiday at sea is recommended. In the great majority of cases a man who leads an active business or professional life selects his form of holiday as much for what he gets away from as for what he gets to. The desire to get out of harness and to escape from the weary treadmill of the recurring cares, from which few active men are free, is never better met than by a voyage. To such men exercise is a secondary consideration. Fresh air and the incidents that vary the monotony of sea life are sufficient to give all the benefits that any change can give, while the gentle exercise of walking the deck is sufficient to stimulate the appetite and promote digestion. The impossibility of doing anything more energetic than walking the deck is a safeguard to persons of this class; for, after the first flush of youth is over, the sudden transition from a sedentary life to severe exertion is more apt to be attended with risk than with benefit.

Prevalence of Diphtheria.

The Milroy lectures this year were on the natural history and prevalence of diphtheria. The lecturer gave it as his opinion that soil and geological formation have something to do with its prevalence; that it is especially common in damp valleys, and that in England it is most prevalent during the last three months of the year.

The greater number of persons attacked are between 2 and 12 years of age, and the liability is greatest between 2 and 5 years.

Many attacks of diphtheria are accompanied by simple sore throat and tonsilitis, and many apparently simple attacks of sore throat have really an infectious character. The same fact has been noted on this side of the Atlantic.

Some physicians look on diphtheria and scarlet fever as modifications of the same disease, and the occurrence of both at the same time in the same family seems at first sight to countenance this view. But the theory is disproved by the entire absence of diphtheria in several thousand cases of scarlet fever treated in the London Fever Hospital.

The probable explanation of the occurrence of both in the same family is that the condition of the throat in a family effected by scarlatina affords a soil favorable for the reception of the diphtheric poison.

When diphtheria does occur in connection with scarlatina, it is almost always as a sequel to it. So, too, the sore throats due to bad hygienic surroundings and imperfect drainage furnish excellent soil for diphtheritic microbes.

Many cases of diphtheria end unexpectedly in fatal heart failure, sometimes when the patient has seemed in a fair way to recovery. In such cases a postmortem examination reveals a fatty and granular degeneration of the muscular fibres of the heart.

This fact emphasizes the need of prompt treatment to secure the speediest possible recovery. It follows, too, that in all cases, until complete recovery, everything should be avoided which makes demands on the heart, a very slight effort often being fatal: and that the physician should always make a careful examination of the heart, and advise accordingly.—*From the Youth's Companion.*

The Use of Pillows.

A pillow is a necessity; but care and judgment should be exercised in its use. No mere matter of habit is the use of a pillow. It has a physiological basis. We sleep, for the most part, on the side, and without a pillow the head would be uncomfortably and harmfully lower than the body. It will be remembered that Jacob, when fleeing from Esau, took a stone for a pillow. He needed something for the purpose, and nothing better than a stone presented itself. Such practices are common in Africa at the present day.

Some people rest the neck instead of the head on hard pillows. In Africa extraordinary headgears make this practice necessary, and many a civilized women has been compelled by a somewhat similar coiffure to forego both the pillow and the recumbent posture. The consideration of the physiological reasons for pillows will suggest their proper thickness. They should merely bring the head to the natural level. Some pillows are much too thick. By bending the neck unduly they interfere with the outflow of the venous blood from the head. The pillow that just fills up the space above the shoulder best suits its end.

Again, pillows of feathers are objectionable. While they furnish the needed support for the head, they are too heating as they have a remarkable capacity for holding and accumulating heat.

It should be remembered that more blood, and hence more heat, goes to the head than to any other part of the body. Head heating pillows are against the wholesome maxim: "Keep the feet warm, but the head cool." There is nothing better than the hair pillows.

Further, the pillow is for the head, not for the shoulders. To rest the shoulders on the pillow defeats the very end for which it is used.

Finally, special care should be taken of infants in this matter. We have seen their heads sunken deep into the softest and thickest of pillows, and their faces, as a natural consequence, covered with great beads of perspiration. It is no wonder that children so treated die.

Ventilation of School Rooms.

In an article in the American *Engineering Magazine*, on ventilation, Mr. Laurence Allen contends that in very many schools the quantity of pure air admitted is not sufficient to expel the foul air. To maintain the air in a good sanitary condition in a properly constructed school room, his experience confirms the amount required as stated by Billings, to wit, 60 cubic feet of air for each occupant per minute. For 100 pupils this amounts to 360,000 cubic feet per hour. There are many schools that contain 100 pupils and do not introduce more than 25,000 feet of pure air per hour, and even that is rendered in a measure ineffective, because the air is not properly admitted. "The pupils," Mr. Allen says, "do not die in the poisoned atmosphere; many of them will appear reasonably healthy. So do many persons who visit and tarry in malarial districts. But though the effects are not immediate and striking, they are sure, permanent, and easy to be traced to their causes, in after years, by those who make a study of disease and its causes. It is scarcely less humane to kill a child than, by willfully ignoring sanitary requirements, to cripple it for life, physically, mentally and morally, as children are being crippled to-day in the vile atmosphere of many schools."

Electricity in Horticulture.

Because the entire animal creation gets tired and seeks periods of rest, it has been popularly supposed that the vegetable creation also gets tired in its efforts at growth, and would be overwrought were it not for the periodic torpidity which the darkness of night brings upon it; hence it has been believed for ages that the growing products of the vegetable kingdom require periodic exemption from the stimulus of sunlight. But experiments which have been made in Europe and in this country, notable at the Cornell Agricultural Station, show that this popular belief has no foundation in fact.

In these experiments a variety of plants has been kept under continuous light for long periods, by turning on electric lights from sundown to sunrise. The results of these experiments are remarkable. They show that periods of darkness are not necessary to the growth and development of plants; that plants do not need rest at night in the sense in which animals need rest; that there is no such thing as a plant becoming worn out or tired out in consequence of the stimulating influence of continuous light.

Plants have a faculty—which some writers call "the vegetable instinct"—of making the best of their situation. Within the temperate zones they have simply adapted themselves to the conditions of alternating light and darkness. During the day they assimilate or make their food, and during the night, when the process of assimilation is stopped, they use the food in growth. But in the Arctic regions, where, during the prolonged days of summer, plants are in almost continuous light, they grow without periods of rest.

By means of the varied and numerous experiments with electricity which scientists have already made, it has been discovered that if plants are kept under continuous light, although the process of assimilation is not stopped, the growth of the plant goes on even more rapidly than it goes on in the darkness of night, the electric light not only promoting assimilation, but often hastening growth and maturity. It has also been demonstrated that the electric light is capable of producing natural flavors and colors in fruit, and that it often intensifies the color and sometimes increases the production of flowers.

The scientific deduction from these facts is that there is good reason for supposing that the electric light can be profitable used in horticulture as soon as the details of its application shall be practically wrought out. It is alleged that the discoveries which have been made and the results already achieved strongly indicated that if the electric light enables vegetables to assimilate during the night and does not interfere with growth, it will ultimately produce plants of great size and marked precocity.—*New York Ledger.*

Edison's Exhibit at the World's Fair.

Thomas A. Edison's display of electrical apparatus at the world's fair is to be the greatest effort of that great inventor's life. He has been working on it for months, and a dozen or more of his ablest assistants have been helping him. The wizard of Menlo Park has just applied for space in the electricity building for his exhibit. He wants one-seventh of all the room in the big building. The electricity building is 345 by 700 feet, and contains exclusive of gallery space, 231,500 square feet of floor room. "I have it from Mr. Edison himself," said Chief Barrett recently, "that his display at the fair is to be the greatest achievement of his life. In talking of his application for space Mr. Edison admitted that he was asking for a large section of the building. 'But every inch will be put to good purpose,' he added, 'I shall not waste a foot of the area assigned to me, but will present a series of the most interesting electrical inventions ever produced.—*Chicago Journal of Commerce.*

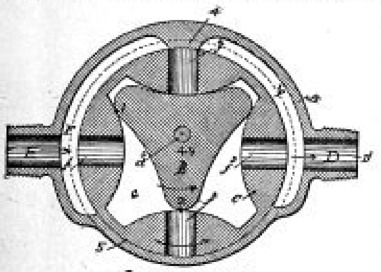
The Dynamo Made Harmless.

F. J. Crough, of Eugene, has invented a harmless dynamo which a child can handle without fear of danger, says the Portland *Oregonian*.

Mr. Crough says his machine is very simple, and adds that the secret of success is in the winding, induction, and proportion of metals. There is another secret which he will not divulge. He says the success of his invention is in one wire, but he does not desire to discuss the matter. Mr. Crough gave his invention a severe test in the presence of several people, including a reporter, recently. His principal purpose was to show that his machine was harmless and that it was impossible to get a shock from it. A feature of Mr. Crough's exhibit is a sixteen-candle power light burning in a jar of water, the naked wire being exposed to the water. Right above the jar is a light and an electric bell on the same circuit. A telegraph instrument has been worked a distance of three or four miles on the same line as an electric light without damage to either branch of the service. Again the incoming and outgoing wires of the dynamo have been run without insulation through mud, and then started lights without any loss of power. Mr. Crough says his dynamo has the power of ten volts. It will run fifty sixteen-candle power incandescents with four and one-half horse-power, including friction. In inventing it Mr. Crough says he cast aside all the theories of construction of electrical machines and started on a new track.

WATER MOTOR.

No. 457,294. James A. Tilden, Hyde Park, Mass. *Patented August 4, 1891.* The rotary piston B is made of triangular shape, as shown. It rotates within the four-sided chamber forming the interior of the ring C. The center of the piston is at d^2 and that of the ring C coincides with the center of the case A at the point 3. Water enters at E and passes through the port f^1 into the interior of the ring, where it presses against the lobes of the piston B. The piston is in contact with the ring at the points 1 and 2. It will be seen that point 1 is nearer the center d^2 of the piston than the point 2 is, consequently the greatest leverage is exerted on the lower lobe of the piston, and it revolves in the

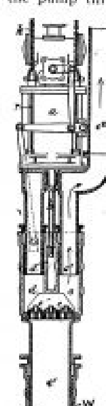


Cross section

direction of the arrow. The lobes of the piston successively enter the four recesses or corners of the chamber in the ring C and they revolve together, the piston making four revolutions while the ring makes three. They work together like a pinion into an internal gear. As the ring revolves the ports f^1 f^2 f^3 f^4 are closed when they reach the port 5 that fits against the ring, and they open into the exhaust D when they have passed it. They pass from the exhaust to the supply side as they go past the bearing 4. The supply and exhaust are thus controlled by the ring C, and no other valves are needed. The motion is reversed by shifting the pressure over to the exhaust side.

MINING PUMP.

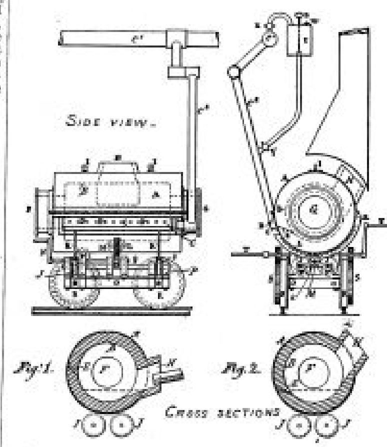
No. 457,023. William H. Bailey and Gustave Lindemann, Salford, England. *Patented Aug. 4, 1891.* One fixed water barrel W and two fixed plungers d^1, c^1, are connected to the steam cylinder a by rods r. The piston rod b, is attached to a pair of water barrels d and c, which are bolted to a large hollow plunger c^2. A set of valves e are attached to a plate bolted between them. The hollow interior of the plunger d^2 serves as an air chamber, and the water passes out of the pump through the plunger c^1.



When the steam piston moves the barrels c and d, and the plunger c^2 downward, the plunger displaces twice as much water as the plungers c^1 d^1 do on the up-stroke. Half of this water fills the space made by the withdrawal of the plungers c^1 d^1, and the remainder goes off up the column pipe c^2. On the up-stroke the plungers c^1 d^1 displace the water which on the down-stroke filled the space vacated by them, and the plunger c^2 sucks in enough water for the next double stroke. The discharge is thus double acting, and the suction single acting.

CONVERTER FOR COPPER MATTE.

No. 456,510. Pierre Manhes, Lyons, France. *Patented July 21, 1891.* This converter is designed for producing copper from matte of any composition. In construction and operation it resembles the converter employed in making Bessemer steel. The cylinder A is lined with refractory material, and has end openings F and G through which the flame from any convenient heating furnace is run for the purpose of properly heating it before receiving a charge of matte. These openings are covered when at work. The cylinder is provided with a vent or nozzle H and a blast box C having a number of tuyeres E which extend through the lining as shown. Blast is supplied through a jointed pipe C^2 C^2. The cylinder is supported on rollers J upon a car as shown. The apparatus can be propelled to any desired place by the handles T. The cylinder is turned over to receive a charge, or to bring the tuyeres beneath the metal, by means of the crank N. The charge is introduced through the nozzle H, when in the position shown in Fig. 1 the blast is turned on and the cylinder is then rotated to position shown in Fig. 2. The reaction commences immediately. The oxygen of the air combines with the sulphur and forms sulphurous acid, and with all the other bodies it forms oxides, which are carried away by the gaseous current. The greater part of the iron which passes to the state of oxide remains in the bath and would soon injure the lining of the converter and quickly render it useless. To prevent this, powdered silica contained in a reservoir U is fed into the blast-pipes, and is brought into contact with the oxide of iron and forms silicate of iron, which melts and floats in the bath of melted matte. The



volume of matte becomes less by the liberation of the sulphur and other bodies. Consequently the converter is turned slowly, in order that the air-blast may still penetrate the matte to the proper depth. The matte is thus concentrated and approximates metallic copper by the loss of the other elements—iron and sulphur—as well as the combustion and volatilization of the metalloids, and metals more easily oxidized. After a time there remains in the converter only sub-sulphide of copper, and this is shown clearly by the color of the flames. The sulphur continues to burn, and the copper is liberated, and descends by gravity below the remaining sub-sulphide. The cylinder is then turned backward slowly, so as to keep the tuyeres near the bottom of the layer of sub-sulphide, until crude copper alone remains. At the middle of the operation, when it is recognized by the color of the flames that all the iron has been burned, the converter is tipped to the postion Fig. 1, and the slag which floats, if sufficiently fluid, is run out, the air which strikes the surface at the rear of the bath being usually sufficient to force it out. If the slag is not fluid, it is raked out by the usual means. The apparatus is afterward turned back to reduce, as aforesaid, the sub-sulphide of copper by still further blowing. By this process poor and impure mattes can be treated at will for obtaining either a white matte absolutely free from iron and other bodies, or crude copper, or even refined copper in condition for rolling, and this is done in less than an hour after taking the matte from the blast-furnace and without consumption of fuel.

VALVE FOR HYDRAULIC MOTOR.

No. 459,736. Elijah B. Benham, Providence, R. I. *Patented Sept. 22d, 1891.* This valve is designed for that class of motors which has several cylinders, eight in the present instance, all of which radiate from one center. The piston rods all bear against one crank pin 63. A retaining ring Z hooks over the shoulder shown on the ends of the rods, and serves to keep them in place. A single port 27

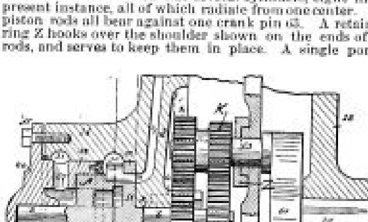


Fig. 1.

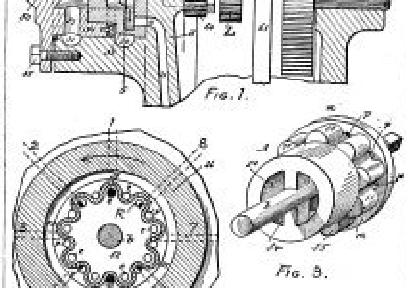

Fig. 2. Fig. 3.

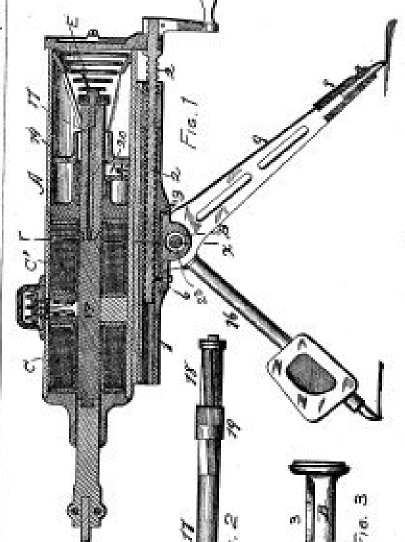
runs from the outer end of each cylinder to the bottom of the steam chest. The eight ports are arranged in a circle at exactly equal distances apart. The valve which controls the admission and exhaust is shown in perspective in Fig. 3, and in cross section in Fig. 2. The face of the valve is a circular plate which fits the bottom of the steam chest. It contains eighteen equally spaced holes, on the same circle as the cylinder ports. The body of the valve is corrugated so as to have each alternate hole open into the inside of the valve, and the intermediate holes open to the outside. The former are the exhaust ports and the latter are the supply or inlet ports. In Fig. 2 it is seen that cylinder port 1 is fully open to the exhaust, and port 5 is fully open to the supply. Port 2 is opening and 8 is closing to the exhaust, 6 is opening and 4 is closing to the supply or pressure. 3 and 7 are closed, both those pistons being at the ends of their strokes. While the valve turns from the position shown, sufficiently to bring the exhaust hole R exactly over the cylinder port 1, or through one-ninth of a revolution, each cylinder port is opened and closed both to the pressure and to the exhaust, in the regular order necessary to secure one full stroke to each cylinder. Consequently the valve makes only one revolution for every nine of the crank, and the wear of the valve is correspondingly slow. The pressure chamber 30 is separated from the exhaust 31, by the cup leather packing shown in Fig. 1, which fits against the circular shell of the valve. The valve is turned by differential gears carried on the end of the crank pin 63. Wheel 60 is fixed, and L is fastened on the valve stem. K and h are keyed together, and turn on the crank pin. h and 60 are equal in size, but K and L are in diameter as 8 to 9. At every revolution L is turned forward one-ninth of a revolution thus giving the valve its proper motion.

ELECTRIC ROCK DRILL.

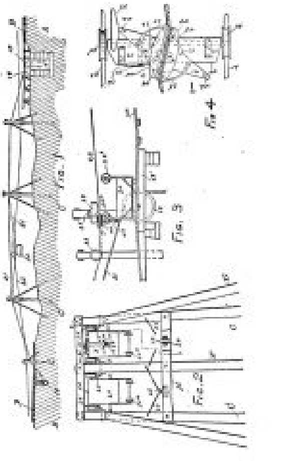
No. 460,089. Charles E. Life, Syracuse, N. Y. *Patented Sept. 22d, 1891.* The drill is attached to the bar 17 by a clamp in the ordinary way. The coils C C^1 of insulated copper wire are employed to operate the drill bar 17. When the electric current is sent through the coil C^1, the bar draws back into the casing until its center reaches the center of the coil, or so far as the coiled spring E will permit. Before it reaches the limit of its stroke in that direction, the current is switched out of the coil C^1, and into coil C. The rod now moves outward, tending to bring its middle to the middle of coil C. Before reaching that point, however, the current is again switched off, and into coil C^1. At or before that moment, the drill strikes the rock, and the pull from coil C^1 catches it on the rebound. The upper part of the drill rod 17 is made into a spiral 18, as shown on Fig. 2. This spiral slides through a ratchet sleeve 19, and pawls 20 serve to rotate the drill in the ordinary way. On the outward



stroke the sleeve turns, but on the inward stroke the pawls hold the sleeve and the drill rod turns. The tripod leg 9 is double, united at the foot, and each side is provided with a disc at the head, which engages the beveled ends of the center block B. The top ends of the legs 16 are also provided with large flanges which are clamped by a center bolt 23 tightly against the outside of the heads of the leg 9. The center block B has on its top side, a circular plate 3, with beveled edges, Fig. 3. The casing A slides in ways in the bar 1, and this bar has a socket and clamp block 6 which takes hold of the swivel plate 3. The drill can be swiveled horizontally on this joint, and can be swiveled vertically by easing off the center bolt 23 thus allowing the center block B to turn between the heads of the tripod legs. The feed screw 2 is operated by hand.

AERIAL RAILWAY.

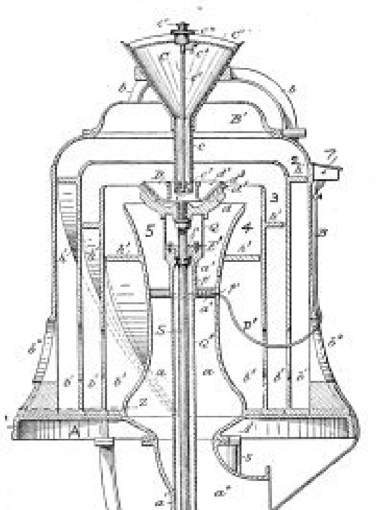
No. 460,587. Alfred H. DeCamp, Boonton, N. J. *Patented Oct. 6, 1891.* In this structure metallic flexible rails are used instead of ropes for the car wheels to travel on. These rails are made of flat iron bars which are arranged to slide through suitable ∩-shaped stirrups which are bolted to the knees 26 which support the track on the trestles C. Each stirrup is covered with a short piece of flat iron, tapered off at both ends and resting on top of the track, for the purpose of passing the wheels over the stirrups without shocks. The end of the rails at the anchorage A are attached to straining ropes and weights shown on the pit 19a. The cars are moved by an endless hauling rope 22. Surface tracks D extend to the ends of the aerial tracks and the cars are provided with two sets of wheels, the upper ones to run on the aerial tracks, and the lower ones for the surface tracks. The haulage rope draws the cars to any desired point on the surface line, where the rope grip is tripped automatically by a block 37, Figs. 3 and 4, fixed above the track on a suitable framework 38. The car is then switched by gravity over to the return track, and the grip is closed by a block overhead 37, similar to the one that opened it. The grip is composed of two jaws which are pivoted on pins 47 to a plate 41. They are connected by small links 49 on the under side. Each end of plate 41 has a lug 42 turned up high enough to be engaged by the blocks 37 which are fastened to overhead timbers at the engaging and disengaging stations. When the plate 41 is thrown around to the position shown in Fig. 4, the jaws are



forced toward each other sufficiently to grip the rope, and the rope is bent as shown. Both ends of the railway are provided with surface track switches and grip operating blocks 37, so the cars circulate continuously and automatically. Fig. 3 shows the end of the aerial track and of the surface track, with a car about to pass from one to the other.

CENTRIFUGAL ORE SEPARATOR.

No. 459,287. THOMAS CLARKSON, LONDON, ENGLAND. *Patented Sept. 8, 1891.* The crushed ore is fed into the hopper C. The feed is regulated by a conical valve at the lower end of the feed pipe, which is adjusted by a handwheel at the top of the hopper. The ore falls into a circular dish d, which is fastened on the top end of the spindle S. This dish is provided with a removable ring d^1, which is constructed with radial grooves d^2 on its top surface. These grooves range in size from $\frac{1}{32}$ to $\frac{1}{8}$ of an inch square, according to the material to be handled. A cover D rests by gravity on top of the ring d^1, and provides a top or cover for all the grooves in it. The pan and its cover are spun swiftly by a belt on the pulley P, and the ore is thrown from the pan, through the grooves d^2, outward and upward at an angle of 45 degrees. The distance that it is thrown

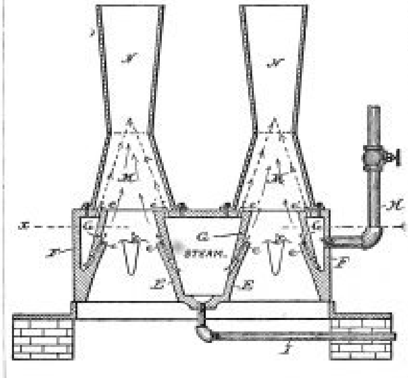


VERTICAL SECTION.

depends upon the weight of the piece. The pieces heavy with metal are thrown farthest into the outer chamber 2, smaller pieces into chamber 3 and the dust into chamber 4, while the finest dust falls into the central chamber 5, from which it is sucked out by an exhaust fan. These chambers are made of circular casings one inside the other, and they are provided with spiral flanges k^1, k^2, k^3, which form inclined bottoms to each chamber, by which the material is directed to suitable discharge holes in the base A. The spindle S runs in ball bearings in the upper sleeve E^1 and at the bottom hanger E. The dust is kept out of the upper bearing by a sleeve Q which slides on the pipe Q^1 and shoves up close under the bottom of the revolving dish d, without quite touching it. Oil is supplied to the bearing by a pipe p^1 which leads from an oil box 7.

STEAM BLOWER.

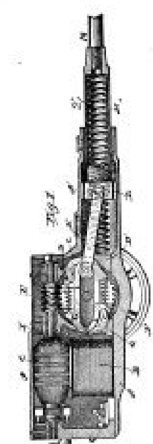
456,435. CHRISTIAN H. SCHARAR, SCRANTON, PA. *Patented July 21st, 1891.* This blower is designed for drawing the gases from the furnaces of steam boilers, etc., and thus create the necessary draft, without the smoke stack commonly employed for that purpose. It is usually set at the end of the flues where the chimney would otherwise be placed. A circular casing F is supplied with steam by the pipe shown. Several conical passages G are made through the casing for the passage of the smoke and gases. A pipe M N having



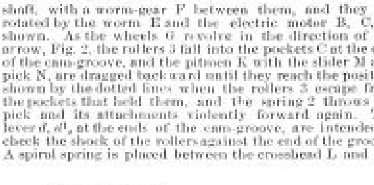
a contraction near the middle of its length, is placed over each passage G. A number of small jets e^1 are provided around the upper end of each passage and a second set e are made on the interior of the passage, as shown. All the jets are so inclined that the streams of steam which issue from them tend to converge at a point near the narrowest part of the tubes M N, as shown by dotted lines. A drain pipe I serves to keep the apparatus free from water when the fires are low, or the steam is shut off.

ELECTRIC MINING MACHINE.

No. 458,184. EDMUND C. MORGAN, CHICAGO, ILL. *Patented Aug. 25, 1891.* The pick N is attached to a tubular holder M which slides through a bearing in the front end of the machine frame and is guided by a crosshead L. A long spiral spring 2 is used to throw the pick forward. To draw it backward, two pitmen K are employed, which have rollers 3 running in the cam-grooves of the wheels G. There are two of these wheels, on the ends of a short transverse



shaft, with a worm-gear F between them, and they are rotated by the worm E and the electric motor B, C, as shown. As the wheels G revolve in the direction of the arrow, Fig. 2, the rollers 3 fall into the pockets C at the end of the cam-groove, and the pitmen K with the slider M and pick N, are dragged backward until they reach the position shown by the dotted lines when the rollers 3 escape from the pockets that held them, and the spring 2 throws the pick and its attachments violently forward again. The lever d, d^1, at the ends of the cam-groove, are intended to check the shock of the rollers against the end of the groove. A spiral spring is placed between the crosshead L and the



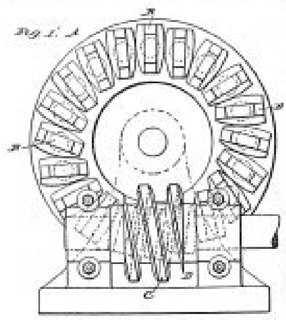
end of its slideway in the machine frame, also to cushion the stroke of the pick. The wheels upon which the machine is mounted, run on stout studs projecting from flat blocks which are arranged to slide in dovetail grooves running horizontally in the sides of the main frame so that they can be shifted forward or back to properly balance the machine.

WORM GEARING.

No. **456,796.** MATTHEW P. CAMPBELL, GLASGOW, SCOTLAND. *Patented July 28, 1891.* The object of this invention is to provide worm gearing suitable for transmitting great strains, and which will mesh properly with worms of different pitches of thread.

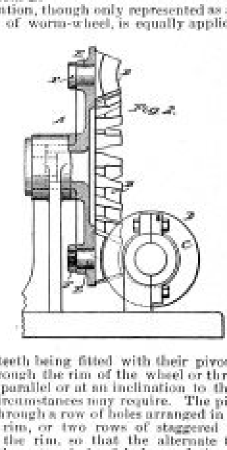
Figure 1 is a face view of the improvement; and Fig. 2 is a side elevation, the parts being in section.

The gear wheel A is provided on its face with teeth B, adapted to mesh into the thread C of the worm D. The teeth B are each provided with a pivot-pin E, fitted to turn in the wheel A, and retained in place by a collar or nut F. Each tooth B is free to oscillate on its pivot-pin E, so that while the pitch or actual distance from center to center of the teeth remains constant, the teeth adapt themselves by swiveling on their pivots to the inclination of the thread of



the screw or worm D with which they gear. The swiveling teeth B are, by preference, enlarged or formed with shoulders, near their roots, bearing against each other, as is shown, so as to distribute the strain throughout the series of cogs or teeth B.

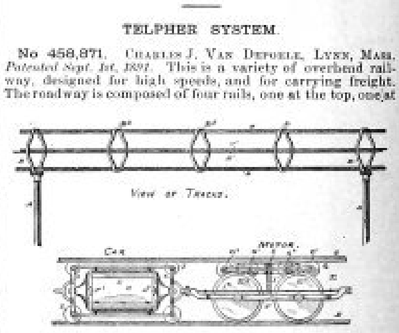
The invention, though only represented as applied to the bevel form of worm-wheel, is equally applicable to other



forms, the teeth being fitted with their pivot-pins passing radially through the rim of the wheel or through the side of the rim parallel or at an inclination to the axis of the wheel, as circumstances may require. The pivot-pins may be passed through a row of holes arranged in a circle round the wheel rim, or two rows of staggered holes may be formed in the rim, so that the alternate teeth may be pivoted in the outer circle of holes, and the others in the inner circle.

TELPHER SYSTEM.

No 458,871. CHARLES J. VAN DEPOELE, LYNN, MASS. *Patented Sept. 1st, 1891.* This is a variety of overhead railway, designed for high speeds, and for carrying freight. The roadway is composed of four rails, one at the top, one at



the bottom, and one at each side. The cars are thus enclosed so that they cannot leave the track at any speed. The rails are used to convey the driving current and also the return. The motors are constructed within the bodies of the driving wheels E^1 E^2 of the locomotive, and are of the kind which have no commutators. The car O is composed of a cylinder which is provided with suitable side doors, and is hung by spring connections to a frame R R. This frame has suitable wheels S which engage the top and bottom rails. Side rollers F^1 F^2 are provided to bear against the side rails and prevent oscillation. As the driving wheels of the locomotive cannot bear against both top and bottom rails at the same time, idler wheels G^1 G^2 are employed to make the contact with the top rail. It is desirable to make the locomotive as light as possible, and in order to get adhesion the wheels G^1 G^2 are drawn toward each other, thus forcing the driving wheels against the bottom rail. The force applied for this purpose is graduated in proportion to the drag or traction of the cars. The drawhead is attached to a rod I^2 which operates a lever I^1. This lever is connected to the axles of the wheels G^1 G^2 in such a manner that its movement draws them together and increases the pressure of the drivers on the rail. The train is stopped at stations by interrupting the circuit and so shutting off the power. As soon as the current is cut off—the brakes (not shown) which have been held off by suitable magnets, are thrown on by springs, and the train is quickly brought to a stop.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 6. SCRANTON, PA., JANUARY, 1892. WITH WHICH IS COMBINED THE MINING HERALD.

THE ECONOMIC GEOLOGY OF LEAD.

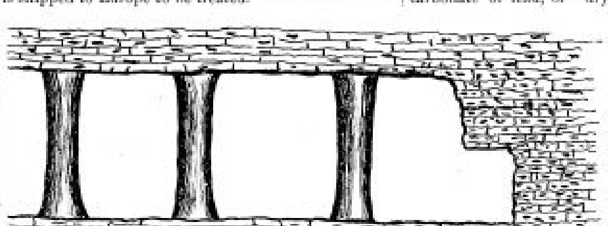
The Mineralogy, Mode of Occurrence, and Production of Lead.

BY H. A. WHEELER, E. M., OF ST. LOUIS.

The second, or South-Eastern Missouri group of lead mines, occur in limestone of lower Silurian age in South-Eastern and Central Missouri.

A series of nearly horizontal parallel beds of sandstone and limestone are found in that portion of the state which are all liable to carry at least small amounts of lead, but only two of the limestones have been found to carry it in paying amounts, and of these two, one produces nearly all of the large product from this district. The limestones are all dolomatized or have been more or less altered into magnesian limestone, which is especially true of the third limestone, which is the name applied to the richest ore, and in which the profitable mines are located. The lead occurs in the other or second magnesian limestone as "pipe veins," "gash veins," "floors," and caves, or similar to the Upper Mississippi region, though very often no zinc ore is found with the lead, while barite, or "heavy spar," is usually associated with the lead, and is sold for $1 to $3 a ton at the mine, according to its whiteness and freedom from iron-staining, to be used as an adulterant for white paint, paper, etc. The galena is often found in huge chunks and cubes of several hundred pounds weight in these gash-veins, and is seldom in small grains or in a fine condition, so that it is usually a very easy matter for the miner to dress his ore by the use of small picking hammers and hand dressing up to 80% lead. On account of the coarse condition of much of the galena, it gives rise to a peculiar local system of mining, known as "patch diggings," in which the miner hunts along the top of the decomposed lead-bearing limestone for the the loose chunks of mineral that have been set free by the weathering or decay of the encasing rock. For limestone is one of the least enduring rocks known, when exposed to atmospheric action, on account of its comparative easy solubility in surface waters; hence in the removal of the lime by atmospheric waters, the galena is left behind, together with the other insoluble impurities of the limestone, or a tough, sticky clay, known as "tallow" clay. In the winter season, when there is little to be done on a farm, it is a very common thing for the Missouri farmers to dig pits down through the clay, to the top of the solid, unweathered limestone, in search of the chunks of mineral, or galena, that may have thus been set free and hence in a condition almost clean enough for direct sale to the traveling ore-buyer. If lead is unusually high, the patch diggings are sometimes worked the entire year, while when low prices prevail, they are almost entirely neglected, though the total production from the patch diggings in a year is seldom large or important, as too frequently the farmers only make poor wages in carrying on this highly speculative hit or miss system of mining.

In the third magnesian limestone, the galena often occurs as finely disseminated granules and crystals in the limestone, which are usually more abundant along certain bedding or joint planes in the limestone. In this case the galena is never found in large masses, and is nearly always of quite low grade or the rock will assay, in paying ground, .5 to 20% in lead, though the usual average is between 6 and 10%. All the ore from this disseminated limestone requires concentration, before it can be smelted, and large mills have been erected in this district for crushing the ore by rolls and then concentrating it in jigs and on slime tables. Some iron pyrites occur with the galena, and at Mine la Matte a nickel cobalt bearing mineral called siegenite is found in sufficient quantities with the lead to annually furnish about $20,000 worth of cobalt nickel matte that is shipped to Europe to be treated.



SKETCH D.

SECTION OF THE ST. JOE MINE.—GALENA DISSEMINATED IN MAGNESIAN-LIMESTONE.

The largest producer in this region and in the Mississippi Valley is the St. Joseph Lead Co., at Bonne Terre, which produces about 12,000 tons annually, operating a narrow-gauge railroad over 50 miles long in carrying on its business, that has been built out of the profits, and which has been a dividend-paying mine for many years. At the St. Joe mine the lead-bearing limestone has been found to be over 400 feet thick, though the workings as yet do not exceed 200 feet in depth. The lead is found to follow certain quite and well-defined chutes or "runs" through the limestone, varying from 100 to 300 feet wide, and in working out a level or bench, 20 to 40 feet high, large round pillars of 15 to 25 feet in diameter are left to carry the overlying roof, which are spaced 30 to 60 feet apart, as shown in sketch D. These pillars are the only supports used in the mine, as the limestone is usually so solid as to give no trouble or require timbering.

Another mine in this district that produces about 3,500 tons annually, and which very much resembles the St. Joe is the Doe Run Mine, near Delassus. The lead-bearing limestone is here much thinner, and rests directly on the underlying archaean granite as shown by some of the workings of the mine, in which granite bosses have "come up and cut out the limestone," to use the miner's mode of expressing the trouble.

A famous historic mine in this South-Eastern district is Mine la Matte, which now produces about 3,000 tons of lead annually, and which has been more or less regularly worked since its discovery, in 1720, by la Matte in prospecting for silver.

The earlier workings were mostly superficial, and did not go below the water-level, and the curious blunder was made by the earlier miners of throwing away the carbonate of lead, or "dry bone," as they termed it, that was found at or near the surface. A shrewd miner, who subsequently observed this, quietly bought up the old dumps containing the "dry bone" before he announced that it was a valuable lead ore, and made a handsome profit with very little trouble, as the carbonate is the easiest ore of lead to smelt. The lead-bearing limestone is found to carry ore for a depth of 10′ to 150′ at this mine, and while the ore chutes are not so large or continuous as elsewhere in the district, they are usually richer or will run 10% to 20% in lead.

Recent explorations at Flat River in this South-Eastern district indicate that the output from the disseminated deposits is likely to continue to grow as it has done for the past 25 years, instead of diminishing, as has been the case of many of the other Mississippi districts, since the strong competition of the far Western lead has had to be contended with.

The South-Western Missouri lead region is much younger in age than the other Mississippi districts, as the lead is found in cherts and limestones of sub-carboniferous age or just under the true coal measures, and bitumen, as a product of the coals or bituminous shales that formerly overlaid (?) this region, is quite frequently found in association with the lead ores, while it is unknown in the others. The district includes not only the South-West corner of Missouri but also overlaps and extends into South-Eastern Kansas. The ore is found as irregular bodies in caverns in limestone and in highly brecciated or shattered chert filling the cracks and seams in the broken chert that occurs as "bars" or beds in the limestone, and the ore horizon has not yet been proved to be any deeper than 150 to 200 feet below the surface. The lead occurs as galena or the sulphide, though a little carbonate was found in the early workings, and is associated with large quantities of zinc blende and some iron pyrites. In the upper part of the ore formation the galena predominates, while the "jack" or zinc blende is in subordinate quantities, and was thrown away in the early history of the district, as was done elsewhere in the Mississippi Valley, under the impression that it was worthless; lower down the zinc decidedly predominates over the lead, and has given new life and greatly extended the area of production in this district, as now the miner finds that the zinc pays better than the lead, and only handles the lead as a by-product, while it has now become the heaviest zinc-producing region in this country, and hence a further description will be postponed until the occurrence of zinc is considered.

Other lead deposits occur throughout the Appalachian belt, as fissure veins, which have been worked in New England, Pennsylvania, New York, and elsewhere, but they have all failed to pay, as the veins are narrow and the ore chutes have thus far proved to be too small. The Wheatley Mine, in Pennsylvania, is well known for the beautiful specimens of quite a variety of the lead minerals that have been found in it, but as a lead producer it has not been a success.

In order to compare our production of lead with the large European producers, the following estimates are given from the *Engineering and Mining Journal* of January 3, 1891, for the year 1890:

United States	187,000 tons.
Spain	120,000 tons.
Germany	90,000 tons.
England	50,000 tons.
Belgium	30,000 tons.
Italy and Austria	20,000 tons.
France	12,000 tons.

Of the German output, 26,000 tons was the product from one concern, the Mechernich Co., which works the lowest grade lead ore, at a profit, of any concern in the world, or a heavy bed of galena-bearing sandstone, in Western Germany, that carries about 3 to 4% of lead. Mexico, South America, and Japan are small producers of lead that are not considered in the above figures, but, excepting the former country, their output is of little importance in the lead world. Mexico sent nearly 30,000 tons into this country, in 1888, as smelting ore, but our new tariff has nearly stopped this importation, and what is now produced there is smelted at home and the metal shipped to England for a market. But there is no doubt that under favorable conditions the Sierra Mohada and other lead-producing mining camps in Mexico could produce quite heavily, and what their maximum capacity amounts to has still to be determined.

A NEW COAL CUTTING MACHINE.

The undercutting of coal by machinery is an important problem for the mining fraternity. The undercut may be made by hand, but this method not only adds largely to the expense of mining coal, but also makes a large quantity of fine coal or slack, which is comparatively a waste product except in certain cases. A successful machine not only cheapens production, but also increases output, insures the mining company in a large measure from delays and shutdowns incident to strikes of ordinary miners, and simplifies mine management. There are several types of machines on the market and in actual operation, but the one herewith illustrated works in an entirely different line from other machines.

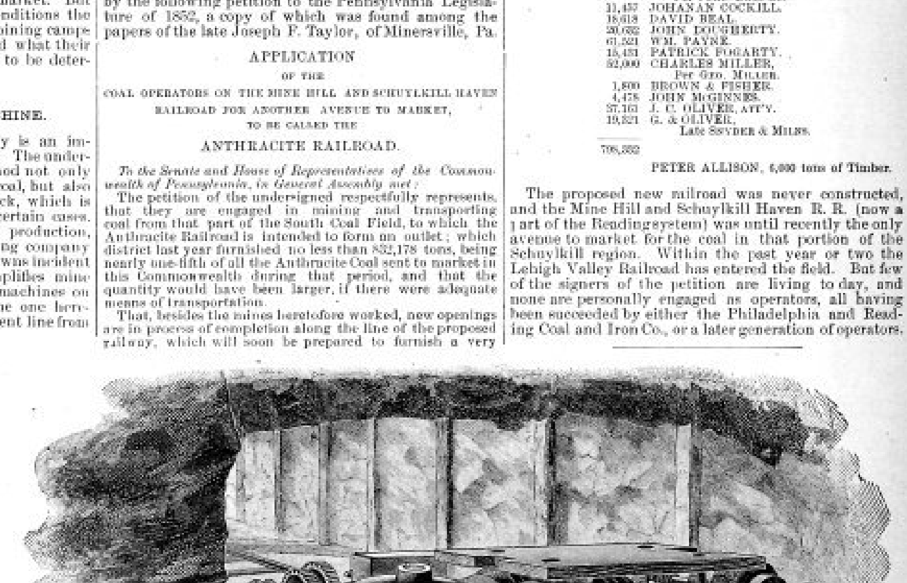
The new Arc Machine consists of the following parts: A heavy iron base cast in one piece, carrying two pairs of axles, one at right angles with the other, the parts serve as a foundation for all. The gauge of one pair of axles is fixed to suit the regular track gauge of the mine wherein the cutter is to work and these axles carry small flanged wheels upon which the cutter is easily moved about the mine and in and out of the rooms. The second pair of axles carry small wheels for supporting the cutter when in actual operation and carrying it along the face of the wall being cut. They are not flanged but are kept upon the track by two pairs of single and two pairs of double guides, as shown in the illustration. The support of the machine is easily changed from one pair of axles to the other by means of a cam worked by screws, the larger flanged wheels being raised out of the way when the cutter is in actual operation, as shown in the illustration.

The motive power is furnished by a 15 H. P. motor, which in the latest machines is somewhat changed from that shown, the motor being perfectly water tight and thoroughly protected from all danger of mechanical injury. The armature shaft carries a bevelled pinion at each end. That nearest the commutator is made to engage by means of a controlling lever, either one of the two bevelled gears shown in the illustration, thereby giving the shaft on the right a right-handed or left-handed rotation. By means of the chain of gears and an ingenious mechanical device, this shaft operates the feed chain at practically any desired speed. The feed chain is made fast to a post ahead of the machine, and in this way the cutter is drawn forward at a speed under control of the operator, and which can be varied with the hardness of the coal. The same gearing, by means of another controlling lever is made to move the arm from a position alongside the machine at the beginning of the cut to the position shown in the illustration, where it is held rigidly during the remainder of the cut. The second pinion on the armature shaft operates the endless chain carrying the cutting knives about the arm. The controlling devices are such that the cutter may be held stationary while the knives are in operation, an important point in cutting through particularly hard formations. The length of the arm carrying the endless chain is made to suit the requirements of the mine in which it is to operate, the undercut usually being made of a depth equal to the thickness of the vein.

The length of the arm is adjustable within certain limits in order to take up the stretching of the chain due to wear. The chain and knives are drop-forged and of a strength to withstand the hardest usage. The knives are easily detachable from the chain so that a new set of sharp knives may be substituted for the old set in a very short time. The track along the face of the work consists simply of two rails with an iron cross tie, and may be laid and removed in a very short time and with a small amount of labor. By the use of this track and this type of machine necessity for moving a heavy piece of apparatus by hand, oftentimes in a very low room, is avoided, a very important point as anyone who has had experience in these matters can testify. For its operation the cutter requires two men, one of whom is at the machine itself controlling the rheostat and operating devices, and the other keeps the track laid ahead and sets the posts for anchoring the feed chain. All trouble with the slack clogging up the cut is obviated as the knives themselves bring nearly all the slack outside the cut, leaving a clean space.

The machine is thus seen to possess very important advantages in all kinds of working, and for large rooms or a Longwall system these advantages become all the more prominent. It is operated on a 220 volt circuit, making it entirely harmless electrically.

The New Arc Cutter is handled by the Thomson-Van Depoele Electric Mining Co., 620 Atlantic Avenue, Boston, Mass., to whom should be addressed all inquiries regarding it.



ANTHRACITE OPERATORS VS. RAILROAD COMPANIES.

That transportation companies and individual operators of forty years ago had their disputes regarding rates of toll, etc., the same as they have to-day, is evidenced by the following petition to the Pennsylvania Legislature of 1852, a copy of which was found among the papers of the late Joseph F. Taylor, of Minersville, Pa.

APPLICATION

OF THE

COAL OPERATORS ON THE MINE HILL AND SCHUYLKILL HAVEN RAILROAD FOR ANOTHER AVENUE TO MARKET,

TO BE CALLED THE

ANTHRACITE RAILROAD.

To the Senate and House of Representatives of the Commonwealth of Pennsylvania, in General Assembly met:

The petition of the undersigned respectfully represents, that they are engaged in mining and transporting coal from that part of the South Coal Field, to which the Anthracite Railroad is intended to form an outlet; which district last year furnished no less than 832,178 tons, being nearly one-fifth of all the Anthracite Coal sent to market in this Commonwealth during that period, and that the quantity would have been larger, if there were adequate means of transportation.

That, besides the mines heretofore worked, new openings are in process of completion along the line of the proposed railway, which will soon be prepared to furnish a very large additional quantity towards meeting the greatly increasing public demands. Also, that owners of lands and others interested in the Second Coal Field, contemplate sending large quantities from that region over the extension of the Mine Hill and Schuylkill Haven Railroad, authorized to be constructed by a recent Act of the Legislature.

That the supply of coal from all of these sources finding its way to market by the valley of the West Branch of the Schuylkill, at the average rate of geometrically increasing consumption of this important fuel, must soon double the present quantity, and will render necessary all the facilities of transport which existing and projected lines of railways can furnish.

Your petitioners would further represent that the Anthracite Coal trade has now become so important an element of the prosperity of this great Commonwealth, that power to control, direct, or limit its extent, should not be granted to any corporation, nor should the fancied claims to "vested rights," set forth by existing lines of transit, be permitted to interfere with, or check its full development.

And that it is in accordance with the progressive spirit of the times, to extend similar legislative rights, to all parties desirous of making investments in improvements calculated to promote the public prosperity; as thereby oppressive monopolies are prevented, and the vast natural resources of the State called into greater activity.

Your petitioners allege, that their operations are now controlled by a corporation, which not only claims the exclusive and perpetual right to transport their products to market, but which has evaded, and continues to evade, the necessity of, and legislative right to, a reduction of charges imposed by its Act of incorporation, and by numerous supplements authorizing an increase of capital, which has now grown from the original $100,000 to $1,300,000; upon all of which your petitioners are liable to be taxed to the extent of 15 per cent. per annum; in consequence of which, they are at present compelled to pay about $80,000 more than would be charged them upon the new railroad applied for on the same quantity.

Your petitioners, (who of the total 832,178 tons, furnished in 1851, supplied 718,332 tons.) therefore ask your honorable bodies to extend to them the right to construct a road for the transport of their products to market, and pray for the passage of an Act to Incorporate the Anthracite Railroad.

And they will ever pray, etc.

PETER ALLISON, 6,000 tons of Timber.

The proposed new railroad was never constructed, and the Mine Hill and Schuylkill Haven R. R. (now a part of the Reading system) was until recently the only avenue to market for the coal in that portion of the Schuylkill region. Within the past year or two the Lehigh Valley Railroad has entered the field. But few of the signers of the petition are living to-day, and none are personally engaged as operators, all having been succeeded by either the Philadelphia and Reading Coal and Iron Co., or a later generation of operators.

Mr. H. A. Kingsbury, dealer in mine supplies, has in his window at 435 Spruce Street, in this city, a photograph of one of the longest wire ropes manufactured in this country. The length of the rope is 34,500 feet, or a little over six and a half miles, and the whole rope, which is 1¼ inch in diameter, weighs 93,845 lbs. As it stands on the car wound upon a reel, the diameter of the roll is over 14 feet. Mr. Kingsbury is agent for John A. Roebling's Sons & Co., of Trenton, who are the manufacturers, and is prepared to give estimates for any of their goods.

HISTORICAL SKETCH OF COAL MINES AND MINING OPERATIONS IN ALLEGHENY CO., PA.

BY SELWYN M. TAYLOR, M. E.

[In Reports of Inspectors of Mines of Pennsylvania for 1890].

That portion of Allegheny County lying south of the Ohio and Allegheny Rivers is practically one coal field of the Pittsburgh bed.

That part of the county lying north of the rivers is too low, or rather the rise of the measures to the north has carried the coal out of the hills.

That part of the county, however, as well as the southern part, is solidly underlaid by the "Freeport bed," which, on the failure of the gas supply, may become an important feature of the coal production of the county in the near future.

That part of Allegheny County between the Allegheny River on the north and the Monongahela and Youghiogheny Rivers on the South and East, originally had a coal area equal to about one-fourth of its entire extent, the larger part of which has been mined. This field, or portion of the field, consisted principally of small bodies of coal lying high in the hills with an overlying strata seldom more than one hundred feet in thickness and averaging perhaps sixty feet. A number of these detached bodies lay in what is now the city of Pittsburgh, those in the city limits, however, are nearly all exhausted.

The principal operations in the field north of the Pennsylvania Railroad have been those of the New York and Cleveland Gas Coal Company. The territory through which its operations extend has been quite a large one, and the systematic manner in which its coal has been mined has been remarkable as compared with other operations under similar conditions. That part of this field lying between the Pennsylvania Railroad on the north and the Monongahela River on the South, was quite a small one, and has been practically all mined out by two companies; W. H. Brown & Co., from the river front, and one mine on the Pennsylvania railroad, near Wilmerding station.

That part of Allegheny County south of the Ohio River and north of the Pittsburgh, Cincinnati, Chicago, and St. Louis Railroad has from one third to one-half of its area underlaid with the Pittsburgh coal bed.

The principal operations in this field are from the Montour's Run Railroad mines, and two or three mines on the Pittsburgh, Cincinnati, Chicago, and St. Louis Railroad. This coal also lies high in the hills with light overlying strata, this is practically yet a solid field, the coal that has heretofore been mined comprising but a small portion of the whole.

That part of the county lying between the Monongahela and Youghiogheny Rivers was almost entirely underlaid with coal, about one-third of which has been mined. This field generally lies from one hundred to two hundred feet above the river, but the hills rising abruptly back from the river has given it a thick overlying strata. This field is at present the seat of the principal operations of W. H. Brown's Sons, Horner & Roberts, and a number of small operators shipping their coal by river, and of W. L. Scott, who ships by rail.

This field has been, and will probably continue to be, one of the most valuable in the district owing to its natural advantages both for mining and shipping of coal.

The remaining part of the county lying south of the Monongahela River and P., C., C. & St. L. Railroad, which comprises one-half of the county, is underlaid with the Pittsburgh bed of coal, substantially throughout its entire area, with outcroppings on river and railroad of nearly one hundred miles. This field has its outcrop always at a sufficient height above the river and railroad to make it convenient for operating.

The mining and shipping of coal has always been divided into two methods—that of shipping by rail, and that by river, but the river operations are by far the elder, as they date back some sixty or seventy years.

The mines on the river are classed in what is known as "First," "Second," and "Third" pools—that is, all lying below Lock No. 2 on the Monongahela River are in the First pool, and those above, and on that part of the Youghiogheny that is navigable, as the Second pool, and all lying between Locks Nos. 3 and 4, the Third pool. The front hills, as they are usually termed, meaning those adjacent to the river, are very high and bluff; the coal outcropping near the tops of them. In these hills the first mining operations were conducted, and, indeed, it is only within the present decade that the operations have been extended into the second range of hills.

Mines in the first pool now in operation are those of Keeling, Walton, Castle Shannon, Hay's Estate, Rishers, and Munhall's. Nearly all of these mines are old ones, and their operations are being conducted at from two to four miles from the river front, the coal being hauled either by locomotive or wire rope. These mines still have large and almost unlimited field of coal back of them, and they will be enabled to continue in operation for many years to come.

The mines in the second pool on the west side of the Monongahela River have not nearly the quantity of coal back of them that those in the first pool have; many of them are already worked out, their field of coal being cut off by the "creek outcroppings," a short distance back from the river.

The mines which are known as railroad mines are mostly located on the P., C., C. & St. L. R. R., several are on the Wheeling division of the B. & O. R. R., the New York and Cleveland Coal Company's on the Allegheny Valley, Pennsylvania and Montour Run Railroads, and W. L. Scott's mines on the P., McK. & Y. and the P., C. & Y. R. R.'s. Nearly all of these mines, with the exception of those located on the P. R. R., and Allegheny Valley Railroads have an unlimited coal area to draw from.

Of the early mining operations in Allegheny County but little of good can be said as, the coal lies high in the hills with outcroppings on every side, natural drainage was almost always to be had, and the coal having to be hauled but a very short distance to the pit mouth, the need for scientific or economical mining was not felt. The sale of the coal always yielded a large profit, no matter how much it cost to mine it. During these early operations, disputes between the operator and miner in regard to the wages to be paid were constantly occurring, but there was seldom any effort made to economize in any other direction.

The mines were all worked on the single-entry system, and usually with only a single main entry, and air-courses were even driven as far apart as possible, three or four hundred yards sometimes intervening between them. No care was taken in the driving of rooms as to the width of the room or the thickness of the pillar.

Entries were seldom driven straight and the entry pillars were left as small as possible. No one ever dreamed of making a "cut-through" from one room to another, and ventilation in ninety per cent. of the mines was "natural" exclusively.

The supply of timber to the miner was limited, through a false notion of economy, in consequence of which, large bodies of coal were lost in almost every mine, for the loss of five or ten acres of coal that perhaps had cost the operator, when developed, from six to eight hundred dollars per acre, did not trouble the superintendent or pit boss at all, and rather than put in a pump or a limestone drain, ten or fifteen acres of coal would be abandoned forever, and the advice of a mining engineer was seldom asked, for the certainty that if the entries were driven far enough they would come to daylight was deemed sufficient.

Fire-damp was seldom met with and never in dangerous quantities, and if occasionally the mine boss would decide to drive an entry to hit a certain point or an air course sometimes he would do it by "sound," (mostly bad) guessing, and sometimes he would call in a surveyor.

Occasionally an operator, curious to know how much coal he had remaining unmined, would employ a surveyor and have a map made, and such a map! Often the entries only would be shown and sometimes the rooms would be indicated by a straight dotted line at right angles with the entry with the distances indicated in rods; and the mining out of other people's coal was the rule rather than the exception, for sometimes the coal from an entire tract would be taken without the owner's knowledge or consent.

Accidents were frequent, not from machinery or explosive gas, but from falls of coal, etc., and from narrow entries.

No business could have been more chaotic than that of mining coal in Allegheny County fifteen years ago. The average output of the mines of the district was probably about five thousand bushels a day for each mine, or about two hundred tons. There were required from thirty to fifty cents per ton for expenses, outside of that for mining, and yet the margin was large enough to make the business immensely profitable.

It would be difficult to trace each step that has been taken towards improvement, but the greatest of them probably dates from the taking effect of the Bituminous mine act of 1885, the operators being compelled by the provisions of that act to introduce some sort of ventilation into their mines, following this, the increased product consequent upon numbers of new mines being opened and the increased competition where before there had been none, tended to set the operators to thinking how their coal could be handled more economically outside of the cost of the actual mining, and wire rope haulage was rapidly introduced until now few mines that have been worked for many years are operated without it.

The "double-entry" system came next, and what a hard task it was to persuade the operators and mine bosses that it was not going to be twice as expensive as the old single-entry air course system was, without any advantages over it, but it was accomplished, and is now in almost universal use. Next came "fan ventilation," and the scrupulous mining of every ton of coal that was contained in an acre.

It was the prevailing idea among coal men, that the average quantity of merchantable lump coal to the acre was 80,000 bushels. The writer well remembers an occasion when a number of reputable operators and superintendents testified that not more than 90,000 bushels to the acre could be taken out, which was very probably true at that time, but now in our best mines the yield per acre is from 110,000 to 116,000 bushels, and in some cases as great as 120,000 bushels of lump coal over an inch and a half screen. In one year's work, in a large mine, the writer estimated that not more than one per cent. of coal remained unmined, a result hardly obtainable in any other vein of coal in the world.

The mining act of 1885 was certainly a great benefit to the operator as well as to the miner, as it started the weeding out of the old and ignorant class that had ruled the mines for so many years; how much the operator of this district left to the mine boss, for the operator seldom having any knowledge of practical mining himself, he felt that the mine boss who had been in his employ for so many years, and had never yet failed to get out the few thousands of bushels of coal that was expected to be produced, knew all about it and must be, of course, a first-class mining man, no matter how grossly ignorant he seemed to be, but the "certified mine boss system" has to a certain extent done away with this class and it has also led to reading, study, and inquiry by many of the miners who aspire to the position of mine boss or fire-boss and consequently to the general promulgation of mining information amongst the miners and others connected with the mining of coal.

The present condition of the mines and mining in Allegheny County may be summed up as follows:

First. As to their sanitary condition, fifteen years ago, perhaps 80 per cent of them were very poorly ventilated, now 80 per cent. are well ventilated and the drainage has also been greatly improved, and the Allegheny County mines, as regards the health and safety of the miners, are above the average.

The principal cause of accidents is from falls of roof, no marked decrease in such accidents is apparent; this is a matter which now lies almost entirely with the miner himself, for the operator furnishes him with an unlimited supply of timber, but he does not use it.

Second. As to the production of coal in large quantities by the mines, there are at present about eighty mines in the county shipping coal either by river or rail, of these about half have wire rope haulage plants in operation, and coal is being produced and hauled in some cases several miles underground at from five to twenty-five cents per ton, exclusive of the price of mining, and it is often produced the cheapest where the longest haul is necessary, and haulage has been reduced to a minimum in probably fifty per cent. of the mines, in many of the mines in the county, however, it is crude and expensive.

Third. Improvements in the mining of coal. While the system of entries has been exchanged from the single to the double, yet the old system of room and pillar which has always been in use in this district has undergone no change, nor has anyone attempted to make what might be called an improvement on it; the rooms are usually twenty-one feet wide and ribs twelve or thirteen feet thick, the coal is all taken out, but what a fortune in timber is buried each year in our mines! Occasionally some person who has a mine in leased coal and has no conscience as to the quantity of coal that is destroyed, tries driving rooms with the road in the center, "gobbing" both sides and burying the rib, this is not often done however.

No reliable experiment has ever been tried, to the writer's knowledge, to operate by any of the systems of Longwall, or to introduce any system which would economize in the timber supplies that are now wasted.

While the improvements noted have been the rule, yet there are quite a number of operators who are living and endeavoring to grow rich under the old order of things, and they will only reform when the heavy hand of the law compels them to use first-class appliances which will necessarily call for the employment of first-class men.

ENGINEERING ASSOCIATION OF THE SOUTH.

The regular December meeting of the Engineering Association of the South was held at the new headquarters of the Association in the Cumberland Publishing House, Nashville, Tenn., on the evening of December 10th. In the absence of the President and both Vice-Presidents, Mr. Hunter McDonald of Atlanta, Ga., engineer in charge of the Western and Atlantic R. R., presided with about thirty members and visitors present.

Applications for membership in the Association were received from Mr. William Hewitt, Engineer and Vice-President of the Trenton Iron Company, Trenton, N. J., and Mr. J. S. Walker, U. S. Assistant Engineer in charge of construction of locks on the Cumberland River Improvement. The Secretary presented the specifications governing the competition for the cash prize of $1,000 offered by the Board of Public Works of Duluth, Minn., for the best plans for a drawbridge across the ship canal at that place.

Mr. Olin H. Landreth brought before the Association for consideration, the question of instituting under the auspices of the Association a competitive trial of machinery used in highway building such as graders, ditchers, surfacers, rock crushers, steam and horse-rollers, etc. After an extended discussion by Messrs. E. C. Lewis Hunter McDonald and W. H. Lyle, which in the main was favorable to the enterprise, a committee was appointed by the Chair to investigate and report at the next regular meeting the feasibility of instituting the competitive trial proposed. Messrs. Olin H. Landreth, W. G. Kirkpatrick, and J. A. Fairleigh comprised the Committee.

The paper of the evening entitled "Refrigerating Systems" was then presented by Dr. Wm. L. Dudley, of Vanderbilt University, Nashville, Tenn. The paper comprised an historical account of the development of refrigerating methods, and after classifying the several processes under the head of "absorption" and "evaporating" systems, proceeded to develop a comparative exhibit of the chemical and mechanical results obtained by each process. The paper was illustrated by diagrams showing the working of the different systems as well as lithographs and photographs of modern machinery, as now built. In the discussion which followed Mr. W. G. Kirkpatrick suggested that the cooling effect of expansion of compressed air might be utilized both to cool and aerate the water of cisterns in summer by a portable air compressing apparatus with coils for cooling the compressed air. In many sections of the South roof water preserved in underground cisterns is the chief dependence for domestic supply, and the proposed method of cooling and aerating and thus rendering the conditions unfavorable for development of disagreeable taste and odor was referred to, the low thermal conductivity of the soil surrounding cisterns is a favorable circumstance to the permanence of the effect of such cooling.

The new headquarters of the Association occupied for the first time at this meeting, are in one of the most desirable portions of the business quarters of the city. The principal room is 43x23 ft., with excellent illumination, and has been neatly fitted up at the expense of the local members. Already a large list of exchanges have been received and an order is now out for a full list of all the leading technical journals. Non-resident members and other Engineers visiting Nashville are cordially invited to visit the rooms and make them their headquarters while in the city. Stationary and draughting accommodations will be found here for the benefit of the membership and guests.

THE PROGRESS IN MINING.

Reviews of Important Papers Relating to Mining in the Proceedings of the Mining and Scientific Societies, and in the Mining Journals of Europe, United States, and Canada.

Improvements in Drawing and Loading Coke. Mr. C. M. Percy, of Wigan, England, whose name is familiar to our readers as an authority on the mechanical engineering of collieries, has lately described an apparatus for drawing and loading coke which he considers of great importance. The patent, which is the property of Messrs. Chambers and Smith, is fitted up at the works of Newton Chambers & Co., Ltd., Thornecliffe, Sheffield.

It consists of a small vertical steam engine and boiler erected on wheels and capable of being run along the full length of a row of ovens. Connected with the engine by pinion gearing is a long rod running on rollers. At the end of this rod is a flat plate like a shovel with which to extract the coke. The rollers on which the rod runs are alterable by hand gearing, so that the shovel may be directed at any horizontal angle to reach all parts of the oven without the use of rakes. The apparatus can be adapted to any class of oven. Along the mouths of the ovens is a traveling belt to receive the coke, whence it is conveyed to an elevator which raises it to a suitable height where the coke is put down by the elevator buckets on to a vibrating screen.

By this patent a Beehive oven containing three tons of coke can be drawn in eight minutes, and in the erection described by Mr. Percy one machine is now actually drawing twenty-five ovens per day. In consequence of this saving of time 20 per cent. more coke can be produced by each oven, and, owing to the small time occupied in the drawing, the cost of repair from excessive expansion and contraction of the ovens is reduced.

In a block of fifty Beehive ovens, thus fitted up, the entire cost of coking, including charging, drawing, and loading, and repairs to ovens and machinery, does not exceed twelve cents per ton.

Accidents from Blasting in Collieries. Mr. James Ashworth, M. E., in a paper recently read before the Manchester (Eng.) Geological Society, points out that where a two-inch diameter hole had been used while blasting with powder the same size of hole was still continued for high explosives, and hence instead of occupying eight or more inches of the length of the hole the high explosive occupied only from one to two inches, and the pressure exerted was as great or even greater on the tamping as on the sides of the hole where the power was required and he suggested that high explosives should be put in a hole with a diameter proportionate to their strength as compared with blasting powder, because seven inches of tamping in a one inch diameter hole is as effective as eighteen inches in a two inch hole.

Mr. Ashworth also stated that the worst disasters from blasting had occurred where the shots faced the ventilating current, a detonating vibration apparently ensuing, whereas, if the force of the shot went with the air no such effect was produced.

Greenwell's Patent Screen for Sorting Coal. This consists of a series of parallel short-linked endless chains, driven by engine power, and working between fixed bars of a particular section and of various widths. The coal is tipped on to the screen, and is carried forward by the chains, which travel at a slow speed, and as it passes forward, the dirt and stones are picked out by boys stationed at intervals on each side receive it. It will be at once seen that the screen may be erected of any length and with any num-

FIG. 2.—Section on B B Nuts.

ber of sections, and that by putting a sufficient number of small guiding pulleys to keep the chains steady, the coal may be very accurately sorted into as

FIG. 3.—Section on C C Cobbles.

many different sizes as required. The accompanying plan, elevation, and sections will explain the method. The chains travel at a speed of seventy-three feet an hour, they pass 100 tons of coal per hour at a cost of half a cent per ton, and the cost of erection for each screen is $500.00.

Centrifugal Ventilators. Mr. E. Van A. Norris, of Wilkes-Barre, Pa., read an interesting paper on the above subject at the Glen Summit meeting of the American Institute of Mining Engineers. Mr. Norris treated the subject in a very exhaustive manner, and while the mathematical details of the paper may not be of great interest to the majority of our readers his deductions are interesting as showing how little attention is paid here to obtain reliable data of the work done by fans. There were twenty-five fans in all with which tests were made, and unfortunately, as the author states, "the detailed results of each test show a mass of contradictions from which it is exceedingly difficult to draw any satisfactory conclusions."

The influence of the mine on the fan is so varied in the various tests as to indicate that to obtain any practical comparative results on this point would require that each type of fan should be tried under the same conditions.

The influence of the diameter of the fan on its capacity seems to be *nil*; a large fan having the advantage of requiring a lower speed. The increase of width of a fan seems to increase the quantity exhausted.

The curve and shape of the blades of a fan does not seem to have any influence on the efficiency of the fan. The shape of the spiral casing is important, and results of tests indicate that the best shape of spiral casing would be one so constructed that the air between each pair of blades could discharge freely into the space between the fan and casing the whole being swept along into the *evasee* chimney in a gradually decreasing proportional speed.

The regulating shutter has advantages in that it can be made to suit the varying speed of the fan. Pieces of paper dropped into the *evasee* chimney of a fan have been known to be sucked down and after having made a revolution with the blades to be expelled. Such is not the case when the regulating shutter is applied.

In concluding what is undoubtedly an interesting and instructive paper, Mr. Norris suggests that variations in the methods of taking the observations of the water-gauge and the measurements of air prevent the possibility of obtaining unvarying results, and he trusts that his paper may awaken interest in a somewhat neglected subject. The efficiency obtained in his series of tests varies from 23 to 91·5 per cent., and it would be interesting to compare this percentage with some well conducted experiments upon such a fan as the Waddle, which is so commonly used in England.

Method of Mining the Iron Ores of Danville, Pennsylvania. The ores of this district are of two distinct sorts. (1). The fossil ore, which is simply a fossil limestone impregnated with iron. (2). The sandstone, or block ore, which is a sandstone impregnated with iron. The first named is divided into three splits by partings of sand-slate.

The section is as follows:

SLATE TOP.

Upper Split	5 to 6 inches.
Sandstone Parting	6 to 8 inches.
Buncombe Split	15 to 20 inches.
Sand Slate	10 to 12 inches.
Bottom Split	5 inches.

SLATE BOTTOM.

The block ore ranges from eighteen to twenty-four inches thick with a roof and bottom of sandstone.

The system of mining is the Longwall method. Gangways are driven level, 90 feet apart, each gangway being always a little ahead of that above, or to the rise of it.

These gangways are 7 to 10 feet wide and 5½ to 7 feet high. The working face is generally at an angle of 45° from the line of gangway, and to obtain height in the gangway and to facilitate loading from the chutes the bottom rock is blown up so that the chute enters the gangway next the roof. The chutes are about twenty feet apart, and as all the ore is taken out by the working, as it proceeds, the chutes are maintained by a rock pack on each side.

When first driven, the gangway is timbered on the upper side, but, as settling takes place, this timber requires to be withdrawn and the roof ripped down to maintain height. The props in the gangway are placed two to six feet apart, dependent on the nature of the roof. The length of each working face is twenty-four feet, and is worked by one miner and one laborer, or two miners will combine and work two breasts.

The cost of mining including all expenses to the delivery of the ore at the stock house is $1.37 per ton.

An Improved Mechanical Coal-Getter. Mr. E. Mould, of Whitebarn Colliery, England, recently read a paper descriptive of this machine, (Fig. 4), of which he is the inventor, before the Colliery Managers' Association. It is composed of four distinct parts.

(1). The head.
(2). The cylinder.
(3). The mandrel.
(4). The piston rod, side pieces, and pump handle.

The last named are the only loose parts there are. The "head" contains the pump, and in part, answers the purpose of a reservoir. The cylinder is simply a round parallel barrel, screw-threaded at each end, and is connected to the head at the top end and to the mandrel at the bottom end. This cylinder is covered by a shell cylinder, leaving a cavity between the two. The inner cylinder is perforated on the sides at the bottom end, to allow the water to pass from the under side of the piston, while it is being forced into the cylinder on the top side of the piston by means of the pump, thus supplying the pump during the operation of breaking loose the material in which it has been placed. It has been already said that the inner cylinder was screw-threaded at each end. While it is being screwed together, the outer shell is drawn on to faced joints at both top and bottom ends, and is so made water-tight, and becomes a portion of the reservoir for water.

There is, therefore, ample provision in the head, the cylinder, and the cavity to avoid the necessity of continually refilling with water, which may be more or less unclean.

The mandrel is screwed into the bottom end of the cylinder, and so becomes a permanent joint. The mandrel is also provided with recesses, constituting incline planes. In these incline planes are placed side pieces or wedges, thus making the mandrel cylindrical in form, in which condition it is placed in the hole prepared for it.

There is also a piston-rod. This rod passes from the piston in the cylinder through the mandrel, and on the bottom end there is placed a collaring, so as to enlarge the bearing, because this becomes the base of pressure.

It is very important that the machine should go quite to the far end of the hole (and to ensure this the drill should always be one-eighth of an inch larger in diameter than the machine). Now, supposing the machine is in the hole, and quite at the far end, the moment pumping is commenced, the piston-rod, being at the end of the hole, cannot go forward; therefore the machine moves outward, and the friction on the sides of the hole being greater than that of the incline planes, the side pieces become fixed, and the machine moving outward produces lateral pressure by means of the incline planes, thus forcing asunder the material in much larger blocks than when exposed to the shattering influence

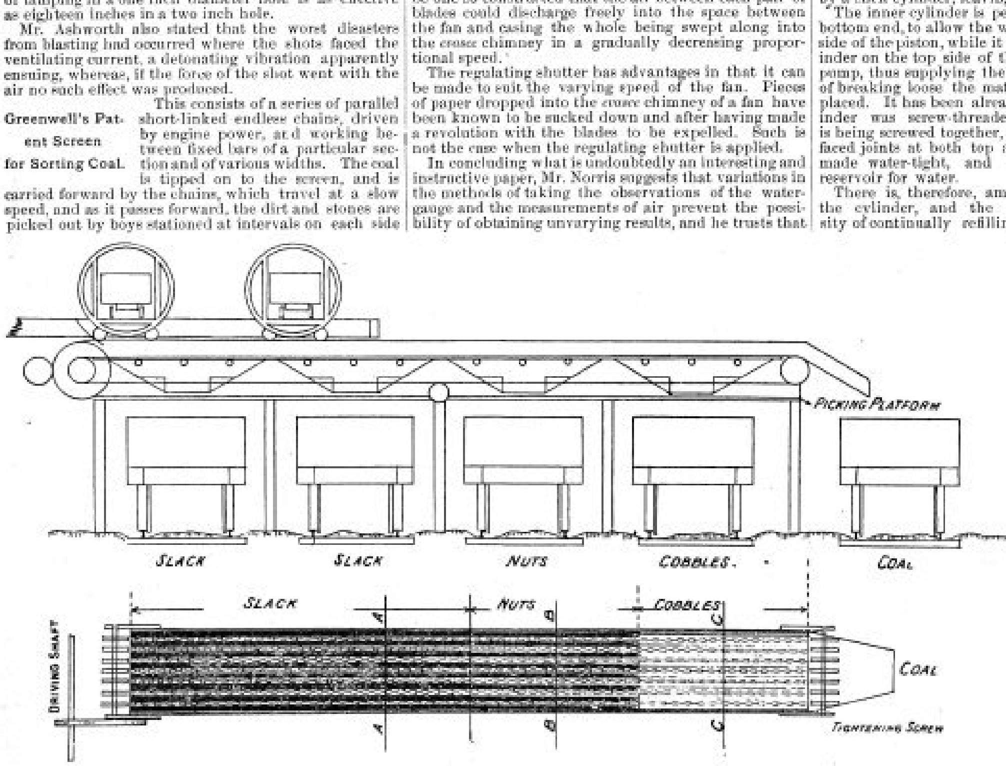

FIG. 1.—PLAN AND ELEVATION OF GREENWELL'S PATENT SCREEN.

and the various sizes of small coal drop through between the chains and bars into wagons placed below; the smallest size passing through in the first length, and the larger sizes in the succeeding lengths, until at the end of the screen the large coal is delivered, free from small and dirt, into the wagons placed ready to of an explosive, securing better results, and at the same time avoiding all the evils contingent on the use of explosives.

This machine has been severely tested and the following merits are claimed for it:

(1). Efficiency.
(2). Portability.
(3). Economy.
(4). Simplicity.

It weighs only 60 lbs. when charged with water, the same water may be used over and over again so that the whole pump is very intact. This is accomplished by means of a screw. When the operation of wedging down a body of coal is completed, by turning this screw

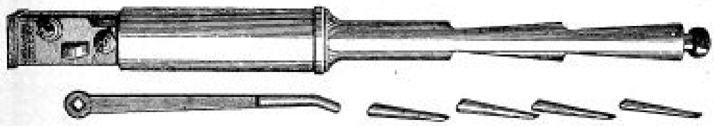

FIG. 4.

the water returns to the under side of the piston, and by tightening the screw again the operation may be repeated indefinitely. The first cost of the machine is low and as the parts are few it is not liable to get out of order. If the pressure requires to be exerted in an upward or downward direction the wedge pieces are placed in the top and bottom, but if the pressure is to be exerted sideways the wedges are placed along the sides of the hole.

The wedges are placed in the recesses of the mandrel and then the machine is put into the hole, and pumping commenced, and in less time than a hole can be rammed for an explosive the body of coal is burst down on to the sprngs.

The machine may also be effectively used as a hydraulic jack.

Hand Power Diamond-Boring Machines. Mr. G. Nordenstrom recently read a paper before the English Institution of Civil Engineers on this subject. It seems that the use of bore-holes underground in Sweden for the discovery of fresh ore deposits has been in vogue for a long time. In 1872 diamond boring was tried by machine at a cost of $10 per foot for which price shafts could have been sunk in the same ground. After that an American prospecting machine, driven by compressed air, was tried in a bore passing through granite, felstone, and limestone.

This machine did 8 ft. 8 in. a shift and a maximum of 16 feet in one shift was attained in the limestone, but the cost was about the same as levels could be driven through the strata, so that the only saving was in point of time.

Four years ago a light portable hand-boring machine was adopted. The rods are hollow tubes 1·29 inches outside and ·98 inches inside diameter. They are screwed together in 5 foot lengths. The boring bit is fitted with 8 diamonds, 4 inside and 4 outside, at a total cost of about $100. The entire boring apparatus including the force pump and gear for flushing the bore, and 55 yards of boring rods weighs only 400 lbs. The largest bore made by these manual machines was 200 feet. The borings were mostly underground; 25 per cent. was vertically downwards, 37 per cent. horizontal, and 38 per cent. varied between 58° upwards and 78° downwards. Four to six men were required to work the machine and about 1½ gallons of water were required per minute for flushing the hole. The rate of advance was from 2½ to 5 feet per shift, and the total cost from $2.12 to $2.28 per foot.

The Use of the McClave Grate and Argand Steam Blower in Utilizing Small Sizes of Anthracite, or Bituminous Slack in Boiler and Similar Furnaces. This is the subject of an illustrated paper contributed to the American Institute of Mining Engineers by Mr. Rufus J. Foster, M. E., of THE COLLIERY ENGINEER.

This grate presents no long lines of metal in contact with the fire. It is constructed of two or more rows of bars, which run across the fire; these bars are each connected with rod and lever by which a shaking movement may be simultaneously applied to the entire grate surface. The advantage in the McClave over other oscillating grates is that at no point of the movement is there any increase in the size of the openings between the bars.

The Argand Steam and Air Blower opens into the ash pit, just under the bars, and gives a thorough supply of air with a small amount of steam to the furnace. In the Argand blower the percentage of steam is very small because it has been proved in practice that an excess of steam generates carbonic oxide, while a moderate supply furnishes oxygen by dissociation at the proper point or stratum in the fire and helps to consume the carbonic oxide, which would otherwise be formed and passed off unconsumed.

The steam also keeps the clinkers soft and porous, and moistens the fine ashes from the grate upwards as fast as they are made.

British Society of Mining Students. The annual meeting of this society was held recently. In the absence of the President the address from the chair was delivered by Vice-President Mr. H. W. Hughes. This address touched first on the subject of coal-dust, and reference was made to the recent experiments of Mr. Hall, one of Her Majesty's Inspectors of Mines, and Mr. Hughes failed to see that in all cases coal-dust was of itself explosive when unmixed with gas, but he would not assert that some varieties of coal-dust were not so. One argument against the explosive properties of pure coal-dust was that no explosions had ever occurred in non-fiery districts.

Touching upon the subject of haulage, Mr. Hughes pointed out the advisability of members bringing forward papers dealing with details of haulage. In general the system of haulage at each colliery is practically the same, but the details to suit particular circumstances at each are different, and may assist other managers in getting out new works.

Mr. C. H. Cobbold, the new President, in his address drew up an advisable course to be undertaken by a young man starting out as a mining engineer. First, he said, "let him take fixed residence for six months at a colliery, which would enable him to test his liking for the work, and ground him in the rudimentary working of the mine; then nine months actual work in a general engineering shop and foundry, where colliery break-downs were the principal work, but where engines are built; twelve months fixed at the colliery where he commenced, during which time he should have leisure to attend mining classes at one of the technical schools, rather than in making himself useful in doing clerk's work at the colliery; then six months apart at say six collieries in different mining districts. This could be carried out by those engineers who take pupils arranging a system of interchange; the result of the six months to be put down in six written papers; lastly, three months at a large sinking where he would learn sinking, tubbing, walling, pumping, and the laying out of a large colliery. The embryo mining engineer would thus, at the end of three years, be fit to come back to his original master, and take charge of a district of the mine, his sphere being gradually increased with his capacity for it."

The British Society of Mining Students is not a society which holds periodical meetings, but all the papers are printed and circulated amongst its members who reside all over the country. It is another feature in education by correspondence.

Automatic Tipping Apparatus. We give, in the accompanying illustrations Figs. 5 and 6, two views of a new automatic tipping apparatus for use on inclined railways, recently illustrated in the *Colliery Guardian*, and which has been in successful use for some time past at the Homeward Bound Gold Mine, Yalwal, New South Wales. As will be seen by reference to the illustrations, a spring is bolted to the bottom of the truck, which presses on a lever working on the axle of the front wheels. In its

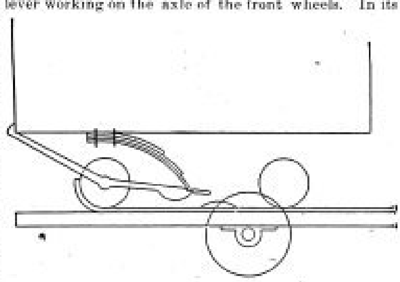

FIG. 5.

normal position, Fig. 5, a catch keeps the door of the truck closed, but should anything lift up the spring, the

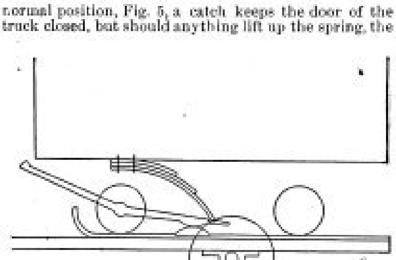

FIG. 6.

door is then released, Fig. 6. At the bottom of the inclined line what is termed a "kick-up" is fixed, the axle on which it turns being a little out of center so that when a truck runs on it, it will overbalance. In order to keep the "kick-up" table in its place ready for a truck to run on it, a weight attached to a rope passing over a pulley connected with the axle of the apparatus counterbalances the greater half of it. Between the lines of the "kick-up" is placed a chock of wood, so that when a cam on the lever passes over this, the spring is pressed back, and the catch of the door is released just at the moment the "kick-up" is tilted. In returning, the cam passes over the chock of wood just as the kick-up rights itself, and the door of the truck swings to so that everything is ready for the truck to be refilled, when it reaches the top of the incline.

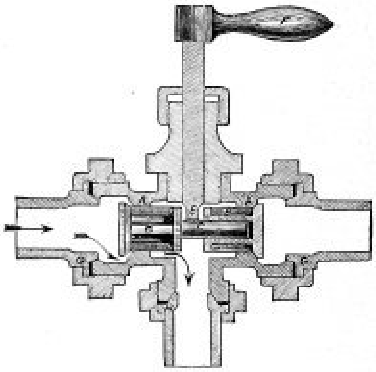
Automatic Cylinder Cocks, for Slide-Valve Engines and Pumps.

The Lunkenheimer Automatic Cylinder Cock is a simple valve contrivance, which, when applied to slide-valve steam engines or pumps, will in every instance result in the saving of steam, amounting in value per annum to many times the cost of the device. It is perfectly automatic, requiring no attention whatever.

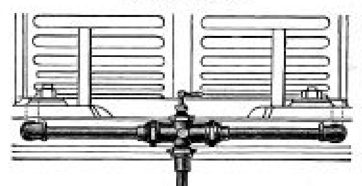
DESCRIPTION.

In consists of two simple, winged check-valves B B, which close alternately against seats A A with a lever E F which can be turned to hold both valves open; union joints G to connect with the drip-pipe from both ends of cylinder, and H with pipe leading the drip away, all arranged in a compact, convenient form.

When steam is admitted to one end of the cylinder, the valve B for that end closes under pressure, and forces open, by means of stem C, the valve for the other



SECTIONAL VIEW.



AS APPLIED TO A CYLINDER.

end, holding it open for the whole stroke of piston, and allowing the water of condensation to flow out into the drain-pipe. This action is reversed when steam enters the other end of cylinder, and so on, alternately, always leaving the exhaust end of cylinder open for the escape of water.

If desired, both valves can be held open by turning lever F down.

Mr. J. Parke Channing, of the East New York Iron Co., writes the manufacturers (The Lunkenheimer Brass Mfg. Co., of Cincinnati, Ohio) as follows:

"Please ship us by express two more ½" automatic cylinder cocks for my hoisting engine.

"The two that I bought from you have been in constant use on a Worthington mine pump since last May and have done their duty admirably. Without them we were obliged to keep steam leaking all the time and in addition to the loss, the level was more or less filled with steam, much to our inconvenience.

"We have ordered them for the hoisting engine and feel convinced we will soon save their cost in steam and packing."

As a guide to the size required for different size cylinders, we append the following table:

Size	⅛ in.	¼ in.	⅜ in.	½ in.	¾ in.	1 in.	1¼ in.
Adapted to Cylinder.	Up to 6 in. in Diam.	From 6 to 10 in. in Diam.	From 10 in. to 14 in.	From 14 in. to 20 in.	From 20 in. to 30 in.	From 30 in. Upwards.	

These cocks are manufactured only by the Lunkenheimer Brass Mfg. Co., who will cheerfully furnish any further information desired.

Tin Plate Manufacture at Piqua, Ohio.

On October 16th the Cincinnati Corrugating Co. started an extension to the works at Piqua, so as to more extensively engage in the manufacture of tin plate. The additional machinery consists of one pair of cold rolls, six annealing, boxes, four Morewood tinning pots, one five-roll Morewood tinning machine, one pump for liquid tin, etc., etc.

The extension to the works is necessary to contain part of the new machinery, etc., for the tin plant, as there was not room for all in the original buildings. As soon as completed the Corrugating Co. will have increased facilties for making either bright or terne tin plates of highest grade. The steel sheets will be rolled as heretofore by the Piqua Rolling Mill Co.

If the Corrugating Co. finds the operation of the plant above referred to as profitable as they have reason to expect they propose to double or treble it as fast as good business policy dictates.

RECORDS FOR GEOLOGICAL PURPOSES.

The Importance of Systematically Preserving Records of Bore-Holes.

We referred recently to the great importance of the Geological Survey as a means of establishing the value of land and making known the resources of the country generally.

We are indebted to a valued English correspondent for the following article showing the important office in obtaining reliable geological knowledge, bore-holes are made to perform in England and suggesting that the law compel the preservation of the records of all bore-holes made in the United States. Our correspondent also describes a box which is much used for preserving such records in England.

"England has for years been pretty well mapped out in a very detailed manner. All fences, foot-paths, cattle ponds, wells, springs, and even erratic boulders appearing on the Ordnance Survey maps, which may be obtained either to the scale of one inch to the mile or six inches to the mile, as well as to a still larger scale of twenty-five inches to the mile, and in towns five feet or ten feet maps can often be obtained. With a six inch map in hand the labors of the geological surveyor are much reduced, and where any particular stratum extends over large areas the work is practically confined to coloring the whole sheet one uniform color indicative of the surface rock.

In other cases, of course, where the dip is quick, and faults come in to destroy the uniformity, there is much more work involved.

An example of this is seen in the country south of London where the district known as the Weald is bounded on both sides by the cretaceous rocks which have in places very acute dip, and their outcrop on the map is confined to a mere streak of color only $\frac{1}{16}$ inch wide on the one inch map. It has been remarked that in a journey from East to West of England, a matter of 200 miles or so, the traveler may start on the latest drift and travel over the outcrops of every geological period until he reaches the outcrop of the lowest known granitic and trappean rocks. This result of quick dip necessarily adds much to the amount of work to be given by the geologist, but still this must be less than what is necessary over the Continent of North America.

Compared with the mapping of the solid rocks, the proper delineation of the drift presents, if not more difficulty, at least more labor, of a sort, though the drift being a superficial sheet is readily determined itself whilst adding to the difficulty of properly defining the boundaries of the solid rocks beneath, and the English "solid" maps frequently bear the words "obscured by drift."

The geologist receives an immense amount of assistance from the work of practical men in England. For example, the English railways have very much more largely than American railroads been constructed with heavy works in the shape of tunnels, cuttings, and embankments. Many such works were constructed in the early days of railway engineering entirely with the idea that easy gradients were a prime necessity, for the locomotive of that period was a small affair compared with that of to-day. From the sections thus presented precise and valuable information became open to view and enabled points to be fixed with accuracy from which boundaries could at least be often closely inferred. For deep work, however, a very useful source of information has been the boring of artesian wells.

These have proved of immense value to the English Geological Survey, and we cannot too strongly emphasize the importance of preserving a truthful record of every boring into the earth's surface, which may be made.

Unfortunately well-borers are in many instances men of little education, and large numbers of bore-holes have been made of which no record whatever exists. Often, too, such record as does exist is due not to the workmen but to the scientific knowledge and interest of some resident in the locality who has made it his special care to watch the progress and note the strata passed through.

The better class of artesian well engineers have, however, kept sample bores of every boring they have made, not merely as a matter of scientific interest, but as a useful record for possible future operations in the same locality, and these, of course, are most serviceable to the geologist. The English Geological Survey, whose headquarters are at Jermyn Street, are always glad to afford information relative to the probabilities of a boring for water in return for the information given them by the engineers. The evidence thus gradually accumulating is daily rendering the geological knowledge of the country more complete. But, even in a small country like England, there is still an immense amount of information lacking to complete the mapping of the deeper rocks.

It has long been held that beneath the Southeast of England there is a ridge of older rocks rising up to the base of the cretaceous rocks which form the surface, or are but little sunk below it.

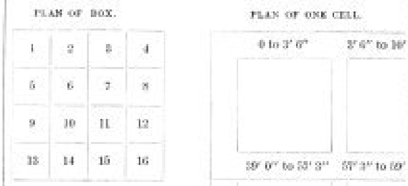
The truth of this theory seems to have received confirmation by the penetration at 1,200 feet below surface of what appear to be Devonian rocks immediately underlying the chalk at a brewery in London, the whole of the strata properly interposed and superficially, indeed, forming the whole breadth of England being absent. It is now reported that a boring in the country about seventy miles north of London, has, at a depth of less than 700 feet below the surface, reached the base of the chalk and passed directly to a bed of Palæozoic rocks as in the above named London boring, thus supplying another link of evidence confirmatory of the opinion that a ridge of older rocks thus exists.

In the London boring there was but little doubt that the rock reached was Devonian, of course completely below the coal measures. In the recent boring there appeared, at first, a doubt whether the rock was not a portion of the coal measures *above* the coal, but the latest opinion seems convincing to the effect that though the coal measures were the rocks reached, it was only one of the series below the coal seams which had been denuded, if ever they existed. A discovery like this, however, is as interesting to the pure and simple geologist as though a valuable coal field had been discovered, and indicates how very unexpected results may prove without the slightest surface indication. Indeed the surface of England above this ridge comprises a portion of the most level tract in the country. The fact of there being no coal at this particular spot is, of course, no evidence that on the slopes of the ridge and at somewhat greater depths coal will not eventually be discovered. Had it been proved in this instance it might have changed what is now the most rural portion of the country into a hive of manufacturing industry.

Every fresh boring may add something to the existing knowledge of the earth's crust, fixing the slope of the hidden rocks and giving data from which to estimate probable depths at a distance.

In much-faulted districts, too, borings are invaluable as a means of measuring the vertical displacement, and too much stress cannot be laid on the importance of keeping a record of what is passed through.

Such a record, to be most valuable, should not be merely in writing but should consist of actual samples of the *debris* from the boring preserved in a properly partitioned box and marked for depth as per sketch.



Each cell may be 3" × 3" × 3" and above each its extension should be marked, whilst a paper pasted in the cover may contain a written description, if desired. Such boxes, when carefully filled, are of abiding value as *known facts*.

America, as compared with England, is as yet barely touched. Her railroads form a far less proportion to her area than do the railroads of England, and bear less evidence in the shape of cuttings. Heavy works, indeed, have formed so serious an item in English railways that a story is told of one engineer who was sent to a foreign land to survey a line. Said foreign land was level and flat and the engineer pronounced it quite unsuitable for a railroad. "Where," he exclaimed, "will you run your tunnels?" He could not understand a railroad without tunnels. In borings too, except over a limited area, America has relative to area a small number and hence the wisdom (before spending money on boring the large numbers which will some day exist) of making provision—advisably by law—for preserving records of every boring made. Without their confirmatory evidence the horizontal section maps cannot be more than inferentially correct. With their evidence they become positive statements of fact, and in this way they may frequently prevent the useless expenditure of money on works of engineering and mining, which has so often been incurred.

The search for coal in Eastern England has so far had as one cause for its being not undertaken the extreme depth at which it must exist. Now, a single boring to a small depth upsets this objection and introduces the opposite one of possible denudation, following upheaval, previous to the deposition of the later post carboniferous rocks, though it opens at the same time a book of study and research which contains many blank leaves to be written up.

With such possibilities in a narrow field, how wide an area remains to be filled out in the blank book of the United States."

METHOD IN OUR WINTER TEMPERATURES.

BY H. GAWTHROP, PHILA., PA.

The weather reports of the cities of Boston, New York, Philadelphia, Buffalo, and Chicago show a striking resemblance in their Winter temperatures, when comparing one with the other as to the variation in the mean temperature for each month. Changes to cold or warm are uniform throughout the territory covered by these stations, so that any one of them may be taken as representative of all, in this respect.

Taking the mean temperature at Philadelphia for the six coldest months of the year, November to April inclusive, since the first observations in 1871, the average for the twenty years is found to be 38·87 degrees. It is found also that nine of these periods average above and eleven of them below that of the twenty years. In the table below, the averages and extremes of the mean temperature for the months of each period are given. For sake of brevity, they will be called Warm Winters and Cold Winters respectively.

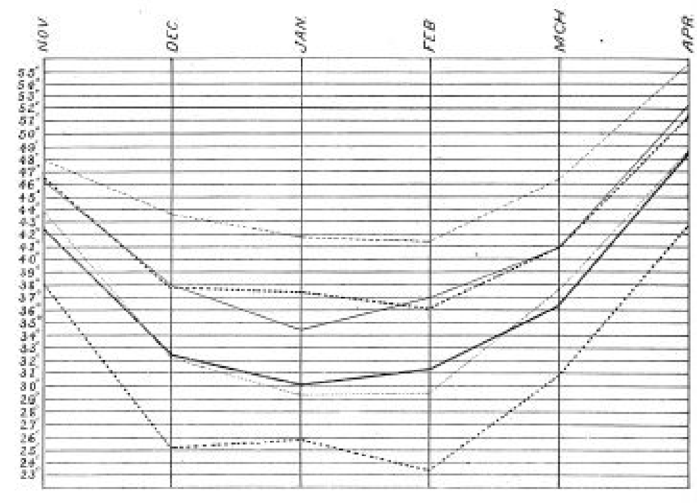
MONTHLY MEAN TEMPERATURE.

For Nine Warm Winters.	Nov.	Dec.	Jan.	Feb.	Mar.	Apr.	Av.
Highest	48·0°	42·6	41·8	41·4	46·4	55·6	44·1
Average	46·2	38·9	34·5	37·0	40·9	52·2	41·5
Lowest	43·8	33·2	29·4	29·5	37·6	48·7	39·9
For Eleven Cold Winters.							
Highest	46·5°	37·8	37·4	36·1	40·9	51·3	38·6
Average	42·3	32·4	30·1	31·2	36·4	48·5	36·8
Lowest	38·0	25·1	25·8	23·4	30·8	42·6	36·8

The chart gives a graphic view of these figures, the dark line for the averages, and the heavy dotted lines for the extremes, of the cold winters; and the faint line for the average, and the light dotted lines for the extremes, of the warm winters.

It will be seen that, with the exception of the broadening, from the greater range of temperatures, in mid-winter, the lines are nearly parallel throughout the six months, and the winters continue and end as they commence. It may be said that, as goes November, so goes the winter. The only variation from the symmetry of the hole, and that but slight, is the close approach of December and February temperatures to that of January in the cold winters, the extreme cold seeming to cover a greater period than in the warm winters.

The limitation in the extremes for each period is noticeable. In the warm winters, the extremes go but



slightly below the average of the cold winters; and, except in January, the line of extremes in the cold winters follow closely the average of the warm winters. Each group has its well defined course and limit.

For the next twenty years, there will probably be a similar result, and this uniformity in the winter temperatures may be accepted as a rule; but when weather observers turn prophets, they take much risk, because of the striking exceptions. Nature in her various forms, insists on exceptions to all rules, but the geologist or botanist does not hesitate to formulate the rule and gives slight heed to many exceptions. In the weather department of Natural Sciences, however, phenomenal temperatures, blizzards, and floods are so prominent that advocates of rule are without honor.

For this present season, the mean temperature of November (44·2), has been close to the average of twenty years (44·1), so that the winter may be considered as commencing with an average temperature. During the twenty years under consideration, but one winter, classed as warm, has begun with less temperature in November than this year, and it turned out to be close to an average winter. In the same period, five Novembers with a higher average, preceded cold winters.

It will be left to the readers to draw their own conclusions and to prophecy as to remainder of the winter

THE FUEL SUPPLY OF THE UNITED STATES.

A Sketch of the Progress of Twenty years in the Economy of Production and Consumption.

BY JOHN BIRKINBINE, PHILADELPHIA, PA.

[Presidential Address at the Glen Summit Meeting of the American Institute of Mining Engineers, October, 1891.]

Four meetings of the Institute have been held in the Anthracite coal fields of Pennsylvania, and excursions into the district, in connection with meetings elsewhere, have familiarized our members with the development of this unique region. But the progress of that development has been so marked that, in view of our assembling within a few miles of where, two decades ago, the Institute was organized, a brief *resume* of the history of the Anthracite coal mining industry, and some thoughts upon the fuel problems of 1871 and 1891 seem to be specially appropriate on this occasion.

Seventy years ago, the "burning stones" which we recognize as Anthracite coal, were first mined, but what has now become a magnificent industry grew with comparative slowness for two decades; and it was not until 1842 that 1,000,000 tons of Anthracite coal per annum were produced.

The opening of this fuel-field, however, soon exerted a stimulus upon railway and canal construction, some of the earlier enterprises and numerous later additions having been projected and maintained to carry Anthracite coal to points of consumption or to navigable waters. And this stimulus reacted upon the industry itself. Larger shipments were demanded to meet the requirements of the market developed by these improvements.

From 1842 to 1864 the annual production of this form of fuel increased tenfold, from 1,000,000 to 10,000,000 tons, and this amount was again doubled (to 20,000,000, tons) in 1873. The shipments of Anthracite coal for 1890, show another step in geometrical progression: for, if to the 36,000,000 tons of Anthracite shipped, we add the coal used at the mines, a production exceeding 40,000,000 tons is accounted for.

The astonishing record of the mining industry within this limited area can be best appreciated by comparing the output with that of another mining industry. Thus, the weight of Anthracite coal mined in Pennsylvania in 1890 was nearly three times as great as the total iron-ore product of the United States; and this coal was obtained at greater average depth, and under conditions generally less favorable, then are found at the iron-ore mines.

The total output of the Anthracite regions of Pennsylvania for the past seventy years, approximates 750,000,000 tons. Of this, over 12 per cent. was obtained in the forty years between 1820 and 1860; 15 per cent. in the decade following; nearly 25 per cent. between 1870 and 1880; and for the past ten years the output has averaged about 35,000,000 tons annually, aggregating nearly 48 per cent. of the whole.

Of the total output of the Anthracite coal region as recorded, one-half has been mined since 1879, and the period of twenty years which marks the existence of the American Institute of Mining Engineers, covers a reported production of Anthracite coal of nearly 540,000,000 tons, or 72 per cent. of the total output of the region.

Mr. J. H. Jones, special census agent, places the value at the mines of the Anthracite coal product of Pennsylvania in 1889 at $65,721,578, demanding, at 362 regular establishments, the services of over 124,000 employes, who received in that year nearly $40,000,000 as wages. The capital invested in the coal lands amounts to almost $162,000,000; and this valuation does not include undeveloped properties nor any surface improvements, except such as are necessary for mining and preparing the coal. If to the above amount were added the coal lands held in reserve, the numerous dwellings, and the enormous railroad facilities specially built and maintained to convey the product of the mines and breakers to trunk lines, the valuation would be greatly augmented; for no part of Pennsylvania is so well supplied with railroads as the Anthracite coal fields, and few points in the United States are connected with as many competitive systems of transportation as the section which the Institute visits during this meeting.

Our *Transactions* demonstrate that much of the progress in mining methods and appliances by which the above results were accomplished is traceable to members of the Institute; and of those we can truly say, "the half has not been told" in the printed papers forming part of our publications.

An approximate review of the consumption of all kinds of fuel, for the past twenty years may be obtained from the following census data:

	1870.	1880.	1890.
Gross tons of Anthracite coal,	13,925,229	25,580,189	40,714,721
Gross tons of Bituminous coal,	15,356,619	38,242,641	85,383,059
Bushels of charcoal,	....	74,008,972	90,000,000*
Cords of wood,	....	145,778,137	180,000,000*
Barrels of petroleum,	5,260,745	26,286,123	34,820,306
Natural gas, value in coal displaced,	No report.	No report.	$20,000,000*

*Estimated.

The fuel consumed in the United States, exclusive of natural gas, but including the coal and wood converted into gas, requires the conveyance, by various methods, of nearly one and a half million gross tons each day of the year (no unimportant factor in the national problem of transportation), and demands the energies of over one million wage-earners to mine, cut, handle, and convey it to points of consumption. The fuel-consumption, *per capita*, in the United States, is in calorific value equivalent to 3½ tons of coal per annum. Possible economies may reduce this to 2½ tons for the same amount of work performed.

By reason of the extended area of the Bituminous coal-fields, their development has greatly benefited the entire country. This fuel has supplied most of the illuminating and fuel-gas, and in addition to its liberal use for domestic and steam-producing purposes, the coke resulting from its distillation has influenced the iron industry to a wonderful extent, as is shown by the following figures, taken from the reports of the ninth, tenth, and eleventh censuses:

	Gross tons. 1870.	1880.	1890.
Pig-iron, ...	1,832,876	3,375,912	8,553,374
Manufactured iron, ...	1,287,347	2,101,183	2,518,193†
Steel, or, finished product; & ingots	41,426e	1,022,060	3,988,227†

†As the census statistics have not been issued, the above figures are taken from the report of the American Iron and Steel Association for 1890.

The output of Bituminous coal, added to the production of Anthracite in 1890, brings the total of coal mined in the United States to 75 per cent. of that mined in Great Britain, the country which supplies nearly as much coal as all others in the world combined, exclusive of our own. In other words, the United States now produces about 30 per cent. of the world's output of coal, while it consumes, in addition, great quantities of wood, charcoal, oil, and natural gas. The United States is the great fuel-consumer of the world.

Over 2,000,000 cords of wood are annually cut to produce the 90,000,000 bushels of charcoal which I estimate were used in smelting ores of iron and of the precious metals, and for other specialties. The cordwood used as fuel for various purposes largely exceeds that cut for charcoal, but the amount can only be roughly approximated. The total wood of all kinds used for fuel is estimated by Mr. B. E. Fernow, chief of the Forestry Division of the United States Department of Agriculture, at 180,000,000 cords per annum.

Peat is used to a moderate extent only; but various methods of drying or preparing it are passing through experimental stages.

In thirty-two years the product of petroleum has grown from 2,000 barrels to 35,000,000 barrels annually, reaching a total for the whole period of 450,000,000 barrels. Of the present output, approximately 40 per cent. is used for fuel; and this has a calorific value, three barrels of petroleum being taken as equivalent to one ton of coal, of over 4,500,000 tons of coal annually. The convenience of application favors the use of petroleum in localities where coal commands relatively high prices, and in cases where intermittent firing is employed; and we may anticipate a growing demand for this form of fuel.

It is perhaps impossible to determine the quantity of natural gas used in this country, but a measure of its importance may be found in the equivalent money-value of coal it has displaced, which is calculated to approximate $20,000,000 annually. Moreover, the extensive introduction of natural gas for industrial and domestic uses has stimulated the employment of producer-gas, and in many instances the manufactured gaseous has supplanted the natural solid fuel.

The magnitude of the quantities represented by our fuel-supply emphasizes the importance of economies in its use. A saving of one per cent. of the fuel of all kinds consumed in the United States would be equivalent to 2,300,000 tons of coal per annum. Each of our members will aver that, in almost every case of which he is cognizant, one per cent. of the fuel used could be readily saved, and in numerous instances the possible economies appear to be much greater. If all the fuels produced in the United States were used for one year for the generation of steam, they would furnish continually, through boilers and engines of ordinary efficiency, nearly 12,000,000 horse-power; but if applied to boilers and engines of high economy, the resulting energy would be augmented to 25,000,000 or even 30,000,000 horse-power. An average reduction in American blast-furnaces of one hundred weight of fuel per ton of pig-iron made would amount to an annual saving of nearly a half million tons of coal, and proportionate economies in iron and steel manufacturing processes would more than double this saving.

The crowds of coal-pickers covering a city's ash-heaps attest the waste of fuel imperfectly consumed for domestic and manufacturing purposes, and the "smoke nuisance" (the abatement of which is always in the future) is constantly before us as an indication of improvidence. The evil is to be overcome, if we believe the announcements of trade-circulars, by patented boiler-settings, which facilitate the evaporation of water at a rate in excess of theoretical perfection; by smoke consuming devices, which effect such economies that it will pay to burn coal merely to utilize the smoke; or by stoves or furnaces which, through some secret of nature confided to the inventor only, utilize upward and downward draughts in the same chimney, the downward draught bringing the combustible myth to intensify immensely the heat of the normal fire. Economies are also claimed for special details in blast-furnaces, heating-furnaces, puddling furnaces, or other metallurgical constructions, some promising a return of more heat units than are accepted as theoretically attainable.

While many of the so-called fuel saving inventions are farcical, because they are based upon unsound theory, we are indebted to others for marked economies in fuel-consumption, which have made it possible to advance metallurgy and manufactures to the position they now occupy. It requires but a brief retrospect to recognize the true economies, and for this we need note only improvements made during the existence of the American Institute of Mining Engineers.

Suppose for a moment that the quantity of pig-iron and manufactured iron and steel now demanded by the United States had to be produced, manufactured, manipulated, and transported by methods in use two decades ago—how many tons of fuel would be wasted in producing the 8,553,374 tons of pig-iron we made in 1890, if the blast-furnaces were equipped with open fronts and fore-hearths, following the custom of charging more fuel than the furnace could consume, so as to shovel it out at the bottom? What additional fuel would be required if gas-producers were not connected with the furnaces in our mills and steel-works, or if the direct methods of conveying molten metal from blast-furnace to converter, and hot ingots or billets from converter to mill, or from one mill to another, were abandoned, and if our mills returned to the former practice of allowing the metal to cool between each two stages of treatment.

The developed coal mines of the United States could not possibly supply the present demands of the country if our industries, our locomotives, and steam-vessels consumed fuel at the rate per ton of product or per horse-power that they did in 1871. Neither could the coal mines, as opened and equipped in 1871, produce the fuel now demanded.

Among the economies already achieved, none are more notable than those adopted in and about the mines, by which the coal is removed with less loss in mining, and prepared so that, of that which formerly went to the dump piles, nearly all that is combustible is reclaimed. The application of finer sizes, and even of the slack coal and dust to useful purposes, is entitled to a prominent position among the fuel economies.

A critical review of the advances made in the methods and processes of mining, preparing, handling, and transporting coal, of producing and using steam, of smelting, refining, and manufacturing metals, would probably show that we are now able to accomplish with one ton of combustible mined, results which, twenty years ago, would have required the mining of two tons or more. If then he is entitled to credit as a benefactor who causes two blades of grass to grow where one grew before, we have cause for congratulation and for just praise, that in 1891, one ton of combustible taken from the mines benefits the country as much as, or possibly more than, two tons as removed, prepared, and used in 1871.

Such results, however, are not due to one man; to accomplish them, thousands of active minds have worked in one general direction, against difficulties and discouragements. The geologist, the mineralogist, and the explorer have done their part in locating and developing additional sources of fuel supply. The mining engineer, with the aid of the constructor and the mechanic, has brought to the surface, prepared, and delivered to consumers the solid, liquid, or gaseous fuels at low cost, while the laboratories of the chemists and physicists have contributed valuable data as to the composition and utilization of various fuels to assist the metallurgist and engineer in applying them. All of the classes mentioned are represented in the list of members of the American Institute of Mining Engineers. Our roll of 2,300 embraces in each department distinguished specialists, whose contributions to the *Transactions*, or work in practice, have aided in no small degree to accomplish what has been achieved. Yet, as indicated, there remains much to be accomplished, and the purpose of these remarks has been to invite attention, in a general way, to the magnitude of the fuel problem, and, while recognizing the advances made in the past twenty years to encourage the endeavor after further economies in the utilization of fuel.

A Growing Business.

The Webster, Camp & Lane Machine Company, of Akron, Ohio, manufacturers of Mining Machinery and Corliss Engines, has completed arrangements by which a part of its business will be removed to Kent, Ohio, ten miles east of Akron, where buildings will be erected for the manufacture of heavy machinery.

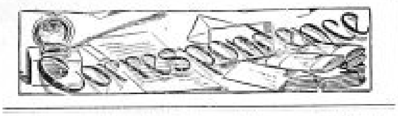
While the Company will continue its offices in Akron, and the use of its present shops for local work, it will erect at Kent complete shops, consisting of machine shop and main erecting shop 100 ft. wide x 400 ft. long, built with 25 ft. galleries on either side of a 50 ft. crane span; foundry building 100 ft. wide x 300 ft. long, with wing 75 ft. x 100 ft.; smith shop 60 ft. x 80 ft., besides pattern shop and pattern storage building. Both machine shop and foundry will be equipped with thirty-ton electric cranes of most approved pattern.

All buildings are to be of brick, and erected on a twelve-acre tract of land situated between N. Y., P. & O. Division of the Erie Railway, and the Pittsburgh & Western Division of the B. & O. Railway. The Cleveland, Canton & Southern Railway runs across the south end of the property, so that the Company will have unsurpassed shipping facilities.

The Company has been very much cramped for room in its old works, and so hemmed in on all sides that additions there were out of the question. It expects to start the new works with three hundred men in addition to the force employed in Akron, and this number will be increased as fast as required.

The Webster, Camp & Lane Co., has won a trade through the superiority of its machinery, that will, we have no doubt, require still further enlargements in the near future. This new move gives it a chance to make these enlargements as fast as business demands them. It is a live Company, and the officials are energetic, enterprising men.

We have recieved from the Lidgerwood Manufacturing Co., of 96 Liberty St., New York, a copy of a very handsome and interesting illustrated pamphlet, entitled "Phosphate Mining." The book is issued to illustrate the use of the Improved Suspension Cableways in phosphate mines. All the sketches are made from photographs, and are therefore true to actual existing circumstances. These cableways have been used for years in handling materials of all kinds, and have proven their superiority over other methods. Readers of this journal should send for a copy of this book, which is mailed free on application to the Lidgerwood Mfg. Co., 96 Liberty St., New York.



This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.

Mensuration.

Editor Colliery Engineer:

SIR:—In answer to "Trackman," in your October issue, I submit the following which I think is right, if I understand the question:

A tree 80′ long, 6′ diameter at butt end, tapers to 1′ diameter, how long a rope will it take to coil around it, the coils to be close together, also how long will the rope have to be, allowing 12″ between coils?

From the two end diameters we find the mean diameter to be $3\frac{1}{2}'$. The proof of which is

$$1 + 3\tfrac{1}{2} + 6 = 10\tfrac{1}{2} \div 3 = 3\tfrac{1}{2}'.$$

Then,

$3\frac{1}{2} \times 3{\cdot}1416 = 10{\cdot}9956$, the circumference, which multiplied by the number of times the rope goes around the log will give the number of feet required to cover the log, thus

$$10{\cdot}9956 \times 960 = 10555{\cdot}7760'.$$

Now, for the rope to go around every 12 inches it will take 80 times, then

$10{\cdot}9956 \times 80 = 879{\cdot}6480'$. Therefore, allowing 12″ between coils, it will require 879·6480′; and if the coils are close together 10555·7760′.

Yours, etc.,
JAMES PAYNE.

Adger, Jeff. Co., Ala., Nov. 21st.

Mechanics.

Editor Colliery Engineer:

SIR:—As I have not noticed any answer to "J. T. G.'s" question which appeared in the September issue, I offer the following:

On an incline rising 1 in 10, the loads weighing 12,000 pounds, and the empties 3,000 pounds, the drums, ropes, and sheaves 5,000 pounds; the friction of the cars equal 1% of their weight, and the friction for drums, ropes and sheaves $\frac{1}{40}$ of their weight. When they are being let down by a brake, it takes 4 minutes to run 300′ now what is the amount of friction applied by the brake?

$$12{,}000 \text{ lbs.} - 1\%, \text{ or } 120 \text{ lbs.} = 11880 \text{ lbs.}$$
$$3{,}000 \text{ lbs.} + 1\%, \text{ or } 30 \text{ lbs.} = 3030 \text{ lbs.}$$
$$8850 \text{ lbs.}$$

Then

$$8850 \text{ lbs.} \div 10 = 885 \text{ lbs.}$$
$$5000 \text{ lbs.} \div 40 = 125 \text{ lbs.}$$

760 lbs. actual load tending down plane without any resistance, whatsoever. This load turned loose at head of incline 300′ long rising 1 in 10 would travel the distance in 13·7 seconds out; our load must only travel 300′ in 4 minutes or 240 seconds.

The vertical height of a plane 300′ long that will give a body a velocity of 300′ in 240 seconds by the following formula is ·096 feet.

$$\frac{300^2}{240^2 \times 16{\cdot}08} = {\cdot}096'.$$

This deducted from total height of plane which is 30′ will leave 29·9′; and $29{\cdot}9' \div 30 = {\cdot}9966$ co-efficient of friction, therefore

$760 \times {\cdot}9966 = 757{\cdot}4$ lbs. of friction which will have to be applied.

Yours, etc.,
H. L. D. W.

Cincinnati, Ohio, November 24th.

Answers to Miscellaneous Questions.

Editor Colliery Engineer:

SIR:—I submit the following in reply to "S. W.," of Irondale, Ohio:

(1.) *a.*—Suppose the ventilation to be produced by a *force* fan; a fall occurs partially closing or contracting the inlet, the fan still making the same number of revolutions, the result is the water rises in the opposite leg of the w. g.

b.—Suppose the same fan with two parallel headings. Suddenly, by some means, the stoppings are removed making the air course larger, the w. g. will fall.

(2.) Density so far as air in mines is concerned may be diminished by applying heat, say at the upcast and rarifying it. Also, density can be increased by using a powerful force fan with small return airways and heavy drag.

(3.) The depth of shaft must be according to the square root of the quantity:

$$60{,}000^2 : 70{,}000^2 :: 400' : x,$$

$$\frac{49 \times 400}{36} = 544{\cdot}44'; \text{ subtracting}$$

the 400 we have 144·44′ as height of stack.

(4.) *a*—First

$20' \times 20' \times 10' = 4000$ cu. ft. of water to be raised 60 ft. in 30 minutes. Then, $4000 \div 30 = 134$ — cubic feet in one minute = 8375 lbs.

$$8375 \times 60 = 502{,}500 \text{ units of work.}$$

Allowing $\frac{1}{4}$ for slip of pump, we have 628,125, and one-half of this last sum for friction of machinery, etc., we have 942,158 units of work to be performed which divided by 33,000 equals 28·55 H. P.

b.—From THE COLLIERY ENGINEER POCKET-BOOK we get the formula

$$D = \sqrt{\frac{F}{L \ N \ {\cdot}00545}}$$

Where

F = cu. ft. per minute.
L = length of strokes.
N = No. of strokes.
$\cdot00545$ = constant.

I would use a double action pump making 67 cu. ft. per minute for each pump, then

$$D = \sqrt{\frac{76}{40 \times 2 \times {\cdot}00545}} = 12{\cdot}4, \text{ allowing}$$

$\frac{1}{4}$ of the area of plunger for slip of pump, or what is the same multiply the diameter by $\frac{1}{8}$, we have

$12{\cdot}4 \times 1{\cdot}125 = 13{\cdot}95$, or say 14″ as diameter of pump.

Now

$$A = D^2 \times {\cdot}7854 = 153{\cdot}93.$$
$$60 \times {\cdot}434 = 26{\cdot}04 \text{ lbs. per inch of plunger,}$$

and

$$153{\cdot}9 \times 26{\cdot}04 = 4000 + \text{ lbs. total weight.}$$

Add 50% to this for friction, etc., and we have

$$4000 + 2000 = 6000 \text{ lbs.}$$

Say the steam pressure is 40 lbs. per inch, then

$$\frac{6000}{40} = 150'' \text{ as area of steam cylinder.}$$

Then diameter equals

$$\sqrt{\frac{a}{{\cdot}7854}} \text{ or } 13{\cdot}8'' \text{ as diameter of steam}$$

cylinder.

$$\frac{2 \ A \ P \ R \ S}{33{,}000} = 29 \text{ H. P. practically the}$$

same as before if the decimals had been carried out. Therefore 14″ pump with 14″ steam cylinder would do the work.

Yours, etc.,
J. V.

Punxsutawney, Pa., Nov. 26th.

Ventilation.

Editor Colliery Engineer:

SIR:—The following question was asked at an examination in Nova Scotia:

It seems there are several different opinions regarding the proper solution, some solve it by Mauchline's rule, given on page 53 of his book, while others work it out differently. I hope it will be freely discussed until we can all see it in the one true light.

"What *pressure* and *power* will it take to get 10,000 cubic feet per minute through an airway 6,300 feet long, of which 6,000 feet is 5′ × 8′ and 300 feet 2′ × 5′; also, what quantity would you get with the above pressure, if the airway was 6,300 feet long and 5′ × 8′ area?"

I wish your correspondents would discuss the question from three standpoints, viz., (1.) The 300′ × 2′ × 5′ being at inlet; (2.) The 300′ × 2′ × 5′ being in the center of airway, and (3.) The 300′ × 2′ × 5′ being at the outlet.

Yours, etc.,
H. L. D. W.

Cincinnati, Ohio, Dec. 4th.

Pumping.

Editor Colliery Engineer:

SIR:—The question of "Beginner," of Mt. Pleasant, Pa., in your August issue, has become interesting, and the four solutions which have appeared in your journal showed that "Beginner" has hit upon a question that needs to be discussed and properly solved. Please allow me to contribute a mite to this end.

The question is: "In a shaft 100′ deep a pump is placed with 5′ suction and 95′ discharge. Will it require more or less power if the pump is placed up the shaft, with 20′ suction and 80′ discharge?"

In your October issue "J. V.," of Punxsutawney, Pa., and "T. S. A.," of Anita, Pa., state that with 5′ suction it requires 6·51 lbs. per square inch more power. Having discussed this question with a great number of pumpmen, engineers, and surveyors, I find about nine-tenths of them of the same opinion. But I am much pleased to note that in your December issue "F. B.," of Macean, N. S., and "J. N. K.," of Mansfield, Pa., have given us a much more satisfactory solution, by stating that the power required in both positions of the pump is one and the same. No doubt this is correct, and they have made a noble attempt to explain the *modus operandi* of a pump. In his attempt to do so "F. B." states that if we raise water in the suction 5′ we must create a vacuum of 2·17 lbs., to raise 10′ we must create a vacuum of 4·34 lbs., and 20′ the vacuum must be 8·68, and 30′, 13·02, and so on until we reach perfect vacuum. Again, we get the same principle with "J. N. K.," as follows: "The suction is only an indirect way of lifting water: in the suction pipe there is a pressure of 14·7 pounds of air to the square inch. Now without computing anything for friction, in order to get water up to the piston of the pump we must exhaust the air until only a pressure of 6·02 lbs. remains. 20′ of water will weigh 8·68 lbs. per square inch of area, and in order for the atmospheric pressure to force the water up the pipe we must exhaust a pressure of air from the pipe of 8·68 lbs., which is the same as if the water was lifted."

After reviewing the above I am compelled to disagree with the mode of operation described. That we create a vacuum equal to the height of the suction when a pump first takes its water is true. After that to me it is an impossibility for that operation to continue, but as soon as the working barrel is filled with water, the plunger is withdrawn against the pressure of the atmosphere of nearly 14·7 lbs. to the square inch of this area. But we also find the water forced into the working barrel and against the bottom of the plunger with the same pressure to the square inch—14·7 lbs., and in a 5′ lift 2·17 lbs. of this is utilized to raise the weight of the water to the plunger, while the balance of 12·53 lbs. per square inch is forcing the water against the plunger to that extent (no allowance made for friction or weight of valves), and compensating for that amount of work done by the plunger, or in other words, assisting the plunger to that extent; so that actually the power attached to the plunger is only to lift actually the weight of the water, as stated by "F. B." and "J. N. K." But to use the term creating a vacuum of so many lbs. when a pump is in operation, is out of place, as we here find a continuous solid body of water and plunger obstructing a broken body of air from coming together, which is with all its power seeking its equilibrium. The above conclusion is true of all pumps except the pulsometer and kindred pumps, where expanded or exhaust steam is condensed to continuously create vacuum. In these kinds of pumps with every inch we lift the water is a clear gain in power. In harmony with the above, solution to "Beginner's" question is as follows:

The constant ·434 used in these formulæ is the weight of water 1″ square and 1′ high. With the pump 5′ above water the discharge is $95' \times {\cdot}434 = 41{\cdot}23$ lbs.; suction 5′ = 14·7 lbs. minus 12·53 lbs. compensated or returned power = 2·17 lbs, then 41·23 and 2·17 = 43·4 lbs. per square inch required. With pump 20′ above water, the discharge is $80' \times {\cdot}434 = 34{\cdot}72$; suction 20′ = 14·7 lbs. to be deducted for compensated power 6·02 = 8·68 lbs., then 34·72 and 8·68 = 43·4 lbs., the power required per square inch of plunger, friction and weight of valves not considered.

Yours, etc.,
D. W. E.

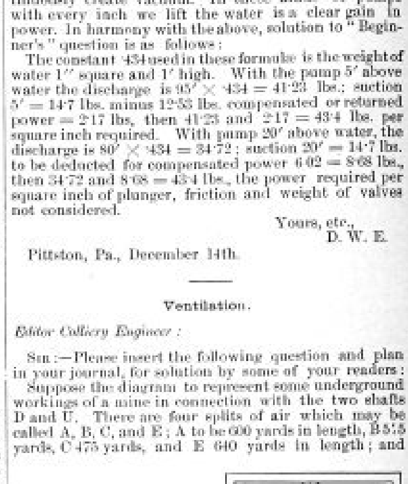
Pittston, Pa., December 14th.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following question and plan in your journal, for solution by some of your readers:

Suppose the diagram to represent some underground workings of a mine in connection with the two shafts D and U. There are four splits of air which may be called A, B, C, and E; A to be 600 yards in length, B 535 yards, C 475 yards, and E 640 yards in length; and



from bottom of downcast to split C E to be 150 yards. Air crossings are supposed to be built at points marked H; now, what quantity of air will circulate through each split, their areas being all 8′ × 8′ and subject to the same pressure at downcast, say, ·25 inch w. g.? In the diagram let H represent two overcasts over A and B; D the downcast, and U the upcast shaft.

Yours, etc.,
E. R.

Hopwood, Pa., Nov. 30th.

Mensuration.

Editor Colliery Engineer:

SIR:—I would like to venture a brief solution to "T. W. Hale's" question in your May issue, as worked out by simple mensuration. "A horse is tied to the corner of a barn 25 feet square by a rope 100′ long. How many square feet of surface can the horse feed over?

$$200^2 \times {\cdot}7854 \times \tfrac{3}{4} = 23{,}562 \text{ sq. ft.}$$

And

$$75^2 \times 3{\cdot}1416 \times \tfrac{1}{2} = 8835{\cdot}75 \text{ area of half}$$

circle with a radius of 75′,

$$(55{\cdot}22 \times 2) \times (50 \times 2) \times \frac{{\cdot}7854}{4} = 2168{\cdot}4894'$$

area of quarter circle.

Then,

$$23{,}562 + (8835{\cdot}75 - 2168{\cdot}4894) = 30{,}229{\cdot}2606'$$

the required area.

Yours, etc.,
Inquirer.

Nanaimo, B. C., Dec. 3d.

Discussion Upon Questions 14, 18, 20, and 21, Given at the Iowa Examination of Candidates for Mine Inspectors April 9th, 1890.

Editor Colliery Engineer :

SIR :—In the October issue of THE COLLIERY ENGINEER you publish by request some answers to the above mentioned questions.

Question 14 is not stated correctly, and there being also an error of multiplication, the answer arrived at is very different from the correct answer.

Question 14, stated correctly, is as follows: "If a water-gauge shows a difference of reading of 1·2 inches between the intake and the return of a certain portion of a mine; and the anemometer indicates a velocity of 10 ft. per second, size of entries 6 × 8 ft.; what effective horse power has been expended in the ventilation of that part of the mine?"

We find the pressure per sq. ft. to be 5·2 lbs. × 1·2 inches = 6·24 lbs., and volume of air = 6 × 8 × 10 × 60 = 28,800 cu. ft. per minute.

$$\text{H. P.} = \frac{6{\cdot}24 \times 28{,}800}{33{,}000} = 5{\cdot}45$$

instead of 50·7 as given.

The answer given to Question 18, which is, "In what part of a mine should observations with the anemometer be taken, and why?" is correct as far as it goes but it does not say why; nor does it cover the point aimed at in the question.

The point desired to be brought out by asking Question 18 is, that the return air or "the last of the air," as it is called, is always traveling at a different velocity from the intake current, its velocity being affected by the rarefication or otherwise of the return air, due to the relative temperatures of the pit and the outside air; also by the presence in the return current of the mine gases which often largely increase the volume of the air; and last, but by no means least, the return current has been relieved of the pressure of the pit, which is often two or three atmospheres and sometimes much greater, and its volume and consequently its velocity is proportionately increased.

From the above considerations it is very evident that readings taken with the anemometer upon the return, may show a large amount of air passing, while the face of the workings and the entire pit are deficient of the required amount. It is always most important and absolutely necessary to take readings at the face of the workings or the inside headings, to be assured the entire amount of air in the split is passing around the face and does not leak through imperfect stoppings; but to obtain correctly the amount of pure air passing in a pit, the calculations must be based upon observations taken upon the intake and not the return.

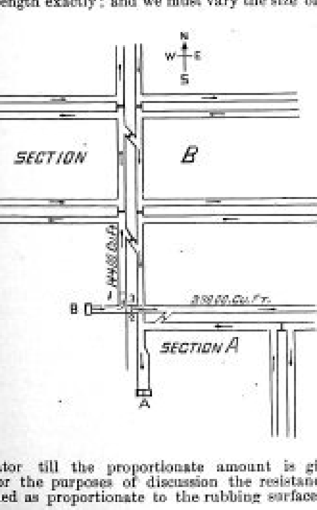
It is interesting to note in passing that the observer should stand a little to one side and as far from the instrument as possible, while taking the reading, in order that his body shall not obstruct the area of the entry and thus create a higher velocity than actual.

Question 20 is: "In the section of the mine mentioned in Question 14, which we will designate as Section 'A,' the air travels 6,000 ft. of entry, including the return. In Section 'B' of the same mine there is required 14,400 cu. ft. of air per minute, but it must travel 12,000 ft. of entry, including the return, how would you arrange the regulator, or in what proportion would you split the air for these two sections to equalize the ventilating currents in them? Size of entries in both sections is the same."

This question might have been better stated by asking. "How would you arrange the regulator or in what proportion would you split the air for these two sections to give to each its required proportion of air."

This is the meaning of the question and not that each section should receive an equal current, as explained in THE COLLIERY ENGINEER; as the question states explicitly the amount of air required in each section.

The discussion in regard to regulators, which follows in THE COLLIERY ENGINEER, is partly right and partly wrong. It is right in saying we determine the size of the regulator by experiment; for the reason that no two airways in a mine of the same sectional area, will offer a resistance to the air current proportionate to their length exactly; and we must vary the size of our



regulator till the proportionate amount is given. But for the purposes of discussion the resistance is assumed as proportionate to the rubbing surface.

But, on the other hand, it is by no means clear that the only way to divide the air current proportionately, is by increasing the resistance in one of the airways till it becomes equal to the resistance offered by the other airway. This a wrong basis to start from; and, as stated, entails a large amount of dead work. Every regulator that is placed in an airway on this principle is an obstruction to the free passage of the ventilating current; it increases the drag of the mine and consequently the power necessary to ventilate. It will accomplish the dividing of the air in any proportion provided the power is present to drive the air; but it is based on no scientific principle and is expensive.

To fully explain the principles of "splitting" the air in mines, would require more space than allowed to us; but we may in a simple manner, and by reference to the accompanying diagram, make plain some points.

Let B be the air-shaft (downcast); A the hoisting shaft and upcast; the ventilating motor a force-fan; S denotes a split, and X an overcast. There is 43,200 cu. ft. of air coming down the air-shaft per minute. Of this 28,800 cu. ft. is required to pass over the overcast and travel East to ventilate Section "A." The length of this split is say 6,000 ft. The remaining 14,400 cu. ft. travels north and ventilates Section "B." The length of this split is say 12,000 ft. to where it escapes up the upcast. We note that the velocity of the current in Section "A" is twice the velocity of the current in Section "B" since the size of the entries is the same in each.

Suppose we stop the air course leading to the north by a door at (1), and also the air course leading to the east by a door at (2), thus shutting of all entrance of air to the mine from the air shaft. Now if the fan be kept running at a uniform velocity the pressure in front of these doors will continue to rise until a fixed point is reached, and the pressure at that point will indicate the ventilating power of the motor at that velocity. And further, until this working pressure is reached in the mine, the full capacity of the ventilating motor is not used.

Again, behind these imaginary doors at (1) and (2) lurks the resistance or "drag" of the mine. This resistance exists in the mine as a force directly opposed to the movement of the ventilating current; and until this force can be overcome by the pressure of the air current, no movement can take place. What is called the "static" resistance or force necessary to create a circulating current is much larger than the dynamic resistance or the force necessary to maintain such a circulation after it is established. The dynamic resistance is what interests us most, and is what is known as the resistance of the mine. It varies as the amount of the rubbing surface varies; and as the square of the velocity of the current. We are dependent upon the working pressure of the air current to overcome the resistance.

Again, if we open the imaginary door at (2) leading to Section "A" the "static" pressure is at once relieved and a working pressure soon established, which is equal to the dynamic resistance of Section "A." All the air is now passing through Section "A." Did Section "A" offer no resistance to the air current the working pressure would be *nil*. The working pressure at the intake of any section or split can never be greater than the dynamic resistance of that split but is always equal to it. We must remember here that the dynamic resistance and consequently the working pressure varies with the square of the velocity of the current; and as all the air is now passing through Section "A" the velocity will be greater and the working pressure, at the point where the split is to be made, higher than when Section "B" is open also. This is as it should be, because the greater the egress of the air, the less the pressure behind it; although some would say more work was being done and the working pressure should be higher. But one of the chief advantages of splitting the air is that with the same expenditure of power a larger volume of air can be moved. Now, if we open the imaginary door at (1) leading to Section "B," just a little, some of the air will escape and pass down through Section "B." We can open this door enough to allow the proportionate amount of air to pass. But now let us abandon the imaginary doors at (1) and (2), which were only supposed for the purposes of discussion and in their stead build a brattice, from the corner where the two air courses meet, out into the entry so as to cut the air coming from the air shaft, and make the last five or six feet of this brattice to swing as a door. This can be set to the right or left so as to regulate the proportionate flow of air to Section "A" or Section "B."

Thus far in this discussion the term "working pressure" has been used relatively and denoted the *unit* of working pressure or the pressure per sq. ft. of area. We will now multiply this unit of working pressure by the area of the entry coming from the air shaft before it is cut by the edge of the brattice. The product will give the moving power of the current or the motive force of the current, opposed to the total dynamic resistance of the mine. Now this motive power must be divided between the two sections of the mine in proportion to the resistances of those sections. And consequently the brattice must be swung so as to divide the area of the entry in the same proportion. It is well to note that the unit of working pressure changes as it passes the brattice or regulator and adapts itself to the enlarged sectional area of entry. The velocity of the current is also changed at this point.

This form of regulator splits the air current proportionate to its work and introduces no obstruction or increased resistance. In the present instance the regulator should be swung so as to divide the air in the ratio of 1 : 2 in favor of Section "A."

Yours, etc.,

J. T. BEARD,

Secy. State Board of Examiners.

Ottumwa, Iowa, Dec. 21st.

Correction.

Editor Colliery Engineer :

SIR :—I wish to thank "S. U. P." for pointing out my error in the December issue in my answer to his question. But if he will go over his solution again he will find that he has made a mistake also in the volume. The volume I obtained was 53,168′, if "S. U. P." were to carry his figures out to three decimal places the result would be 53,410′.

Yours, etc.,

L. P. H.

Avoca, Pa., Dec. 14th.

Ventilation.

Editor Colliery Engineer :

SIR :—Please publish the following question in your next issue so that some of your able correspondents may answer: If we have 6,250 cubic feet of air traveling in a mine through an area of 25 sq. ft., and wishing to have 22,500 cubic feet per minute in the mine with the same power, how large should the area be?

Yours, etc.,

CARBON.

Lemont Furnace, Pa., Dec. 14th.

Speed of Fans.

Editor Colliery Engineer :

SIR :—In Inspector G. M. Williams' report of the disaster at the No. 3 shaft, South Wilkes-Barre, he says. "In order to accomplish what was desired it was necessary to change and reverse the direction of the air current leading to the 'Stanton,' so that the smoke would be driven back towards the South Wilkes-Barre fan, therefore the South Wilkes-Barre fan was run up to a speed of 200 revolutions per minute."

Would Inspector Williams be kind enough to tell us what kind of a fan it was? I would also like to know what is the maximum speed of a 20 foot Guibal fan connected directly to the crank of a engine.

Yours, etc.,

WM. WEST.

United, Westmoreland Co., Pa., Dec. 14th.

Pumping.

Editor Colliery Engineer :

SIR :—In the August number of THE COLLIERY ENGINEER the following question was asked: "In a shaft 100 ft. deep, a pump is placed with 5 feet suction and 95 feet discharge. Will it require more or less power, if the pump is placed up the shaft with 20 feet suction and 80 feet discharge?"

Theory and practice support the fact that the power will be the same in either case, but the short suction will give the best results. Calculations on power to lift water must always be based on the vertical height from the point of lift to the point of delivery, no matter whether it is to be a long or short suction.

Yours, etc.,

ROBT. RAMSAY.

Mt. Pleasant, Pa., Dec. 14th.

Arithmetic.

Editor Colliery Engineer :

SIR :—Please insert the following in answer to question asked by "A. A.," of Buena Vista, Pa., in your last issue:

If we obtain 25,000 cubic ft. of air from a furnace and 22,000 cu. ft. from a steam jet, or other means, what will be the quantity of air if the two are acting together? The combined effect will be according to the square of the one quantity added to the square of the other, and extracting the square root of the product gives the result, or

$$\sqrt{25{,}000^2 + 22{,}000^2} = \text{answer.}$$

Then $25{,}000^2 = 625{,}000{,}000$, and $22{,}000^2 = 484{,}000{,}000$, and $625{,}000{,}000 + 484{,}000{,}000 = 1{,}109{,}000{,}000$, then

$$\sqrt{1{,}109{,}000{,}000} = 33{,}301 +.$$

Yours, etc.,

CARBON.

Lemont Furnace, Pa., Dec. 14th.

Haulage.

Editor Colliery Engineer:

SIR :—I would be pleased to have some of your correspondents give me their ideas as to the best way to work incline and kind of brake to use in the following question:

I desire to bring coal from an upper to a lower level by means of inclined plane and have the loaded cars pull back the empties; the distance is 3200′ and incline 5°. The distance being considerable, I want to let down as many cars as possible each trip.

Yours, etc.,

X. Y. Z.

Rock Springs, Wyo., Dec. 16th.

A Peculiar Mine Gas.

Editor Colliery Engineer :

SIR :—I beg leave to submit the following reply to John A. Carroll's question, page 106, of December issue:

From the odor of the gas and the fact of its being heavier than air, I judge it to be sulphureted hydrogen, a gas evolved from the decomposition of pyrites or mundic. In a mixture with air, a candle will burn, but, of course, not if plunged into the gas, for it has nothing on which to support combustion. A breath of it is debilitating, if not poisonous.

Inherently it is not dangerous, it forms no explosive mixture with air, but is indicative of heat, and is a symptom of spontaneous combustion. For in the decomposition heat is developed which threatens danger to coal and waste in isolated spots and goaves. A mine having this gas should be carefully watched for a local rise in temperature, and a correspondingly cooling. This gas weighs 96 lbs. per 1,000 cu. ft. (air 81 lbs.)

Yours, etc.,
M.

Golden, Colo., Dec. 13th.

Miscellaneous Questions.

Editor Colliery Engineer:

SIR:—Will some of your able correspondents favor me by solving and giving formulæ for the following questions:

(1). An airway 10′ × 10′ and 2,000′ long is passing 60,000 cu. ft. of air per minute, what would be the required area of an airway to pass 15,000 cu. ft. per minute its length being 1,800′, the pressure remaining the same?

(2). What is the least inclination of a self-acting incline 600′ long to run a set of cars in two minutes, the total weight of full set over empty set being 6,000 lbs., and the total friction on wheels, rope, etc., being $\frac{1}{10}$?

(3). What weight would an ordinary mine prop sustain, its length being 8′ and diameter 6″? Give formula and work out.

Yours, etc.,
J. W. S.

Westville, N. S., Dec. 14th.

The Practical Work of Engines.

Editor Colliery Engineer:

SIR:—The practical work of engines has been discussed by several correspondents during the past year in your columns but it does not seem to me that any very satisfactory conclusion has been reached. With your permission I will reopen the discussion.

It is important to have reliable rules by which to calculate the starting power and the hoisting or pulling power, and in my opinion the most useful rule is one to find the starting power. Whatever an engine will start it will surely pull.

"Theorist," in your August, 1891, number, correctly states the distinction between the static and dynamic aspects of the case, but it seems to me he is in error in other points.

In an engine about to start, or just starting, we may make an allowance for inertia and friction overcome which we call f or co-efficient friction of engine. In "Theorist's" first formula for "static equilibrium," I question the correctness of the first half, viz., 2 A a P C f.

This cannot in my view be true unless the cranks of engines are set at 180° or opposite each other. With engines at 90° apart as is the usual custom the position at starting will be one crank at top of stroke, the other on dead point, in which case we have only the action of one cylinder to consider.

In such case also we can use full boiler pressure since the throttle is wide open and the engine about to start. The internal resistances of engines is usually reckoned at 10% of power in locomotives and is probably not more in a good hoister. I would, therefore, call f = coef. friction of engine $\frac{1}{10}$. For resistances we have (1) the strain in rope produced by load (2) strain in rope, produced by resistance of sheave pulleys to turning on their axles and by the resistance of ropes to bending around pulleys and drum. These all act at circumference of drum and hence have leverage. "Theorist's" formula would therefore read:

$$A\ P\ C\ f = L\ R + R \text{ (strain in rope due to friction).}$$

If we assume (strain in rope due to friction) = $\frac{1}{28}$ load and solve with the dimensions given by "Equity" we have load = 6552 lbs., which is *not load*. For the dynamic case the simplest rule in words "total available pressure on cylinders × space traversed = resistances × space traversed." In this since one revolution of drum is produced by two complete strokes of each piston we can deduce from the formula expressed in terms of piston strokes and drum circumferences (or space traversed by resistance) the strain or load on the rope. If we call $f = \frac{1}{10}$ and rope friction $\frac{1}{28}$ load as before the formula should read

$$\left(L + \frac{L}{28}\right) D = 2\ A\ a\ P\ 2\ s\ \frac{9}{10},$$

which being solved with dimensions as above gives load = 8273 lbs. which is *not load*.

In such cases we have the action of both cylinders throughout full strokes and hence must use "average" or mean effective pressure.

For a geared engine the same rules apply, making proper provision for the gearing and correspondingly increased allowance for friction of gearing—say $\frac{1}{15}$ the pressure between teeth.

If an engine is geared 1 to 5 for example, then one revolution of drum means 5 revolutions of cranks or 10 strokes of pistons.

In determining size of engines for use under given conditions it would be wise to make a liberal allowance to insure ample power for all contingencies and emergencies.

If I understand "Equity's" case correctly it does not appear a fair test of his engine's starting power. His water box appears to be submerged in the sump at starting. If so, he has at the instant of starting only the weight of rope or 2956 lbs. by his figures (since the box will displace the bulk of water it contains) and if there is any buoyancy in the wood he may have even less. This case is analagous to starting a train of cars with slack couplings and is more a dynamical than a statical question. The load being added to the engine by successive increments.

If my reasoning herein is incorrect I would like to see others discuss the question that we may arrive at a definite and satisfactory conclusion.

Yours, etc.,
R. M. H.

Denver, Colo., Dec. 30th.

Thanks the Correspondents.

Editor Colliery Engineer:

SIR:—I feel that I must thank the many correspondents who took part in the discussion of "Examination Question"; that the temperature of the upcast shaft is 137° there is no doubt in my mind. My reason for expressing any dissatisfaction was only to draw out as full a discussion as possible as one of *the then* Board of Examiners contended that 119.9° was correct, as per Mauchline's rule on page 104, question 4, of his book. This did not agree with the teaching in our mining class, as we found temperature from weight of air. This difference of opinion tended to cause a division which was not wished for, hence the desire for a full discussion.

In reply to "F. B.," would say that I am not one of the unappreciable kind, I appreciate very much the information given in THE COLLIERY ENGINEER and esteem its usefulness and many of its correspondents.

Yours, etc.,
J. W. S.

Westville, N. S., Dec. 14th.

Arithmetic.

Editor Colliery Engineer:

SIR:—"A. A.," of Buena Vista, Pa., asks if some one will solve the following problem as found in Fairley's book:

$$\sqrt{25{,}000^2 + 22{,}000^2} = 33{,}301.$$

The square of 25,000 = 625,000,000, and
the square of 22,000 = 484,000,000,
adding, we have 1,109,000,000.

Now, the square root of 1,109,000,000 is found to be 33,301 as follows:

```
          11'09'00'00'00 (33,301
           9
     63    209
           189
     663    2000
            1989
     66601    110000
               66601
               43399.
```

Yours, etc.,
J. S. K.

Canon City, Colo., Dec. 16th.

Ventilation and Mechanics.

Editor Colliery Engineer:

SIR:—Please insert the following answers to questions by "J. M.," of Morrisdale Mines, Pa., in your December issue:

(1). Assuming that a fan making 80 revolutions per minute produces 40,000 cubic feet of air, how much more would it produce if the revolutions were doubled?

It would produce 56,445½ cu. ft. per minute, which is found by proportion thus, as the square root of 80 is to the square root of 160 so is 40,000 to x, the required quantity, or

$$\sqrt{80} : \sqrt{160} :: 40{,}000 : x, \text{ or } 56{,}445\tfrac{1}{2}.$$

(2). How would you practically test the safety-catches of a cage in a shaft?

I would raise the cage, say, two or three feet above the top of the shaft, covering the mouth of the shafts with timber sufficiently strong to catch and hold the cage in case the safety-catches failed to hold the cage when the main bolt was drawn. Then knocking out the bolt, I suppose, would be the only true test that could be made.

Yours, etc.,
J. S. K.

Canon City, Col., December 16th.

The Necessity for Greater Technical Knowledge for Miners.

A subscriber in Allegheny County writing from the standpoint of an intelligent miner, says:

"There is considerable talk of reform in mining to be brought about by legislative enactments, which, while it may be right as far as it goes, is not the only way by which effective reforms can be accomplished. If all persons desirous of reform would begin at once by raising the standard of mining intelligence among the mining population, reforms would come much sooner, and they would be more effective.

"For instance, if every colliery official who has, by study, qualified himself for his position, would use his influence to get his miners to read such journals as THE COLLIERY ENGINEER, and to read carefully the annual reports of the Inspectors of Mines a vast amount of good work would be done. The Mine Inspectors' reports, which ought to be supplied to the miners, whom they would benefit, instead of to merchants and farmers, show in many different ways what causes led up to the accidents, and how they might have been prevented.

"Again, if the operators would make it a point not to employ as officials, men whose sole qualifications did not lie in the fact that they held certificates of competency; but to employ men who also had the faculty of governing workmen in such a way as to win their respect by taking an interest in them and by treating them as men, instead of men who seem to be the incarnation of petty meannesses, as are sometimes met with in official positions.

"If all colliery officials were men that would endeavor to increase the standard of intelligence among the miners, and would encourage them by example and kind words to lift themselves up to a higher plane, we would find in a short time such reforms brought about as legislative enactments would not accomplish in a generation, if at all. I think it is evident to all thoughtful men, that if we are to advance the most potent factor must be the better technical education of the miners.

"Before concluding, I cannot help commending your journal. I have taken it for several years, and it has been a great help to me.

"Your editorial articles have always convinced by their aggressive and comprehensive character, that the editors are fully informed in the science of mining, and they are continually laying before their readers descriptions of the improved methods of mining, and of modern research in connection with the working of collieries.

"As a miner, I must say, that if miners remain ignorant on the subjects relating to their calling while having such opportunities as your journal presents, the fault is their own.

"Hoping that all colliery officials may take more interest in recommending it to their workmen, I conclude with an earnest wish for a long and successful life for THE COLLIERY ENGINEER."

Important Change of Colliery Officials.

Mr. J. I. Hollenback, of Audenreid, Pa., who, for a number of years has been superintendent of the Lehigh and Wilkes-Barre Coal Co.'s collieries in the Lehigh region, resigned his position on the 30th ult. By order of President J. R. Maxwell, Mr. E. H. Lawall, Superintendent of the Wyoming division has been appointed General Superintendent of all the company's collieries. Mr. Lawall has appointed Mr. David R. Roberts, of Audenreid, Assistant Superintendent. He will have charge of the company's operations in the Lehigh region, and will report to and receive instructions from Mr. Lawall.

This widening of the authority of Mr. Lawall, and increase of responsibilities thrown on him by his superior officers is evidence that his efforts to advance the interests of the company and his efficient management of the Wyoming region collieries, have been highly appreciated.

A recent letter from the Jeffrey Mfg. Co., of Columbus, Ohio, states that they are having wonderful success in introducing their coal mining machines and drills, and their coal handling machinery. Their recent customers have been as follows:

MINING MACHINES, DRILLS, PUMPS, ETC.

Robbin's Coal Mining Company, Pittsburgh, 1 Mining Machine, 1 Power Drill; Sunday Creek Coal Co., Columbus, O., 3 Mining Machines, 2 Power Drills (second order); Gaslee & Lockwood, Evansville, Ind., 1 Power Drill; Hocking Valley Coal Co., Nelsonville, O. (Wm. Job, President, formerly General Manager of The Morris Coal Co.), 5 Mining Machines, 3 Power Drills; Union Colliery Co., Victoria, B. C., 1 Electric Mine Pump; Egyptian Mining Co., Du Quoin, Ill., 2 Power Drills; Harris Coal Co., Jobs, O., Additional Order 1 Mining Machine; Cambria Mining Co., Cambria, Wy., 5 Power Drills; Monongah Coal Coke Co. Monongah, W. Va., Additional Order, 1 Mining Machine; New Pittsburgh Coal Co.; Nelsonville, O., Additional Order 1 Power Drill; Glen Mary Coal Co., Glen Mary, Tenn., 3 Power Drills; Upson Coal Co., Shawnee, O., Additional Order 1 Mining Machine; H. D. Turney & Co., Columbus, O., Complete Electric Plant, consisting of Engines, Boilers, Electric Machinery, including the Jeffrey Mining Machines.

COAL HANDLING MACHINERY, ELEVATORS AND CONVEYORS.

Mt. Carbon Co., Mt. Carbon, W. Va.; Luhrig Coal Washing Co., Mt. Carbon, Ill.; North Bend Coal & Coke Co., North Bend, O.; Mud River Coal and Coke Co., Mud River, Ky.; Union Pacific Ry. Co., Rock Springs, Wyo.; Texas & Pacific Coal Co., Thurber, Tex.; St. Louis & Big Muddy Coal Co., Carterville, Ill.; New Pittsburgh Coal Co., Farmersburgh, Ind.; Louder Wooley Coal Co., Evansville, Ind.; Crystal Plate Glass Co., St. Louis, Mo.; St. Louis Ore and Steel Co., Murphysboro, Ill.

Aerated Crude Petroleum.

The use of aerated crude petroleum as fuel in place of coal is rapidly extending, and very many of the largest concerns in this country whose work requires the employment of an intense heat have adopted this system. The chief lines of work for which it has been introduced are iron and steel forging, tempering, welding, annealing, etc., in glass works, for furnaces, glory holes, lears and ovens; for generating steam, burning lime, burning sewer pipe, heating asphalt, tinning and japanning, oxydizing lead, heating retorts in gas works, etc.

An efficient and economical air compressor is a most important factor in the successful operation of these plants, and after a careful examination of the various types of these machines now on the market, the majority of the licensees who were intrusted with the introduction of this new fuel in their several districts, decided to adopt a special design submitted by the Clayton Air Compressor Works, of 43 Dey Street, New York; thus scoring another triumph to the already long list achieved by the makers of these unrivaled machines.

They are now in use in over two-thirds of the oil burning fuel plants in the country, everywhere performing their duty in a manner to merit the highest praise.

MODEL SHAFTS.

Lehigh and Wilkes-Barre Coal Company Officials, visit the Philadelphia & Reading Coal & Iron Co.'s Model Shafts in the Schuylkill Region.

As the Lehigh and Wilkes-Barre Coal Co. will shortly begin to sink a large and deep shaft at Ashley, Pa., and as two new breakers are also in contemplation by the same company, Mr. E. H. Lawall, Genl. Supt., decided that it would be to the interest of his company for himself and subordinate officials to visit the most recent improvements of the Philadelphia and Reading Coal and Iron Co., in the Mahanoy Valley. By such a visit improved ideas in shaft sinking and timbering, arrangement of tracks, and in breaker construction could be inspected and the knowledge gained could be utilized for the benefit of the L. & W.-B. Coal Co. An additional incentive was, that the two shafts to be visited were sunk by contractor John Evans, of Shenandoah, who has secured the contract to sink the Ashley Shaft, and an opportunity was offered to inspect the character of his work.

Accordingly on the morning of the 19th ult., a party consisting of the following persons boarded the Lehigh and Wilkes-Barre Coal Co's. special car at the Jersey Central station at Wilkes-Barre:

E. H. Lawall, Gen. Supt., Lehigh & Wilkes-Barre Coal Co.

W. J. Richards, Chief Engr., Lehigh & Wilkes-Barre Coal Co.

Morgan Morgan, Inside Supt., Lehigh & Wilkes-Barre Coal Co.

W. H. Herring, Outside Supt., Lehigh & Wilkes-Barre Coal Co.

Gib Stewart, Master Mech., Lehigh & Wilkes-Barre Coal Co.

H. W. Saums, Asst. Outside Supt., Lehigh & Wilkes-Barre Coal Co.

E. W. Marple, Auditor, Lehigh & Wilkes-Barre Coal Co.

C. H. Gardner, Shipper, Lehigh & Wilkes-Barre Coal Co.

D. Cottle, Chief Clerk, Lehigh & Wilkes-Barre Coal Co.

J. Davenport, Dispatcher, Lehigh & Wilkes-Barre Coal Co.

W. F. Dodge, Ex-Chief Engr., Lehigh & Wilkes-Barre Coal Co.

C. L. Lippincott Asst. Supt., L. & S. R. R.

J. C. Brastow, Master Mech., Ashley Shops.

G. M. Williams, Inspector of Mines, Fourth Anth. Dist.

James Pollock, Mechanical Engr., and Rufus J. Foster, of The Colliery Engineer.

The car was attached to engine No. 49, and was run via Mauch Chunk and Tamanend to Mahanoy City, where a brief stop was made, and the following gentlemen joined the party:

Geo. S. Clemens, Div. Engr., P. & R. C. & I. Co.

H. M. Luther, Asst. Engr., P. & R. C. & I. Co.

F. P. Weiser, Asst. Engr., P. & R. C. & I. Co.

Christ Muelhof, Master Breaker Builder, P. & R. C. & I. Co.

Noah Owens, Outside Foreman, Indian Ridge Colliery, P. & R. C. & I. Co.

Wm. Stein Inspector of Mines of the Seventh Anth. Dist., and David R. Roberts, of Audenried, the newly appointed Asst. Supt. of the L. & W.-B. Coal Co.

The run to Maple Hill Shaft was made in a few minutes, and here the party was joined by Genl. Inside Supt. John Veith. Asst. Engineer J. H. Pollard, Div. Supt. Jno. L. Williams, Dist. Supt. Jno. G. Davis, and Master Mechanic George Simmons, of the P. & R. C. & I. Co.

The Maple Hill Shaft is situated near St. Nicholas, two miles west of Mahanoy City. It is 719 ft. deep to the Top Split of the Mammoth seam. It is rectangular in shape and has two hoistways and a pumpway. It is one of the most substantial colliery openings in America. The timbering throughout the whole length of the shaft is massive and regular, and its alignment is perfect. The turnouts at the foot are roomy and are timbered with massive squared timbers coated with whitewash. The timbering of these turnouts was done in a particularly careful manner, every set being carefully lined up so that the faces of the legs are exactly parallel with the center lines of the tracks, and the bottoms of the collars are parallel with the gradients of the tracks. The tracks were laid out by the company's engineers, who were careful to arrange easy and regular curves, and such gradients as would conduce to the easy handling of the large output to be annually produced.

All the loaded cars are delivered to the east turnout, and are run by gravity on to the cages, automatic safety catches preventing them from running into the cage pit after the cage has left the bottom. The empties are run off the cages on to the West turnout by gravity, and run by gravity to an inside chain hoist in the rock which elevates them to a point from which they run by gravity to a sort of underground yard, where trips are made up for the various main gangways. The shaft, as was stated before, is sunk to the Top Split of the Mammoth seam, which is 14 ft. thick. Tunnels through the rock cut the Holmes seam, 8 ft. thick; the Middle Split of the Mammoth, 10 ft. thick; the Bottom Split of the Mammoth 16 ft. thick; the Skidmore, 7 ft. thick; the Seven Foot, 7 ft. thick; and the Buck Mt., 16 ft. thick. The tunnels cut all these seams on both the North and South dips, and all seams are in excellent condition.

The breaker, which has just been completed, is an exceptionally fine structure with sides and roof of corrugated iron. It is roomy and light, and is fitted out with the most improved appliances for perfect and rapid cleaning and sizing of coal. It has a capacity of 2,500 tons per day, and was designed and built under the supervision of Master Breaker Builder Christ Muelhof, who is justly proud of his work.

The coal is hoisted out of the shaft by a pair of direct-acting engines with 30-inch cylinders, 60-inch stroke, and 12 feet diameter drum. The mine cars will run from the shaft to the breaker tip by gravity, and, after dumping, they will be hauled up a short incline, by an endless chain, and from the summit of the incline they will run by gravity back to the west side of the shaft, from whence they run by gravity on to the cages. The officials of the Philadelphia and Reading Co. are to be congratulated on the convenient arrangement and substantial construction of this colliery, and Inspector Stein claims that it is the best arranged colliery in the Anthracite regions.

This colliery will be one of the largest shippers in America. It is one of a group of three belonging to the P. & R. C. & I. Co., viz.: the Ellangowan, the Maple Hill, and St. Nicholas, all located within a short distance of each other, which have a combined capacity of about 1,250,000 tons per year, and all three will have an average life of twenty-five years.

After viewing the colliery in all its parts, the party boarded the car, and enjoyed a splendid lunch provided by Mr. Lawall. While disposing of it, the car was run to Shenandoah, via Mahanoy Plane, and the Shenandoah City Shaft, which is modeled on the same lines as the Maple Hill Shaft, was visited, as were also the Shenandoah City strippings. An instructive and pleasant hour was spent here, and a large party went down the shaft under the guidance of District Superintendent John Bradigan. From Shenandoah the car was run to the Patterson Anthracite Mining Co.'s new colliery at Natalie, near Mount Carmel, but as so much time had been spent at Maple Hill and Shenandoah, the schedule arranged by the railroad officials compelled the visit here to be limited to ten minutes, and but a hasty view of the outside improvements was possible. The return journey was commenced then, and after dropping off the P. & R. officials at different points along the Mahanoy Valley, the train arrived at Wilkes-Barre at 9.45 P. M., all on board having enjoyed both a delightful and instructive trip. The Lehigh and Wilkes-Barre Coal Co. are, as was stated before, about to start sinking a shaft at Ashley, which will be 960 ft. deep to the Red Ash Vein. It will have an area for 420 ft. of its length, to the Baltimore seam, of 54′ x 13′ and from the Baltimore to the Red Ash of 27′ x 13′ ft. There will be two hoistways and a pump way to each seam. Two new breakers are also in contemplation by this company, and Messrs. Lawall and Richards feel amply repaid for the trip in the ideas they gathered by the visit to Maple Hill and Shenandoah, and it is safe to say that they will not only adopt some of them, but will be able to add to them in the new work about to be started under their direction.

Such visits are, beyond doubt, of great value to colliery officials and the company they represent, as new ideas are secured and improvements seen, invariably suggest others to them, which can be utilized to advantage in proposed new work.

Daniel Bertsch.

Daniel Bertsch, the president of the Upper Lehigh Coal Co., died on the 17th ult. at the residence of his sister, Mrs. E. Polk, at Mauch Chunk, Pa. He was in the 65th year of his age, and was a native of Mauch Chunk. Death was caused by an affection of the heart, after a sickness since early in October.

The deceased was the eldest son of the late Daniel Bertsch, who during his lifetime was closely identified with the building of the works of the Lehigh Coal & Navigation Company. Mr. Bertsch was a thorough mathematician, and at an early age entered the service of the Navigation Company, in the engineering department, under the late E. A. Douglass. He became identified with the Upper Lehigh Company in 1865, and was its first president. Later he was chosen its superintendent, and this position he held at the time of death.

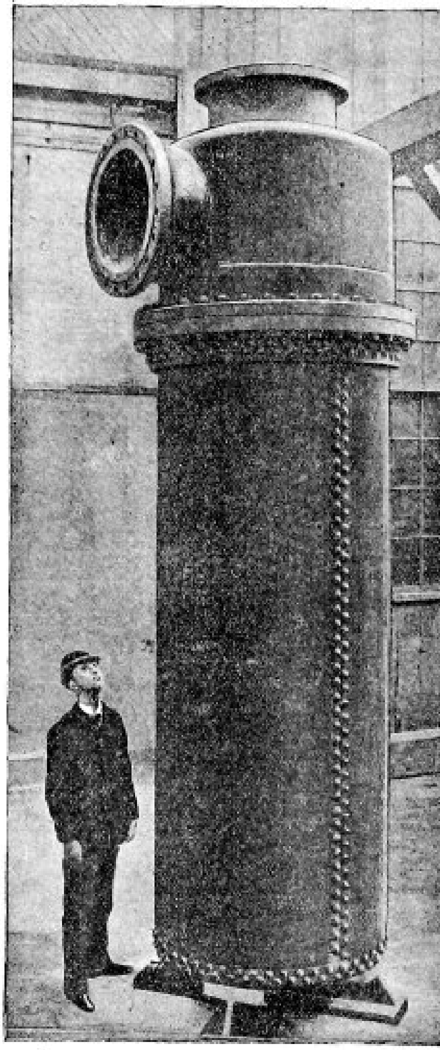
He was also a director of the First National Bank of Mauch Chunk, the Nescopec Coal Company, the Pioneer Mining and Manufacturing Company, of Alabama, and the Mauch Chunk Electric Light Company. He died possessed of large means, with which during life he contributed largely toward all enterprises that benefited his fellows. He was one of the main supports of the Young Men's Christian Association of Mauch Chunk. He was unmarried and is survived by only two sisters; Mrs. E. Polk, and the wife of Associate Judge Samuel B. Price, of Carbon County, Pa.

Sale of a Curious Letter.

A curious letter of Sir Humphrey Davy's has been knocked down at a sale of autographs in Paris. It is dated February 8, 1817, and in it the writer accuses George Stephenson of having appropriated his idea of the safety-lamp. Speaking of the allegations contained in Stephenson's pamphlet on the subject, Davy says that it was in October, 1815, that he was working in his laboratory in London when he hit upon the idea of the tubes with which the lamp was constructed. He protests that he never intended, as Stephenson alleged, to make use of capillary tubes. "To make a lamp that will burn with three capillary tubes," he adds, "is as impossible as to make it burn in a close decanter." The letter was bought by some scientific enthusiast for 105 francs. At the same sale a letter of Madame Sarah Bernhardt fetched only 12 francs, but Alfred de Musset was valued at 128 francs, and David, the painter, at 205 francs.

AN IMMENSE STRATTON SEPARATOR.

The illustration shows what is believed to be the largest separator ever built for separating water from dry steam. It was built by the Stratton Separator Company, of New York City, for the Calumet and Hecla Mining Company, miners of copper ore on Lake Superior, Mich. It was constructed under the strictest requirements, and according to the specifications of Mr. E. D. Levitt, consulting engineer of the Calumet and Hecla Mining Company. It is doubtful if a more perfect piece of work could be constructed.



This immense separator is 3 feet 8 inches in diameter, 14 feet 5 inches in length over all, for a steam pipe of 21 inches diameter, and designed for a working pressure of 185 pounds.

The shell is made from a single sheet of steel, and the top of cast gun metal.

The Stratton Separator Company have furnished the Calumet and Hecla Mining company several separators for high pressure, that seen in our illustration being the most notable.

Steam separators are now being recognized as a necessary adjunct of a perfect steam plant; the absolute certainty that none but dry steam will reach the engine being duly appreciated by every engineer, and we take pleasure in illustrating a remarkable example of one of the best known forms of separators in the market.

Increased Coal Shipments.

The Pennsylvania Coal Co., under the efficient management of the veteran Jno. B. Smith, Esq., has during the year 1891 shipped to market 1,421,581·05 tons of coal, an increase of 267,485·05 tons over the shipments of 1890. This handsome increase of nearly 16% over the shipments of 1890 is abundant evidence of the managerial capacity of Mr. Smith, and the efficiency of his subordinate officials.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED 1881. INCORPORATED 1889.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
ALEX. DICK, MINING ENGINEER, ASSISTANT EDITOR.
THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed
THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Scranton, Pa.

Cable Address—"Retsof, Scranton."

Vol. XII. January, 1892. No. 6.

SOME POINTS OF DIFFERENCE BETWEEN THE ENGLISH AND ANTHRACITE MINE LAWS.

THESE two mine laws are constructed to suit the requirements of two different sets of conditions, and for this reason there are many points in each which could not well be common to both. There are, however, a number of differences which relate to the principles of mining, and directly affect the safety of the workmen, a consideration of which is interesting.

In the matter of ventilation, for instance, the quantity of air required per man is differently treated.

The Anthracite Mine Law of Pennsylvania says:

"The minimum quantity of air produced shall not be less than 200 cubic feet per minute for each and every person employed in any mine, and as much more as the circumstances may require.

The ventilating current shall be conducted and circulated to and along the face of each and every working place throughout the entire mine in sufficient quantities to dilute, render harmless, and sweep away smoke and noxious or dangerous gases to such an extent that all working places and traveling roads shall be in a safe and fit state to work and travel therein."

In the English Mine Law it says:

"An adequate amount of ventilation shall be constantly produced in every mine to dilute and render harmless noxious gases to such an extent that the working places of the shafts, levels, stables, and workings of the mines, and the traveling roads to and from these working places shall be in a fit state for working and passing therein."

There does not seem, at first glance, to be any material difference in these two enactments with the one exception, that the Anthracite Mine Law requires 200 cubic feet per man per minute as a minimum, whereas the English Law requires "an adequate amount * * * to dilute and render harmless." This definite minimum is a mistake in principle. Any one connected with mining knows that where in one mine 200 cubic feet per man per minute is ample, in another it is far from sufficient. It is very difficult to compel some operators and mine superintendents to supply a quantity greater than the minimum demanded by the law, whereas if an *adequate amount* is required by the law the inspector has the power in his own hands to fix the amount. It may be contended that the Anthracite Mine Law also requires "sufficient quantities to dilute, render harmless, and sweep away smoke or dangerous gases." If this be the intention of the law why not say so and be done with it without putting in a clause providing for 200 cubic feet per minute and thus affording an opportunity for any one to violate the spirit of the law while obeying the letter of it.

It is, however, in the regulations relating to the storage and use of powder in mines that the greatest differences are noticeable between the two laws.

The Anthracite Mine Law says:

RULE 26. Gunpowder or any other explosive shall not be stored in a mine, and a workman shall not have at any one time, in any one place, more than one keg or box, containing twenty-five (25) pounds unless more is necessary for a person to accomplish one day's work.

RULE 27. Every person who has gunpowder, or other explosive in a mine shall keep it in a wooden or metallic box, securely locked, and such box shall be kept at least ten (10) feet from the tracks in all cases where room at such a distance is available.

RULE 28. Whenever a workman shall open a box containing explosive, or while in any manner handling the same, he shall first place his lamp not less than five (5) feet from such explosive and in such a position that the air-current cannot convey sparks to it, and a workman shall not approach nearer than five (5) feet to an open box containing powder with a lamp lighted, pipe, or any other thing containing fire.

RULE 29. When high explosives other than gunpowder are used in any mine, the manner of storing, keeping, moving, charging, and firing, or in any manner using such explosives shall be in accordance with special rules as furnished by the manufacturers of the same. The said rules shall be endorsed with his or their official signature and shall be approved by the owner, operator, or superintendent of the mine, in which such explosives are used.

RULE 30. In charging holes for blasting in slate or rock in any mine, no iron or steel-pointed needle shall be used and a tight cartridge shall not be rammed into a hole in coal, slate, or rock, with an iron or steel tamping bar, unless the end of the tamping bar is tipped with at least six (6) inches of copper, or other soft metal.

RULE 31. A charge of powder or any other explosive in slate, or rock, which has missed fire, shall not be withdrawn or the hole reopened.

English Law says:

Any explosive substance shall only be used in the mine below ground as follows:

(*a*). It shall not be stored in the mine.

(*b*). It shall not be taken into the mine, *except in cartridges in a secure case or canister containing not more than five pounds.*

(*c*). A workman shall not have in use at any time in any one place more than one such case or canister.

(*d*). In the process of charging or stemming for blasting, a person shall not use *or have in his possession* any iron or steel pricker, scraper, charger, tamping rod, or stemmer, nor shall coal or coal-dust be used for tamping.

(*e*). No explosive shall be forcibly pressed into a hole of insufficient size, and, when a hole has been charged, the explosive shall not be unrammed, and *no hole shall be bored for a charge at a distance of less than six inches from any hole where the charge has missed fire.*

We have italicized those parts of the English Law to which we wish to draw special attention. From these it will be seen that the conveyance of loose powder and consequent making of cartridges underground is forbidden.

When a miner is making a cartridge he requires a good light. It is a delicate operation and requires careful performance. A defective cartridge is dangerous, and considerable time is lost to the workman if the shot is not effective. There is therefore every temptation to a man to have his lamp close to him when making a cartridge and although the Anthracite Mine Law provides that he place his lamp at least five feet from him when doing this work, the accidents from this cause as given in the Mine Inspectors' Reports show that this provision of the law is not observed. This could all be obviated if the making of cartridges underground were forbidden. We have not the exact figures to go on but we can confidently state that the number of accidents from explosions of powder underground in England is very much below that in the Anthracite regions of Pennsylvania even when allowance is made for the proportionately greater amount of powder used in the latter.

In Great Britain a compressed powder is coming much into use. It is made up in bobbins about 3 inches long and slightly less in diameter than the drill. There is a hole through the center of the bobbin of sufficient size to admit the fuse, and the miner can put in any number of bobbins according to the power of charge required.

Regarding the difference in the quantity of powder allowed to each man there is this to be said, that the amount which would be sufficient in working Bituminous coal, would be quite inadequate in working Anthracite.

The English Law forbids any man to have iron or steel tools used in blasting *in his possession*. The Anthracite Mine Law says: "*In charging holes for blasting in slate or rock* no such tool shall be used." Both laws forbid the practice of forcing a tight cartridge into a hole, and they also prohibit unramming. A perusal of the summary of the accidents from blasting in Pennsylvania Anthracite Mines in 1889 and 1890 given below will show the necessity of removing temptations by forbidding such tools as steel tampers, etc. The English Law prohibits the use of coal dust in tamping. This is a wise precaution in the light of recent investigations which prove that such tamping elongates the flame of the blast and increases the possibility of an explosion. The clause in the English law to prohibit boring a new hole within a certain distance of a missed shot is also of importance. In the Seventh Anthracite District in 1889 by misdirection a hole was drilled into a shot which had missed fire with the result that five men were injured, one fatally. The Inspectors' report does not say how far the two holes were apart at the commencement but too much caution in such matters cannot be exercised.

The following table gives the number of accidents due to blasting operations in the Anthracite districts of Pennsylvania in 1889 and 1890:

Year.	Total accidents during year.	Total accidents due to blasting.	
		Number.	Percentage.
1889	1382	118	8·53
1890	1391	105	7·54
Total	2773	223	8·06

It will be seen that during the two years 8 per cent. of all the accidents was due to blasting operations. After eliminating a majority which were due to premature explosions, 50 remain which have been caused as follows:

Filling cartridges, or using powder with a lamp on head 23
Penetrating cartridge with needle, to put in a new squib or attempting to drill out tamping 17
Forcing in cartridge 10

These 50 accidents are the result of direct violation of the law. It is painful to read time after time in the Inspectors reports that these men attempted to fill a cartridge or handle powder with a naked light on their heads. Such an action in any other walk of life would be called suicidal and it is the duty of the law to put out of the reach all temptations to a practice which is so very dangerous.

THE MECHANICAL EDUCATION OF STATIONARY ENGINEERS EMPLOYED AT COLLIERIES.

IT requires special training before a man can construct a piece of machinery, and yet many people have an idea that after the engine has been built any one can run it. That is why so many of the overwinding accidents at mines occur, and the whole pit is liable to be thrown idle for some one's want of knowledge of the principles of mechanics. The stoker who fires the boilers, the greaser who lubricates the machinery, the mechanic who looks after the shaft fittings and ropes, and the engineer who stands at the throttle valve, are all responsible for the lives of every man at work underground. A hitch in the steam supply, a nut or a pin loose somewhere, a section of machinery unlubricated, even if of no apparent importance to an uneducated mind, may cause a sudden and prolonged stoppage of the ventilating fan and it does not require that state of matters to exist for any length of time to cause a general blow up.

It is necessary, therefore, that every engineer and pumpman should know the principles of mechanics to enable him to attend to his work intelligently, and we predict that the day is not far distant when every man who is in charge of machinery at a mine will be required to obtain a certificate just as those who are in charge underground do at present. And this will be only right. Of what benefit is a certificated man underground as a guardian of life and property if an incompetent person is allowed to play ducks and drakes with the machinery on the surface? This argument is well known and appreciated by many stationary engineers and pumpmen, and it is for the purpose of affording these men a cheap and complete system of education in their special line of business that we have founded The Colliery Engineer School of Mines Complete Mechanical Scholarship.

Each student who goes through the Mechanical Course, which includes Arithmetic, Mechanics, Mechanical Drawing, Ambulance, Mining Legislation, and Mine Accounts, and passes a successful final examination in these subjects, will be awarded The Colliery Engineer School of Mines Mechanical Diploma.

This diploma is of great value to the holder, as it is a guarantee of his knowledge of the laws of mechanics and machine construction, and of his ability to make a mechanical drawing from notes and dimensions taken.

In the State of New York stationary engineers are required to pass an examination as to their competency, and this course of study will give them the required knowledge. As we have already said, the time will soon come when every engineer at a colliery will have to pass such an examination.

All the instruction in the mechanical course is conducted by correspondence and the student is not required to leave his home to study. Each student is a class by himself, and he can proceed with the course as rapidly or as slowly as he may desire, he will have no text-books to purchase, as the Instruction and Question Papers are all the text-books required. All engineers, pumpmen, firemen, or others desirous of advancing their knowledge of mechanics should send a postal card for a Prospectus of The School of Mines, now in operation with over one hundred students from almost every State in the Union and the British Provinces.

EDITORIAL NOTES.

PROF. C. Le Neve Foster, in his inaugural address to the students at the "Royal College of Science," London, which is the new title of the "Royal School of Mines" deplored the absence of a sort of mining *Review of Reviews* as it was impossible for all but those having abundant leisure to pursue the mass of valuable literature which is now placed before the professional mining men. Prof. Foster thinks that even a catalogue of the articles which appear will be of great value.

It is to meet this requirement that we have introduced the department called the Progress in Mining, and we feel sure that the aid it gives busy men in keeping acquainted with the latest improvements and discover ies related to mining is already thoroughly appreciated.

WE congratulate our enterprising contemporary, *The Black Diamond*, of Chicago, on its change from a semi-monthly to a weekly. The editors and publishers have recognized the fact that the coal market is in such a condition that trade news, to be of most value, must be published at least once a week, hence the change.

The first weekly issue presents a handsome appearance, and is brimful of interesting and well selected news for the trade. It is a credit to the editorial force, and we wish them abundant success in their new departure.

The Anthracite Trade.

The Anthracite trade during the past month has been very dull, and this was due to the remarkably mild weather. Had the weather been seasonable there is no doubt but that there would have been a very heavy December business done. Now, however, it is considered between seasons by the trade, and the demand will depend almost entirely on the weather until the spring trade opens. Stocks as a rule are low, and in case this month gives us a continued spell of cold weather many dealers will be caught short and there will be a temporary brisk demand for coal.

The production for the year 1891 will approximate 45,000,000 tons, of which about 40,000,000 was shipped to market. This shows an increase of about 6,000,000 tons over the production of 1890.

As the stocks on hand at tide water shipping points are within 100,000 tons, the same as they were at the beginning of last year, it is evident that the coal shipped has all gone into consumption.

At the beginning of last year there was a surplus of coal at all the prominent markets, and retail dealers were carrying large stocks. This year there is not so large an amount at the markets, but there are large amounts stocked along the lines of the different roads.

The production for January has been placed by the sales-agents at 2,500,000 tons.

The Bituminous Trade.

The Bituminous coal trade, like the Anthracite, has been dull during the past month, owing to the continued mild weather. Stocks on hand are sufficiently large to meet all demands, and from now on till the Spring trade opens, the amount of business done will depend on the weather.

The tonnage produced during the past year, like the Anthracite, will be largely in excess of the tonnage of 1890.

The Coke Trade.

The Connellsville coke trade remains in about the same condition as last month, but it is impossible for anyone to say how much longer it will continue so. Prices remain as follows:

Furnace coke, $1.90; foundry, $2.30; crushed, $2.65; all f.o.b. cars at ovens, per ton of 2000 lbs.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since our Last Issue.

Madison Coal Co.,	Glen Carbon, Ill.
Ozark Lead & Zinc Co.,	East St. Louis, Ill.
Hayden Hill Consolidated Mining Co.,	Bieber, Lassen Co., Cal.
The Miamisburg Mining & Manufacturing Co.,	Miami-burg, Ohio.
The Buckhorn Syndicate Mining Co.,	St. Paul, Minn.
The Azure Mining Co.,	Silver City, N. Mex.
Little Tycoon Mining Co.,	Burlington, Iowa.
Graham Nickel Mining Co., of Chicago,	Chicago, Ill.
Royal Purple Mining Co.,	Joseph, Oregon.
Lithomar Milling Co.,	Alexandria, Va.
Morning Milling Co.,	Milwaukee, Wis.
The Maravillas Mining Co.,	Philadelphia, Pa.
The Jade Mining Co.,	Denver, Colo.
The Colorado City and Manitou Prospecting & Mining Co.,	Colorado, Colo.
The Mount Powell Mining Co.,	Cleveland, Ohio.
Lo Lo Chickmaim Mining Co.,	Lo Lo, Missoula Co., Mon.
Galvin Milling Co.,	Helena, Mon.
The Peralta Consolidated Mining Co.,	Denver, Colo.
The Union Pacific Coal Co.,	Denver, Colo.
Kaministigue Iron Co.,	Minneapolis, Minn.
The Chicago Floated Silica Co.,	Chicago, Ill.
Royal Mining & Milling Co.,	Chicago, Ill.
The Humbolt Mining & Milling Co.,	St. Louis, Mo.
The Gold & Globe Hill Mining Co.,	Colorado Springs, Colo.
Kenova Coal Co.,	Kenova, W. Va.
La Plata Mountain Mining & Milling Co.,	New York, N. Y.
Byron Gold Mining Co.,	Deering Me.
The Illinois Phosphate Co.,	Chicago, Ill.
National Mining and Development Co.,	Spokane, Wash.
Mexican Hidalgo Zaragoza Gold and Silver Mining Co.,	San Francisco, Cal.
Standard Quicksilver Co.,	San Francisco, Cal.
The Homer Coal & Mining Co.,	Jersey City, N. J.
Ka-Ki-na Iron Co.,	Duluth, Minn.
Bitter Root Canal & Mining Co.,	Butte, Mon.
The Lillian Mining Co.,	St. Louis, Mo.
Jupeter Mining Co.,	Ashland, Wis.
Montfort Mining Co.,	Montfort, Wis.
Heckle Mining Co.,	Wallace, Idaho.
Standard Mining Co.,	Wallace, Idaho.
Kentucky Mineral and Timber Co.,	Jersey City, N. J.
The Cripple Creek Consolidated Mining Co.,	Colorado Springs, Colo.
The Mowenqua Coal Mining & Manufacturing Co.,	Moweaqua, Ill.
S. B. Mining Co.,	Santa Fe, N. Mex.
Pacific Mining Exchange,	San Francisco, Cal.
Sheridan Iron Co.,	Duluth, Minn.
The Coshocton Coal Co.,	Cleveland, Ohio.
The Sadler Lead & Zinc Co.,	Bethlehem, Pa.
The West Fork Coal & Coke Co.,	Fairmount, W. Va.
The Slumbering Bonanza Mining Co.,	Deadwood, S. D.
Wilmams' Mining Co.,	Seattle, Wash.
The Twin Metals Mining & Milling Co.,	Pueblo, Colo.
The Fasset Mining & Milling Co.,	Denver, Colo.
The 4-One Mining Co.,	Chicago, Ill.
National Coal & Mining Co.,	Dallas, Texas.
The Waverly Mining Co.,	East St. Louis, Ill.
The Gurney Mining & Milling Co.,	Denver, Colo.
The Pueblo Cement Plaster Co.,	Pueblo, Pueblo Co., Colo.
The Idaho Development Co.,	Bonner's Ferry, Idaho.
The Antelope Valley Marble Co.,	Fairmount, Cal.
Meramec Onyx & Metal Co.,	Boston, Mass.
National Lead Co.,	Jersey City, N. J.
The Bilharz Ore Process Co.,	Jersey City, N. J.
The Bryn Mawr Land & Improvement Co.,	Seattle, Wash.
The Pawnee Mining & Milling Co.,	St. Elmo, Colo.
Limbark Natural Gas & Oil Co.,	Dunkirk, Ind.
The Sterling Coal & Coking Co.,	Columbus, Ohio.
Alpha Slate Co.,	Bangor, Pa.
North American Oil Co.,	Bradford, Pa.
Muskogee Coal & Mineral Co.,	Fort Smith, Ark.
Empire Mining Co.,	Tacoma, Wash.
Pearsall Mining Co.,	Seattle, Wash.
The Forge Hill Mining Co.,	Plainfield, N. J.
Rutland County Marble Co.,	West Rutland, Vt.
Gordon City Mining, Milling & Improvement Co.,	New York, N. Y.
The Pittsburgh Iron Co.,	Duluth, Minn.
The Bachelor Mining Co.,	Denver, Colo.
The Gold Cup Mining Co.,	Denver, Colo.
The Armdue Mining Co.,	Denver, Colo.
The B. V. Mining Co.,	Colorado Springs, Colo.
The Commercial Gold & Silver Mining Co.,	Leadville, Colo.
Capitol Phosphate Co.,	Ocala, Fla.
The Central Florida Phosphate Co.,	New York, N. Y.
American Oil Co.,	Los Angeles, Cal.
Eclipse Mining Co.,	San Francisco, Cal.
Electric Reduction Co.,	Albuquerque, N. Mex.
Dunlow Coal Co.,	Dunlow, W. Va.
The Bullion Queen Mining Co.,	Denver, Colo.
The Western Pipe & Brick Co.,	Golden, Colo.
The Broken Hill Mining Co.,	Denver, Colo.
Excelsior Phosphate Co.,	Jacksonville, Fla.
Saddle Creek Phosphate Co.,	Vicksburg, Miss.
Pharr Phosphate Co.,	Bartow, Fla.
Fresno Oil Co.,	Los Angeles, Cal.
Mabel Consolidated Mining Co.,	Downieville, Cal.
The Mutual Mining & Milling Co.,	Colorado Springs, Colo.
The Alderson Land & Development Co.,	Charleston, W. Va.
The Welcome Mining Co.,	Anaconda, Mon.
Siloam Springs Mining & Prospecting Association,	Siloam Springs, Ark.
Terre Haute Mineral Paint Co.,	Terre Haute, Ind.
Bald Mountain Consolidated Mining Co.,	Oakland, Cal.
The Little Tycoon Mining Co.,	Burlington, Iowa.
The Ore Fine Mining & Milling Co.,	Louisville, Ky.
The Barker Mining & Milling Co.,	Denver, Colo.
The Roderick Dhu Mining & Milling Co.,	Denver, Colo.
Carlisle Mining & Paint Mfg. Co.,	Carlisle, Pa.
Garnet Gold Mining Co.,	East St. Louis, Ill.
Ashland Mining Co.,	Portland, Oregon.
Hidden Treasure Silver Mining Co.,	Minneapolis, Minn.
Shaw Iron Co.,	Duluth, Minn.
The Colorado Copper Co.,	Chicago, Ill.
The International Mica & Phosphate Co.,	New York, N. Y.
The Ulster Granite Co.,	New York, N. Y.
Georgia Pyrites Co.,	Kittery, Me.
The Penasco Reservoir & Irrigation Co.,	Eddy, N. Mex.
The Western Indiana Coal Co.,	Terre Haute, Ind.
Valencia Mining Co.,	Norway, Mich.
The Phoenix Gold Mining Co.,	East St. Louis, Ill.
White Ash Coal & Mining Co.,	Dallas, Texas.
Green River Coal & Coke Co.,	Seattle, Wash.
The Washington Decorative Marble Co.,	Spokane, Wash.
The Quartz Hill Gold & Silver Mining Co.,	Denver, Colo.
Vista Coal Co.,	Pittsburgh, Pa.
Missoula and Victor Mining Co.,	Missoula, Mon.
The Somerset Mining & Milling Co.,	Denver, Colo.
Maine Asbestos Land, Mining, & Smelting Co.,	Portland, Me.
The Indiana Cement Co.,	Jeffersonville, Ind.
Baker City Gold & Silver Mining Co.,	Baker City, Oregon.
Washington Gulch Mining Co.,	Portland, Oregon.
Irvin Mining Co.,	San Francisco, Cal.
The New York Underwriters & Indemnity Association,	Jersey City, N. J.
Moonshine Mining Co.,	Joplin, Mo.
Bainbridge Placer & Quartz Mining Co.,	San Francisco, Cal.
Big Creek Iron Co.,	Mauston, Wis.
Claire Mining Co.,	Milwaukee, Wis.
Briar Hill Coal & Coke Co.,	Fairmount, W. Va.
Brooklyn Coal Co.,	Rush Run, W. Va.
The Minneapolis Mining & Milling Co.,	Minneapolis, Minn.
Continental Phosphate Co.,	Ocala, Fla.
Montana Gold & Gem Exploration Co.,	Helena, Mont.
The Monarch Coal Mining Co.,	New Whatcom, Wash.
Rich Hill Coal & Coke Co.,	Tacoma, Wash.
Osceola Phosphate Co.,	Albion, Fla.
Long Shot Mining Co.,	Chicago, Ill.
Alcazar Mining Co.,	Chicago, Ill.
Gate City Smelting Co.,	Jersey City, N. J.
Commercial Coal & Coking Co.,	Clarksburg, W. Va.
The North Carolina Smelting Co.,	Newark, N. J.
Freeport Gas Co.,	Freeport, Shelby Co., Ind.
The Little Howard Mining Co.,	Denver, Colo.
The Mexico Onyx Quarry Co.,	Denver, Colo.
The Colorado Bonanza and Union Tunnel & Mining Co.,	Central City, Gilpin Co., Colo.
The Andirondack Garnet Co.,	North Creek, N. Y.

"The Jeffrey Manufacturing Company who are known largely throughout the country as manufacturers of malleable and Steel Roller Chains, Hey-Oborn and Special Chains, have added a line of Link Belting, made from their own patterns, which they insure uniform pitch. These are made to work on standard sprocket-wheels and are interchangeable with other makes of corresponding numbers. This company has the largest line of chains to select from in the world and it would be to the interest of all users of chain to have their reduced price-list which can be had by addressing the company at Columbus, Chicago, or New York."

ANTHRACITE COAL STATISTICS.

Statement of shipments of Anthracite coal for month of Nov., 1891, compared with the corresponding period last year Compiled from the returns furnished by the Mine Operators.

	November, 1891.	November, 1890.	Difference.		For Year 1891.	For Year 1890.	Difference.	
From Wyoming Region,	2,099,572·06	1,819,280·00	Inc.	280,292·06	19,440,196·13	16,984,946·02	Inc.	2,455,252·11
From Lehigh Region,	585,966·02	557,572·02	Inc.	28,364·00	5,800,448·16	5,842,448·12	Dec.	41,999·16
From Schuylkill Region,	1,442,048·15	1,124,634·19	Inc.	317,413·16	11,619,717·09	9,962,571·19	Inc.	1,657,145·10
Total	4,127,557·03	3,501,487·01	Inc.	626,070·02	36,860,364·13	32,789,966·13	Inc.	4,070,398·03

The stock of coal on hand at tide-water shipping points, November 30, 1891, was 637,846 tons; on October 31, 1891, 598,833 tons; increase, 39,013 tons.

MINE INSPECTION IN PENNSYLVANIA.

A Review of the Most Important Facts and Suggestions Contained in the Reports of the Pennsylvania Inspectors for 1890.

FIRST ANTHRACITE DISTRICT, *P. Blewitt, Inspector.*

In his report for 1890, Mr. Blewitt refers to his recommendations of the previous year as to the necessity for examining boilers periodically, and as to the qualifications necessary in those who make the examinations. He draws attention to the need of all connected with mining to adhere strictly to the letter of the mine law, and thus reduce the number of accidents.

The President of the Pancoast Coal Co., at Throop, writes to Mr. Blewitt to say that at their colliery they struck a dip, which made more water than twenty men could bail, and that they were drowned out.

They fitted up a Thomson-Van Depoele Electric Pump in thirty hours, which cleared the mine and kept out the water with ease. The entire cost of the pump was less than that of putting in steam pipes for even a much shorter distance than would have been necessary in this case, had a steam pump been fitted.

SECOND ANTHRACITE DISTRICT, *H. McDonald, Inspector.*

Mr. McDonald draws attention to the want of care in setting props to support the roof. These are, he states, placed in every conceivable position but the right one, and the excuse generally made is that they are displaced by shot-firing. The Inspector does not think this is the cause so much as carelessness in setting and want of enforcement of discipline by the mine bosses. As one-half of the accidents in the district were caused by falls of roof and coal he emphasizes the necessity of more care in setting timber by the miners, and of the maintenance by the bosses of more strict discipline in this regard.

THIRD ANTHRACITE DISTRICT, *G. M. Williams, Inspector.*

In this district there were 100 lives lost during the year. Of this number 51 were lost in five disasters, all of which Mr. Williams says occurred "from conditions which arose within a few hours of the time in which they happened, and not from conditions permitted to exist in violation of the law."

Mr. Williams makes the following general remarks prefacing his description of the most destructive accidents which occurred in the district during the year:

"Before entering upon a detailed description of the disasters which occurred in this district during the year 1890, it is necessary to explain the relation of mine foremen and superintendents to the mines, and the part they take in causing or preventing accidents. Whenever a disaster occurs in a coal mine, the public is inclined to believe that the mines, in general, are badly managed, and that the officers have no regard for the safety of the workmen, and that the causes which result in disaster have always existed, needing only a slight mistake, or a heedless act, on the part of one of the employes to cause it. This is wrong and unjust. The conditions which make a disaster even possible are seldom known to exist before the moment it takes place, and, in most cases, the existence of danger has not even been suspected. Five disasters occurred in mines of this district in 1890, and in only one was it known that danger existed before the occurrence of the disaster, and it occurred in that one while efforts were being made to remove the cause of danger. It was the one at No. 4 Slope, Nanticoke. With the exception of the case at the Hollenback and Jersey Collieries, it is not probable that any unusual danger existed which could have been discovered twenty-four hours before the time at which the disasters occurred.

"Superintendents and mine foremen are generally exceedingly careful, but they have hundreds of points to watch, and must trust a large share of that work to assistants. With the exercise of the greatest precautionary care, conditions which make disasters possible arise suddenly and unexpectedly in gaseous mines, now and then, but happily in most cases the dangers are removed without accidents. No man, who has never had any experience in a gaseous mine, should be placed in charge, nor be placed as an assistant, in charge, of such a mine. I regret to state that I believe that if the mine foremen and assistant mine foremen in positions in this district in 1890 all had the experience required to enable them to foresee what every experienced man ought to see, some of the disasters mentioned could have been easily averted. The operator or superintendent who engages a mine foreman or an assistant mine foreman, who has not had the necessary experience, is guilty of gross indifference as to the effect on the safety of the workmen; he places no value on their lives and jeopardizes the safety of his or his employer's property."

While the ventilating capacity is ample at all the collieries there are in some of them certain districts which do not receive a sufficient quantity of air, partly, says Mr. Williams, from lack of ingenuity on the part of the mine foreman.

FOURTH ANTHRACITE DISTRICT, *John M. Lewis, Inspector.*

Mr. Lewis, in speaking of the improvements in his district during the year, refers to the new breaker erected by Coxe Bros. & Co., at Drifton, as described in detail in THE COLLIERY ENGINEER of January and February, 1891, and he recommends all who are interested in improvements in the sorting and cleaning of coal, to give the description a careful perusal.

Mr. Lewis gives a description of the State Hospital at Hazleton, and points out the advantages of such institutions. In the December issue of THE COLLIERY ENGINEER we drew attention to the crying necessity for ambulance knowledge. Here we have a description of the provision of a haven for the reception and care of disabled miners, and we trust that at an early date we may hear of the establishment of the connecting link between the scene of disaster and these hospitals in the existence of a body of men who are able to attend to the immediate wants of the injured.

FIFTH ANTHRACITE DISTRICT, *Wm. Stein, Inspector.*

Mr. Stein tells a tale of depravity amongst coal miners which we feel bound to reproduce. He says:

"I will here give one experience of the law being violated, which was brought to my notice a short time ago. I learned that some of the miners working in a colliery where safety-lamps were absolutely used, lit their squibs with matches. I investigated the matter and found it to be true; in talking with the miner he said, he did not do it any more. 'What do you do now?' I asked; his reply was, 'I suck the flame through the gauze with my pipe, then put the squib in my pipe when I am going to fire a shot.' I threatened to have him arrested when his 'Butty' appealed, saying at the same time 'there is worse than that done in this colliery,' and with some persuasion he very reluctantly told me that some of the men unscrewed the gauze with a nail and worked with the naked flame. This was a very alarming statement, because it endangered the lives of all in the colliery, and the practice may have caused the loss of many lives elsewhere from explosion of gas."

Comment is superfluous. Mr. Stein expresses the same opinion as others of the Inspectors, namely, that if the men would act up to the law, at least 66 per cent. of the death rate from accident would be averted.

SIXTH ANTHRACITE DISTRICT, *Wm. McMurtrie, Inspector.*

Fifty per cent. of the accidents were due to falls of roof and sides and the inspector calls for better care and judgment on the part of the men. Mr. McMurtrie describes a way of tapping old wastes at Mount Carmel Colliery, which is almost identical with the system described in "The Progress in Mining" in THE COLLIERY ENGINEER for December, 1891.

He also mentions some new air-compressing plant and rope haulages, which have been introduced during the year.

SEVENTH ANTHRACITE DISTRICT, *Samuel Gay, Inspector.*

"Notwithstanding the depressed condition of the Anthracite coal trade during the two preceding years, the sanitary condition, as well as the producing capacity of the collieries, has been kept up to even a higher standard than in any preceding year. The output of coal has been largely increased in proportion to the number of fatal and non-fatal casualties.

"In that respect the Philadelphia and Reading Coal and Iron Company has made a rather remarkable showing; having produced over 265,000 tons of coal per each life lost. This company operates thirteen collieries in this district, giving employment to 5,820 persons, under and above ground, the death rate being 1 in every 1,164. These facts, when it is taken into consideration, that a number of these collieries are very gaseous, much more so than in any other part of the district, would indicate that the management and discipline in and about these collieries had been more than usually rigid.

"The individual concerns have also made a showing that is worthy of notice in point of production, having an output of over 300,000 tons to each fatal accident. However, the death rate is much above that shown in the foregoing. The difference being 1 death in 890, as against 1 in 1,164."

Mr. Gay has the following to say with regard to advantages of better discipline in the working of the collieries:

"Notwithstanding that the mechanical appliances for the prevention of accidents in and about these collieries are equal to any in the district, and we may venture to say any in the state, yet accidents of the character we have given a brief synopsis of, have been more frequent at some of these collieries than at others. We have stated elsewhere that according to the evidence of the foreman in charge of these collieries that several of the accidents are attributed to disobedience of orders given. However, it is a well-established fact that, as a general rule, that insubordination is the result of lax discipline. It should be understood by those in charge of mines, that as long as it exists, just so long must they expect the same results."

FIRST BITUMINOUS DISTRICT. *Henry Louttit, Inspector.*

Mr. Louttit touches on the dangers attending the presence of natural gas-pipe lines passing over lands on which the coal is being worked. He says: "The attention of the Legislature is again called to the dangers arising from natural gas mains being laid over coal mines, and the necessity of a law being enacted, compelling the companies owning them to put their pipes on the surface, and I would further suggest that they be placed on trestles or blocks of sufficient height to allow a current of air to circulate under them. This method would allow the air to sweep away any leakage from the pipes, and when it is necessary for pipes to be laid on tillable ground, bridges or crossings could be made in each field for the passage of teams, etc. During the year I have had considerable trouble with this subject, owing to these mains passing over some three mines in this district, their presence being a standing menace of danger to the men and the mine. The natural gas companies' attention being called to the matter, they invariably did not (I will except the Carnegie Company), or pretended at least, to see no danger by the presence of their pipes over the mine, and ridiculed the idea of even a possibility of gas from their pipes entering the mine, as the gas was specifically lighter than air, and would as a consequence go upward even if the pipes would become broken or displaced by a subsidence of the surface caused by the excavation of the coal beneath them. This belief and the silence of the act of June 30, 1885, in regard to this subject, made it a difficult matter to handle, and the only thing we could do for the safety of the mine and those employed therein, was to stop the mine or part of it. I had occasion to stop part of two mines in the district on account of those lines, and when the gas companies who owned the lines were informed of it they adjusted their pipes somewhat as will be seen by noticing in the body of the report on the Globe and Snowden mines. It is erroneous to think because the specific gravity of natural gas shows it to be a little over half as heavy as air that there is no danger of it descending. There are conditions under which it is placed that must not be overlooked in dealing with it; for under some circumstances its specific gravity is a very small factor in the case, as the following will I think prove. A cubic foot of air weighs ·080977 pounds when the temperature is 32° and the barometric pressure 30 inches, which is equal to 14·72 pounds pressure to the square inch; a cubic foot of natural gas will, under the same conditions, weigh ·04421 pounds; this weight of the gas is only under one atmosphere. Now it is evident that the weight per cubic root will increase as the pressure gets higher. We find that when the pressure is 60 pounds per square inch in the pipes, that it has increased from ·04421 to ·1768 pounds per cubic foot; this weight is for the gas at the moment of exit from the pipes, and this will be maintained for quite a distance after leaving them, owing to the great velocity with which the gas travels."

Mr. A. N. Humphries, of Irwin, Pa., furnishes Mr. Louttit with the following report of experiments tried on June 12th, 1890, at the South Side Colliery of the Westmoreland Coal Co., to ascertain whether natural gas will or will not enter a mine.

When the gas mains are laid as the law provides and court instructs, *i. e.*, "in broken stone from which escape pipes, placed one hundred feet apart, lead to the surface of the ground, the broken stone to be covered with tarred paper, and the paper to be covered with clay.

"Experiments were tried under conditions essentially similar to those caused by such breaks in gas mains as must invariably result from subsidence of the surface if the strata be broken by the removal of the coal from underneath. In the first experiment tried two 3″ gas pipes were placed end to end in broken stone in a trench, the top sides of the pipes touching, but the under sides being apart a little over one-sixteenth of an inch (this opening being equivalent to a crack extending partly around a pipe of that size), and each pipe being gently inclined toward the opening; or, as they would be if the ground had sunk slightly after the pipes were laid. These pipes were placed by the side of an inlet to an exhaust fan over a ventilating shaft.

"Immediately beneath the opening between the pipes and three inches distant from it (the space between being filled with broken stone) was placed at the end of a 3″ gas pipe that lead into the fan inlet and on down vertically through the shaft into the mine, and having a valve on the end. A layer of broken stone ten inches thick was placed over the pipes and was covered with tarred paper. Escape pipes extended from the broken stone to the surface of the ground were placed on each side of the opening between the pipes and three feet distant from it, thus affording the gas the best possible conduit to the surface. Finally, the trench was filled above the tarred paper with well-stamped clay.

"After one end of the horizontal pipe was closed with a cap, gas, under a pressure of one and four-tenths pounds per square inch, was admitted to them at the other end, through a half-inch gas pipe. The fan was started and speeded so as to maintain a ventilating pressure equal to a half-inch of water.

"To discover whether the gas would pass through the pipe when the valve would be opened in the mine, was an undertaking attended with not a little danger, as the gas might be highly explosive because of an admixture of air from the escape pipes. A safety-lamp was used to make the test, and we found but little gas coming through the pipes.

"The fan speed was then increased until the water-gauge indicated a depression of one inch, the regular ventilating pressure at this mine. Gas was now found coming through the pipe and in a very explosive form. It would explode within the lamp gauze and put the light out. A miners' lamp of the ordinary kind was fastened on the end of a long stick, and, from a distance, the flame of the lamp brought in contact with the gas issuing from the pipe. The result was an explosion of such violence in the pipe, and about the end of it, that the detonation could be heard through the escape pipes on the surface. This was tried several times. Once the lamp was knocked off the stick by the concussion. During this trial we found that the air continually entered the escape pipes and no gas passed out through them into the atmosphere.

"An experiment was then tried to determine whether or not gas would enter the mine from a break in uncovered pipes. The covering was removed from around the pipes at the opening where the gas was to leak, the size of the opening was increased to three inches, and the cap was taken off the end of the pipe to permit the gas to pass off that way if it would. The top end of the vertical pipe was lowered to a position about five inches from the opening between the other two pipes.

"The gas was then turned on, the fan being in operation, and, curiously enough, a small quantity of it passed off up through the escape pipes, none went out where the cap was taken off, while in the mine the burning gas flamed up fully four feet above the end of the pipes and would have soon ignited the roof coal had the valve not been closed."

The writer has always contended that gas from a broken main would descend through cracks or breaks in the strata and enter any mine ventilated by furnace or exhaust fan. This has now been conclusively proven.

Not a few engineers insist that because natural gas, or say $C\,H^4$ is lighter than the atmosphere it must necessarily rise in the air, like a cork from beneath water, forgetting altogether that the gas in the mains is often under two or three hundred pounds pressure to the square inch, and, therefore, is much more weighty than atmospheric air.

However, the gas used in trying these experiments was much lighter than air; yet escaping under pressure as it did, a very trifling quantity was diffused into the atmosphere; and this, through the action of the fan, seemed to be retarded by the air which was drawn or held nearly stationary in place in the openings through the broken stone.

If the buoyancy of the gas used on this occassion did not cause it to rise, how then would gas under several hundred pounds pressure, act when escaping from a broken main into a crack or rent leading through broken strata into a mine with a ventilating current produced by a fan or furnace reducing pressure? I fear this query will only be answered by the total destruction of some large extensive mine, and the loss of very, very many valuable lives."

SECOND BITUMINOUS DISTRICT, *Wm. Jenkins, Inspector.*

Mr. Jenkins notes improvements in machinery for hoisting and haulage and larger ventilation power, and he reports that the mines are generally in an efficient state. With regard to the prevention of accidents Mr. Jenkins says: "I again urge upon the mine bosses and fire bosses the necessity and importance of a strict observance of the provisions of the mining laws, and rules at the mines, and require that they be strictly carried out, and in no case permit any one to work in an unsafe place. The security of the mines, and the safety and health of the miners are committed to their care, and in view of this, it is their duty to demand that their orders are faithfully and strictly carried out. Thereby not only doing their duty, but at the same time are doing what is required of them. Although many of the lives lost during the past year were carelessness of the victims themselves, yet this must not deter them from enforcing the laws and the rules of the mines, and require strict obedience to them. I desire to call attention to the fact that last year nearly all the fatal accidents happened to old miners, but this has changed, as sixty-five per cent. of the fatal accidents this year were "greenhorns" or men who had little or no experience in the mines, and from present indications, this class of men will be our future miners, as many of our old miners are seeking other employment, therefore great care will be required with the new men until they become thoroughly acquainted with the dangers encountered in mining."

THIRD BITUMINOUS DISTRICT, *Thos. K. Adams, Inspector.*

Mr. Adams, reports favorably of the condition of the mines generally, but points out that many accidents are still attributable to carelessness on the part of the victims. Considerable improvement has been effected in ventilating appliances, and several new air compressors have been introduced.

FOURTH BITUMINOUS DISTRICT, *Jas. N. Patterson, Inspector.*

Mr. Patterson reports marked improvement of a general character in the working and fitting up of the mines.

FIFTH BITUMINOUS DISTRICT, *Wm. Duncan, Inspector.*

Mr. Duncan, gives a detailed report of the Hill Farm disaster. He also reports numerous improvements in fitting, and states that the mines are generally in a good state.

SIXTH BITUMINOUS DISTRICT, *I. T. Evans, Inspector.*

Of the forty-two accidents in this district, Mr. Evans reports that one-half of the injured were unskilled men. Falls of roof are the chief causes of accident. In former years the accidents were greatly due to falls of coal, but a rule which was enforced compelling all miners to put sprags under the coal when undermined, at least every five feet, has reduced this class of accidents.

The miner is greatly to blame himself for not safely propping his working place.

Mr. Evans advocates increased ventilating power in the district, and more effective distribution of the air. Amongst improvements which have been made Mr. Evans describes a double tail-rope system at Webster Colliery, Pa.

With regard to better discipline as means of securing greater safety, Mr. Evans says: "Another great preventive of accidents in our mines would be to have better discipline enforced in them. I can scarcely imagine where it is required to a greater extent than there where, possibly, each man in it holds the life of the rest in his hands. But I am sorry to say that there is a great lack of it in our mines. I therefore hope that in the revision of our mining laws a proper code of rules, governing all employes, will be inserted in it, and penalties attached for the non-compliance with them, so as to bring our mines all down to a good system of discipline. This would be of incalculable benefit to both employer and employe."

SEVENTH BITUMINOUS DISTRICT, *James Blick, Inspector.*

Mr. Blick advocates the stringent application of the law in mines. He reports that the mines are in a good state. Haulage by rope is now in vogue in twenty-two mines in this district. On this important subject Mr. Blick says: "Many of the mines in this section are extended a long way from the tipples, and the cost of underground haulage, where done by horses or mules, is quite an item in the cost of production. The wire rope system of haulage is in use in about twenty-two mines in this district, and it could be adopted in many others to good advantage. The total length of wire line in use in the above mines is about 100,000 yards, or 57 miles, and varies in size from seven-eighths to one-half inch in diameter. The life of a rope depends more upon the care taken of it than upon the aggregate tonnage hauled. On a favorable even grade, with dry roads, a good road bed, and the rope properly tarred at regular intervals, a good rope will probably last in constant use about five and a half or six years. The number of mules required to do the work now being done by the ropes would be about 510. This system of haulage in general admits of a saving to the operators and is of great benefit to the mines from a sanitary point of view. As a rule, the main hauling roads are also used as the main intake for the ventilation, and if a large number of mules are employed thereon the air currents are more or less vitiated before reaching the working places of the miners, which source of pollution is obviated by the use of the wire-rope system."

EIGHTH BITUMINOUS DISTRICT, *Austin King, Inspector.*

In this district the accidents were doubled over the previous year. Many of these were due to carelessness on the part of the workmen. Falls of roof and coal were the causes of 79·1% of the fatal, and of 60% of the non-fatal accidents. Mr. King writes as follows regarding the difficulty in securing good ventilation of the district:

"There is no fire-damp in this district that is discernible or that has ever been detected. This is the chief reason why the means of producing ventilation are usually too small and weak to accomplish the work they are expected to do. Some very good authorities have stated that in their opinion 'fire-damp in mines was a blessing in disguise.' This will almost be admitted to be true if a little thought is given to the great attention and study that has been given the subject of ventilation of mines by many eminent mining engineers in the past century, and especially in the last fifty years, which would not have been given but for the occurrence of explosions so frequently as to compel such attention both from a humane and business standpoint—a large number of the mines taking fire from the explosions.

"It is generally found much harder work to convince managers of the bad or unhealthy condition of the ventilation in their mines, where fire-damp is not given off, than where it is as its presence usually creates a wholesome fear of possible results if ventilation is not ample in quantity and properly conducted to working places. Mines should be well ventilated because, to be healthy, we must have pure air to breathe.

"Operators of mines are not men who care to be classed as altogether void of the milk of human kindness, many of them would give liberally to a workman or his family in necessity, but at the same time would not think it a violation of the decalogue to have his mine so poorly ventilated that men could not be seen by each other six feet apart and would raise quite a storm about the ears of the mine boss, if the cost of lumber, erection of brattices or doors, or yardage of air-courses was greater than perhaps during some short period, when little or none of that work had been done, because some mining boss probably made an effort to build a reputation for cheap coal, at the expense and comfort of the miners in the advance workings of the mine, and, having a certificate to that effect in the form of a letter of recommendation from the operators, would leave for other fields to wear his laurels as a cheap coal producer, while the new incumbent was being soundly drubbed because of his extravagance (compared with his predecessor), while he is endeavoring to set things right. Conditions such as these have been observed in this district and the reasons given are nearly correct in the majority of cases. A more humane spirit should be developed and encouraged, with a standing order to mining bosses something like this, 'take no *risks* where life and limb are likely to be endangered and keep the working places of the mine *well ventilated.*'"

In a circular to the mine officers suggesting how greater safety might be secured, issued Jan. 6, 1890, Mr. King called attention to the inadequate furnace ventilation at many collieries as follows:

"That where furnace ventilation is used, a departure should be made in the direction of deep furnace shafts, the same to be of ample area, instead of the shallow, almost useless, and wasteful furnace shafts in present use in nearly 90 per cent. of the mines ventilated by that means in this district. I would respectfully invite your attention particularly to this matter, and figure out for yourselves the great loss due to shallow furnace shafts as against deep ones, other things being equal. So great is this loss that I do not hesitate to say that—where a furnace shaft is necessary—if the mine boss would intelligently show the operator the cost of coal burned in a shallow as against a deep furnace shaft, he would undoubtedly sink a deep furnace shaft or erect a ventilating fan."

ARE YOU IN IT?

That is, are you in the ranks of those progressive colliery owners and colliery officials who keep posted on the most improved mechanical appliances? If you are not, you ought to be. It will cost you nothing to get this information. All that you need do, is to

Send for circulars illustrating and describing the Excelsior Boiler Feeder, the simplest and best Injector known, to N. A. Watson, 1603 State St., Erie, Pa.

Send for circulars illustrating and describing the new Lightning Rotary Coal Drill, to D. Corgan & Son, Luzerne, Pa.

Send for circulars illustrating and describing the Bellis Patent Mine Collar manufactured by W. L. Bellis, 76 Michigan St., Cleveland, Ohio.

Send for an illustrated catalogue of the Yough Mine Pumps, specially designed for use in coal mines, and manufactured by Boyts, Porter & Co., Connellsville, Pa.

Send for circulars illustrating and describing the Bittenbender coal drill, manufactured by F. T. Bittenbender, Nanticoke, Pa.

Send for circulars describing the asbestos boiler and pipe covering manufactured by the H. W. Johns Mfg. Co., of 170 and 172 North Fourth St., Phila.

Send for catalogue of the corrugated iron roofing, siding, etc., specially adapted for colliery buildings, manufactured by the Cincinnati Corrugating Co., Piqua, Ohio.

Send for circulars of cable grips for endless rope system manufactured by J. E. Carr & Son., Leavenworth, Kansas.

THE MINERAL PRODUCTION OF THE UNITED STATES IN 1891.

In its annual statistical number, *The Engineering and Mining Journal* gives the following interesting figures regarding the production of minerals in the United States:

In 1890 the value of its chief items at the place of production exceeded $650,000,000, and though the cash value of these products in 1891 was probably less than in 1890 owing to the lower market prices of most of them, yet the quantities produced were, with very few exceptions, much greater than in any previous year.

The output of gold is increasing, but in the absence of full returns it is placed, in 1891, at approximately 1,620,000 ounces, or $33,250,000, an increase of 312,000 ounces.

The output of silver has increased much more rapidly, and, in the absence of full returns, it is estimated that it amounted in 1891 to 58,000,000 ounces, the coining value of which would be $74,820,000.

The coal consumption is generally considered to be the best measure of the industrial activity of a country. This rule would hold good for this country during the past year, when general industry was active and prosperous, though a few branches suffered a reaction. The output of Anthracite, from full and accurate returns, amounted in 1891 to 42,839,779 tons of 2,240 pounds, while the production of Bituminous coal, which is in part estimated, amounted to 98,000,000 tons. Prices of coal were, in general, lower than in 1890, though the Anthracite trade, being "regulated," maintained during a portion of the year rather higher prices than in the previous year.

The iron industry suffered a severe "set-back" during the past year, when the make of pig iron declined from 10,307,028 tons of 2,000 pounds, in 1890, to 8,976,000 in 1891, these figures being obtained from official returns made throughout the year. This heavy falling off was caused chiefly by the decline in the make of steel rails from 2,095,996 tons of 2,240 pounds in 1890 to to 1,090,000 tons in 1892—a decline due partly to the poverty of the railroads and partly to the comparatively high price established by the steel rail association.

In phosphate rock, in pyrites, in salt, in aluminum, in copper, lead, and zinc there has been a very considerable increase in output, while tin, antimony ore, and sulphur enter the list with modest but promising beginnings.

COMPARATIVE TABLE OF MINERAL PRODUCTION IN THE UNITED STATES IN 1890 AND 1891.

	1890.	1891.
Gold, ounces	1,588,880	1,620,000
Silver, ounces	54,500,000	58,000,000
Pig Iron, tons of 2,000 lbs.	10,307,028	8,976,000
Steel Rails, tons of 2,240 lbs.	2,095,996	1,090,000
Copper, lbs.	264,920,000	292,020,000
Lead, tons of 2,000 lbs.	181,494	205,888
Zinc, tons of 2,000 lbs.	64,342	76,500
Nickle, lbs.	200,332	144,841
Quicksilver, flasks	22,926	21,022
Aluminum, lbs.	61,281	143,820
Tin, lbs.	....	124,366
Antimony ore, tons of 2,240 lbs.	....	300
Anthracite Coal, tons of 2,240 lbs.	38,006,481	42,839,779
Bituminous Coal, tons of 2,240 lbs.	93,000,000	98,000,000
Phosphate Rock, tons of 2,000 lbs.	637,000	659,731
Salt, bbls. of 280 lbs.	9,717,000	10,229,691
Bromide, lbs.	310,000	415,000
Pyrites, tons of 2,000 lbs.	109,431	122,431
Sulphur, tons of 2,000 lbs.	....	1,200

PERSONALS

Mr. Wm. Leckie, of Plymouth, Pa., District Supt. of the Lehigh & Wilkes-Barre Coal Co., has tendered his resignation, to take effect on the 5th inst., when he will assume the superintendency of the Lehigh Valley Coal Co.'s York Farm Colliery, near Pottsville, Pa. Mr. Leckie is a comparatively young man, but has won a reputation as one of the best practical colliery officials in the Anthracite region. Our acquaintance with him began some years ago when he was a fire-boss at the Phila. & Reading Coal & Iron Co.'s, Shenandoah City Colliery. He has rapidly forced his way up by hard work and a close study of the sciences pertaining to coal mining. As a fire-boss he faithfully performed his duties, and devoted his leisure moments to study, until he secured a mine foreman's certificate of competency. He did not cease his studies when this was accomplished, but continued to store in his mind all the available standard literature on mining subjects, and took advantage of every opportunity to apply his theoretical knowledge to practical use. The result has been rapid promotion and an excellent reputation as a careful and thoroughly competent official. We wish him abundant success in his new field and commend his course as a student to all fire-bosses or working miners who are ambitious to rise.

The Bellis Mining Collar has proved a success whereever introduced and the manufacturer, Mr. W. L. Belli of Cleveland, Ohio, writes us that he is rapidly extending his trade into every coal field in the country, and what is more encouraging is the fact that orders are invariably duplicated. If the collars were not appreciated this would not be the case.

ESSAY ON PENNSYLVANIA BITUMINOUS MINE LAW COMMISSIONS.

BY T. K. ADAMS, MINE INSPECTOR.

[Proceedings of December Meeting of the Western Pennsylvania Mining Institute.]

It might be of sufficient interest to the members of this Institute for me not only to direct their attention to the passage of the concurrent resoluton, at the last session of the General Assembly, creating a commission to revise the Bituminous Mining Act, but to sketch briefly in connection therewith, the reasons for the passage of the different acts, joint and concurrent resolutions, creating mine commissions for the Bituminous regions of this State.

The average citizen of this Commonwealth is very apt to look upon the introduction of resolutions in the Legislature for the purpose of creating commissions to help our usually very capable, honest, and scientific legislators formulate bills for the life preserving and sanitary benefit of certain classes of our people as superfluous, at best unproductive of much good and a useless expenditure of the public money, knowing as he does that men are selected to office at $10 *per diem* to guard and protect the interests of the whole people of the State, whose ability should be of such a character as to fit them to treat justly and intelligently any question of public moment that might be brought before them. However, no matter what the general attainments of our representatives may be, unless they have had an extensive and varied practical experience in the mines and a theoretical knowledge of all that pertains thereto, especially as to the necessary requirements to keep them in a healthful and safe condition they cannot deal intelligently with mining legislation, so that such would guarantee the greatest degree of protection to the lives and health of the miners. We have had ample opportunity of judging of the ability of our representatives in the past and know from very sad experience that they stand very much in need of assistance when attempting to legislate on mining matters.

Pennsylvania legislators do not stand alone in creating mine commissions, because long ago, such nations as Belgium, France, Germany, and England have all called in the assistance of their most expert and scientific mining engineers to help their legislators in framing mining laws, and in fact, some of these nations have been very prodigal in the expenditure of money and of time devoted to such agencies so that they could experiment, investigate, and intelligently determine what was really necessary to afford the greatest degree of protection to their workmen.

When the commissioners are selected from among the best mining talent of the State they will prove to be of incalculable assistance in formulating mining legislation, while if great care is not exercised in their selection, commissions will be burdensome to the taxpayers of the Commonwealth. Scientific knowledge, long practical experience in mines, independence and honesty should be the requisite qualifications of all applicants for appointment to such important positions. Class interests should never enter under any circumstances, as a factor into the appointments. The commissions should never be composed of more than five or seven men, as all above this number will create an unnecessary expenditure of public money. Large commissions do not work as efficiently as small ones. One of the most efficient mine commissions ever appointed in this State only consisted of three members, that was the commission of 1874.

Prior to the year 1877 there was no general mining law in force in the Bituminous regions of Pennsylvania. Prayer had been invoked by the suffering; petitions had been numerously signed and sent to the Legislature informing our representatives of the Siberian conditions of the Bituminous mines and asking for some degree of relief therefrom, but they were excessively delinquent in responding to the urgent appeals of the miners, but at last through the patience and perseverance of the petitioners the consciences of our very Hon. friends at Harrisburg were smitten resulting in the introduction of a joint resolution in the Legislature which was passed and approved the 6th day of May, 1874, said resolution authorized the Governor to appoint three practical and experienced men in mining as commissioners to investigate the condition of the Bituminous mines of the Commonwealth. In pursuance of this resolution Messrs. John O'Neil, coal operator, Augustus Stinner and John Archibald, miners, were appointed. The commissioners were allowed 100 days in which to complete the investigation and submit their report. From the date that this intelligent and honest commission made their truthful and valuable report showing the terrible condition of the mines and substantiating and reinforcing the sentiments contained in the prayers and petitions of the suffering, a better day dawned for the workmen who were required to earn an honest livelihood for themselves and families in the Bituminous mines of this State. Although John O'Neil of the commission was very anxious in having as favorable a report of the condition of the mines as could be had (he no doubt having an idea that mining legislation was unnecessary), he after a careful examination, found that truth proved stronger than fiction, and to his honor be it said he did not falter in performing his duty at the last moment. His action by signing the majority report gave weight and a degree of manliness and independence in asserting his honest conviction. This report should be secured by this Institute, read by all its members, and afterwards placed in the archives thereof. After the report of the commission was received by the Legislature the specious arguments of the enemies of mining legislation to this effect: "If mining laws are enacted, competition being so keen, the mining industry of Pennsylvania will be ruined and invested rights crushed out of existence," which previous to this had served the purposes of the selfish faithfully and well; which had had great weight with our representatives, now began to lose their force, consequently, at the session of the General Assembly of 1877 the first Bituminous mining law was passed. This humane act was not secured without a terrible struggle but justice and right triumphed and the progress of the mining industry has been phenomenal since that date and the invested rights of the capitalists go on as of yore increasing their bulwarks of defence against their enemies.

The results obtained from the enactment of the mining law of 1877 proved very beneficial to all concerned in mining, but owing to the strong opposition this measure met with in its passage through the Legislature many of its good points had to be compromised. An attempt therefore was made six years after the bill passed to perfect the law in such a manner as to meet the then existing requirements. The friends of mining legislation urged upon the members of the Legislature at the session thereof in 1885 to have a commission appointed to revise the law, consequently, "An Act" was introduced and passed the 31st day of March of that year authorizing the Governor to appoint a commission to consist of twenty-five persons, viz., six competent and experienced coal operators, six competent and practical miners, three members of the Senate; four members of the House of Representatives, together with the six mine inspectors. The time allowed the commission to revise the act was not to exceed 30 days, and as the Legislature adjourned about the 11th day of June not much time was given the commission to complete the work assigned to them. Little or nothing was accomplished by this large commission. The revised bill being presented to the Legislature in the closing days of the session and the enemies to such legislation being on hand, as usual, charged with the old arguments, always willing to tear down, but never willing to improve, the bill was finally passed with one essential improvement over the old law, viz., that of requiring mine bosses to pass an examination. This commission will not be remembered for its efficiency or for the good work it accomplished when it is considered as a whole. While there were many brilliant minds upon the commission they were certainly overshadowed by many more weaker ones. The commission was entirely too large to do efficient work and the continual clashing of class interests between coal operators and the miners destroyed the harmony and retarded the work of said commission. Many of the members of the commission had not the necessary ability and experience to perform the important duties of the position intelligently and well.

To give you some idea of the wonderful development that has taken place in the mining industry since the mining law went into effect and for the special purpose of exploding the old fallacies which have done so much duty for the enemies of mining legislation, allow me to make a comparison of its condition in 1879 with that of last year (1890) covering a period of eleven years. In 1879 the coal production was about 15,000,000 tons; 342 mines, and about 21,000 persons employed therein. For last year (1890) the coal production was 40,806,913 tons; 645 mines; and 54,000 persons employed therein. This does not include the 12,630 outside employes, thus showing a net increase in tonnage of 172 per cent., in mines 88½ per cent., and 165 per cent. in inside employes. We might well ask the question: Has mining legislation ruined the coal mining industry of the State? The number of fatal accidents in 1879 was 51, and in 1890 131, showing an increase of 96 per cent. But by taking the ratio of killed to the number of tons of coal produced and the number of employes employed the decrease in the former is 6½ per cent., and in the latter only 1½ per cent. In view of these facts in reference to fatalities the mining law has not afforded that protection to life that might have been reasonably expected from its enactment, hence the anxiety of the friends of humanity to have it thoroughly revised and amended so that such terrible disasters as have occurred in the Bituminous mines of very recent date, whereby many valuable lives were probably unnecessarily sacrificed, might be prevented in the future. With this object in view a concurrent resolution was prepared and sent to friends in the Legislature asking for the appointment of an intelligent commission to revise the Bituminous mining law. The resolution was sent at the beginning of the last session of the Legislature so that it could be presented to it as soon as business could be transacted. The original draft of said resolution provided for the appointment of a commission of twenty-eight members, viz., eight coal operators, eight miners, two senators and two representatives, these four Hon. gentlemen were to be learned in the law, they were to be constitutional lawyers, if you please, such as usually adorn the Pennsylvania Legislature, together with the eight mine inspectors, but before it was introduced the number was wisely reduced to 7 or 9 members. When the resolution went to the House committee of mines and mining it met with strong opposition from the professional labor representatives upon it, they claiming that the miners had not equal representation with the coal operators prejudging, as usual, that the mine inspectors would act and vote with the operators regardless of their honest convictions ("Oh, just Judge, righteous Judge"), consequently, the number was again changed to suit the prejudices of those honorable men so that the miners would have eight members of the commission and the coal operators four, together with four inspectors. The miners were to be appointed upon the recommendation of the labor organizations of the State. In this form the resolution passed the House after much valuable time had been wasted. It was then introduced in the Senate for the gracious consideration of that august body of learned representatives and as the labor representatives of the House had played their innings now came the innings of the senators. They too changed the number of the commission so as to consist of twenty-four members, viz., eight miners, eight operators, together with the eight mine inspectors. They also took the appointing power out of the hands of the Governor as far as the operators were concerned and placed it in that of the judges of the different inspection districts and as some of those districts include five or six different judicial districts, the motive of introducing such an amendment was for the purpose of delay. Finally the resolution passed both Houses and the jugglery was suspended for the time being. Although the concurrent resolution was introduced early in the session of the Legislature the commission was not organized before the 30th day of March, 1891. After the commission was organized the members thereof continued in session for about twenty-eight (28) days and completed the work of their appointment at a cost to the State of about $5,000. The law was changed in form and a thorough revision accomplished. As to the merit of the work of the commission we recognize it to be very meritorious and practical. It is not perfect by any means but it certainly was a great improvement on the present law and if it had passed the Legislature it would have afforded a greater degree of protection to the miners. Although temporarily defeated and almost crushed to death, like Banquo's ghost it will not down, and from its grave it will arise at no very distant date to plague its foes. The bill was presented in the Legislature on the 30th day of April, 1891. It passed the House in about two weeks with but few amendments and was then sent over to the Senate where measures for the benefit of the workingmen receive so tender attention and due consideration. The Senate committee of mines and mining had not the time to consider this humane and meritorious measure, although, those Hon. representatives of the whole people of the State had been going home for weeks previous to the presentation of this bill every Thursday at 1 o'clock P. M., not having work sufficient to keep them in mental exercise, but they were abreast of the times in one particular in that of having sufficient mental and physical ability to enable them to march up to the public crib and draw $10 per day therefrom. Those Senators who are supposed to represent the interests of the people of Western, Pennsylvania, should ever be held in grateful remembrance by the workingmen and especially the miners for the sleepless night they spent in advancing their cause and especially for the noble interest they took in having the Bituminous mining bill considered, but we leave those Hon. friends to the tender mercies of their duped and, it would seem, gullible constituencies.

The commission was composed of men of fair ability. They exercised a wonderful degree of independence and in our opinion, served the Commonwealth faithfully and well. Both the miners' and operators' interests were well and efficiently represented and guarded. The good work of this commission is not lost by any means, and can be taken up and the different provisions of the prepared bill discussed by such unprejudiced and intelligent organization as this Institute. Defects can be remedied and improvements made. No foolish, no inefficient, no unnecessary burdensome legislation should be approved of by this institute or by the Legislature, but above all, neither should the prejudices nor the dollars and cents of the selfish stand in the way of guaranteeing all necessary legislation to protect human life. No more joint or concurrent resolutions to create mine commissions are necessary in this State for many years to come. The members of this Institute, however, may find it necessary, some time in the future, to encourage and assist in having a national mine commission created so that the mining industry or interests in all of the States might become subject, in a measure, to the regulations of one national mining law. The securing of such a law would prove a potent weapon to disarm the arguments of the enemies of mining legislation.

The Lightning Rotary Coal and Rock Drill.

In another column is advertised the Lightning Rotary Coal and Rock Drill, made by D. Corgan & Son, Luzerne, Pa. This is a hand drilling machine for use in coal and rock. The most noticeable point in the machine is the bit which does the cutting. Upon the end of an ordinary twist drill is cast a head of aluminum bronze containing three sockets in which are set three small steel knives. The two outer ones are arranged like the cutting parts of an auger. These cut a ring ¾ of an inch thick around the outside of a 2¼ in. hole while the middle knife breaks up the core which comes out in pieces as large as pea coal. It will be seen that as there is only a ring of coal ¾ inch thick be cut the power required will be much less than where the whole is reduced to powder as in the ordinary machines. The knives are finely tempered and very cheap so that a man can have several sets and if those in use become dull, new ones can be inserted in a few seconds. As will be seen in the cut the machine is very simple. Its weight complete is only 30 lbs., and experience has shown that it is especially suited, on account of its lightness for use in heavy pitching and thick to veins where it is impossible to use the heavier kinds. It can also be set without the use of a hand drill and works equally well in hard or soft coal. It is no more costly than the ordinary machine and notwithstanding its great efficiency in cutting, the bills for sharpening are even less. Messrs. Corgan & Son have sold many of these, which are in daily use under the most trying conditions, and it will pay any person having use for a drilling machine to correspond with them.

The Babcock and Wilcox Company publish in our advertising columns a list of colliery operators who are successfully generating steam at a low cost, and at the same time securing better results by the use of the most improved steam plants. It will pay our readers to glance over this list and then seriously consider whether the improvements that have proven satisfactory to these operators will not be equally valuable to them.

Easy Lessons for Beginners

IN THE STUDY OF THE

Art of Mining

AND THE

SCIENCES RELATED TO IT.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the sciences related to mining and to learn how to answer the questions in ventilation, surveying, and mechanics which are asked at the examinations for mine foreman's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine foremen and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and many calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

One of the most difficult things encountered in teaching penmanship is to make the necessary repetition of the principles without tiring the learner. However, it must be remembered that all of the letters of the alphabet depend primarily for their correct construction upon the four laws of penmanship given in our first lesson, and which have been emphasized in all the subsequent articles.

In this issue we have for consideration the capital letters K and L. The first letter, numbering from the left of Fig. 30, shows the capital K as it should be written. The first part consists of the stem with a

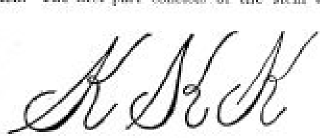

FIG. 30.

right curve extending upward to the full height. The second section begins at the full height of the letter with a graceful curve, which is drawn towards the first section, touching at the middle and connecting by a small loop. The curved line is then brought on a parallel to the bottom of the stem and completed by a right curve extending upward one-third of the full height of the letter. In letter 2, the ellipse of the first section is too large, and is otherwise imperfect. Letter 3

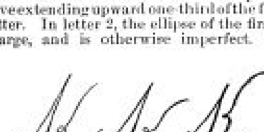

FIG. 31.

shows the first section incomplete, and a violation of the second law of penmanship, namely, all strokes must be proportionate in distance. Letters 1, 2, and 3, Fig. 31, show probable faults in making this letter. It will be seen that the strokes are not parallel; the ellipses are not proportionate in size; curves not elliptical, and in each of them the right section of the letter is not connected with the first or stem.

Figs. 32 and 33 illustrate the development of the capital letter L. Letter 1, Fig. 32, numbering from the left is drawn on correct principles, and is in conformity with the general laws of penmanship. The first curve,

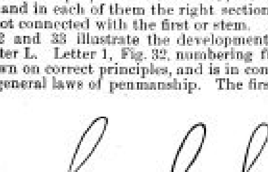

FIG. 32.

it will be noticed, divides the horizontal loop into two equal sections. Letter 2 shows several errors, the upper scroll is too large, the letter being crossed below the middle of the stem. The third letter from the left is a violation of the fourth law of penmanship, namely, all curves should be elliptical.

Fig. 33 shows common mistakes made in writing this letter. In the first letter it will be seen that the main stem has the wrong inclination and the bottom loop is too small. The second letter shows no bottom loop at all, and, as a consequence, offends the eye. Letter 3, counting from the left, is a deformity arising out of the

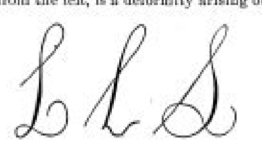

FIG. 33.

imperfect development of the ellipses and is a violation of the fourth law of penmanship.

One of the principal lessons to be learned in the development of the capitals K and L is gracefulness. If the letters are well formed, but combined and arranged without ease or gracefulness, the writing will never be thought beautiful or pleasing.

ARITHMETIC.

CANCELLATION.

Cancellation is a short method of obtaining results by omitting equal factors from a dividend and divisor and on this account it should be employed whenever possible in arithmetical operations. The sign of cancellation is an oblique mark drawn across the face of a figure, as $\cancel{2}$, $\cancel{4}$, $\cancel{6}$, etc.; therefore to *cancel* means to cross out, or reject. Two principles to be remembered in solving problems by cancellation are: First, canceling a factor of a number divides the number by that factor, and second, canceling equal factors of the divisor and dividend does not change the quotient.

In arranging the numbers for cancellation, the dividend may be written above the divisor with a horizontal line between them, as in division; or, as some prefer the dividend may be written on the right of the divisor, with a vertical line between them.

The advantage of using cancellation may be more clearly seen by the following examples:

In exchanging 24 hats at \$5 each, for coats at \$24 each; how many coats would I get?

To solve this question ordinarily we multiply 24 by 5, which gives 120 and divide this by 24 which gives a quotient of 5. Instead of performing this work, indicate it thus,

$\frac{\cancel{24} \times 5}{\cancel{24}}$ then, since dividing either factor of a product divides the product, the result is $1 \times 5 = 5$; the same as would be got by canceling or omitting the 24 from both dividend and divisor.

Multiply 105 by 18, and divide the product by 30. Indicate the operations as follows:

$$\frac{\overset{21}{\cancel{105}} \times \overset{3}{\cancel{18}}}{\underset{\cancel{5}}{\cancel{30}}}$$
$$21 \times 3 = 63,$$

First, we divide the 18 in the dividend and the divisor 30 by 6; this gives 105×3 above, and 5 below and does not alter the quotient, since multiplying or dividing both dividend and divisor by the same number does not change the quotient. Now, the 5 below the line is contained into 105, not yet cancelled, above the line 21 times, therefore we cancel and place the 21 at the left of 105. The quotient is then found to be $21 \times 3 = 63$. As each factor is used in canceling, it is crossed to indicate that there is no further use of it; and each quotient is placed beside the number from which it is obtained. The 21 and 3 being the factors left of the dividend after cancellation, are multiplied together; their product is 63, and as no factor of the divisor is left, the 63 is not to be divided, and is, therefore, the quotient required.

Again, multiply 75, 153, and 28 together, and divide by the product of 63 and 36.

SOLUTION.—The operations are indicated as shown below.

$$\frac{\overset{25}{\cancel{75}} \times \overset{17}{\cancel{153}} \times \overset{7}{\cancel{28}}}{\underset{\underset{3}{\cancel{9}}}{\cancel{63}} \times \underset{\cancel{9}}{\cancel{36}}}$$

We cancel 4 out of 28 and 36, leaving 7 above, and 9 below. Cancel this 7 out of the dividend and out of the 63 in the divisor, leaving 9 below. Cancel a 9 out of the divisor, and out of 153 in the dividend, leaving 17 above. Cancel 3 out of 9 and 75, leaving 25 above and 3 below. No further canceling is possible; the factors remaining in the dividend are 25 and 17, whose product 425, divided by the 3 in the divisor, gives $141\frac{2}{3}$, the quotient.

In the division of fractions also the work is greatly shortened by cancellation, as will be seen by the following problem:

Multiply $\frac{1}{2} \times \frac{12}{25} \times \frac{5}{8}$, and divide the result by $\frac{3}{4}$ of $\frac{2}{3}$ of $\frac{4}{5}$. In arranging the numbers for cancellation in fractions, the numerators of the dividend are placed above the line and the denominators below it. In placing the numbers of the divisor it is *vice versa*, the numerators are put below the line and the denominators above. The question is solved thus:

$$\frac{1 \times \overset{\overset{3}{\cancel{6}}}{\cancel{12}} \times \cancel{5} \times \cancel{4} \times \cancel{3} \times \cancel{5}}{\cancel{2} \times \underset{\cancel{5}}{\cancel{25}} \times 8 \times \cancel{3} \times \cancel{2} \times \cancel{4}} = \frac{3}{8}$$ the required quotient.

From the foregoing facts we deduce the following rule for working problems by cancellation:

Cancel all the factors common to the divisor and dividend, and divide the product of those remaining in the dividend by the product of those remaining in the divisor.

PROBLEMS RELATING TO MINING.

Q. 1.—A gallery in a mine is five feet high and ten feet wide, what is the measure of the perimeter and the area of section of the gallery?

A.—The perimeter of the airway in this question, called the gallery, is the measure of the sides enclosing the airway, so that if the four sides be added together the sum of them will be the perimeter required. Therefore, if twice five and twice ten be added together, we find that the perimeter of this airway is equal to thirty feet, that is thirty feet in line measure or the measure down one side, across the floor, up the other side and across the roof. But the area of section is equal to the space enclosed by these four sides, so that if five be multiplied by ten, the result will be fifty. That is, the four sides of this airway enclose a cross-section of fifty square feet.

Q. 2.—Supposing the airway just referred to was 2,000 yards in length, what number of square feet of rubbing surface would this airway have, and what would be its contents in cubic feet of air?

A.—If the perimeter of this airway in feet be multiplied by its length in feet, the result will be equal to the rubbing surface or the surface against which the air moves in its journey. Now, the perimeter we found to be equal to thirty feet, and there are 6,000 feet in 2,000 yards, therefore, $30 \times 6{,}000 = 180{,}000$ square feet of rubbing surface. Now if the area of the section of this airway which is found to be fifty square feet be multiplied by the number of feet in 2,000 yards, namely, 6,000 feet, the result will be the contents of the air in the drift in cubic feet, or $50 \times 6{,}000 = 300{,}000$.

Q. 3.—If the ventilating current is moving through the drift or airway given in Question 1, at the rate of eleven feet per second, how many cubic feet of air are passing through this gallery per minute?

A.—Eleven feet per second gives a velocity of 660 feet per minute, for in sixty seconds the air must have traveled through a distance of 660 feet. Now, what is demanded is the quantity of air passing through this airway per minute. Therefore, if 660 feet per minute be the velocity, this multiplied by the area of section must be equal to the quantity. Therefore, $660 \times 50 = 33{,}000$. It follows then that quantity of air passing through this drift is equal to 33,000 cubic feet.

Q. 4.—What does the water-gauge or current pressure-gauge measure?

A. The water or current pressure-gauge measures the pressure per square foot setting the ventilating current in motion.

Q. 5.—If a current pressure equal to one inch of water-gauge was required to produce ventilation, what pressure would that be in pounds per square foot?

A.—A cubic foot of water weighs 62·5 pounds, and if this cubic foot of water be conceived to be divided into twelve slabs, each a foot square and an inch thick, each slab must weigh 5·2 lbs., because

$$\frac{62{\cdot}5}{12} = 5{\cdot}2.$$

Therefore, one inch of water-gauge is equal to the pressure of 5·2 pounds on the square foot.

Q. 6.—Suppose the water-gauge is said to read 1·3, that is to say, one inch and three-tenths, what would be the pressure per square foot producing ventilation?

A.—If the $1\frac{3}{10}$ be multiplied by 5·2, the result will be the answer required as follows:

$$1{\cdot}3 \times 5{\cdot}2 = 6{\cdot}76.$$

Q. 7.—A circular pit shaft is eighteen feet in diameter and 500 yards deep, required the rubbing surface in square feet?

A.—First find the perimeter of the section or boundary line that encloses the space called the section, in this case the perimeter will be equal to the circumference of the circle, that is $18 \times 3{\cdot}1416 = 56{\cdot}5488$. Now, if the perimeter be multiplied by the depth of the shaft in feet, that is $56{\cdot}5488 \times 1500$ (500×3) $= 84823{\cdot}2$ the rubbing surface in square feet required.

Q. 8.—What is the rubbing surface in square feet of a shaft fourteen feet in diameter and 312 yards deep?

A.—41167·5264 square feet of rubbing surface.

Q. 9.—Find the square feet of rubbing surface for a gallery in the mine two miles long, six feet high, and ten feet broad.

A.—$32 \times 2 \times 5280$ feet in a mile $= 337{,}920$ square feet of rubbing surface. The rubbing surface is always calculated per square foot of section, the importance of this will be understood when we remark that the friction per square foot of section is smaller for large areas than for small ones, that is to say, the rubbing surface per square foot of section for square and circular airways is inversely as the areas.

Q. 10.—A pit shaft is eighteen feet in diameter and 500 yards deep, what is the rubbing surface per square foot of section?

A.—Let S equal the rubbing surface, and A equal the area of section, and R equal the resistance per square foot of section, then

$$\frac{S}{A} = R,$$

S in this case was found, by problem 7, to be 84823·2 and A will be found as follows:

$$18 \times 18 \times {\cdot}7854 = 254{\cdot}4696, \text{ then}$$

$$\frac{84823{\cdot}2}{254{\cdot}4696} = 333{\cdot}3 = \frac{S}{A} = R.$$

Q. 11. Three airways A B C are ventilated by currents moving at the same velocity each of the airways are, however, of different dimensions. A being 1,000 yards long, the height being four feet and the breadth nine feet. B 2,000 yards long, six feet high, and ten feet wide. C being 3,000 yards long, and eight feet high, and twelve feet wide. What must be the relative heights of the water-gauge in the three cases?

A. The mechanical moments of resistance would be in the proportion of the rubbing surface in each of the cases divided by the area, in short, the moments in each case would be equal to

$$\frac{S}{A}$$

the length is 1,000 yards or 3,000 feet, the perimeter being twenty-six feet, and the area of section would be equal to thirty-six square feet, therefore,

$$\frac{26 \times 3{,}000}{36} = 2166{\cdot}6.$$

And the mechanical moments in B will be as follows: 2,000 yards will be equal to 6,000 feet, the length, and the perimeter will be equal to thirty-two, and the area of section will be equal to sixty square feet, therefore,

$$\frac{32 \times 6{,}000}{60} = 3{,}200.$$

Now, the mechanical moments in C will be found as follows: Length 3,000 yards or 9,000 feet, perimeter will be equal to forty feet, and the area of section will be equal to ninety-six square feet, therefore,

$$\frac{40 \times 9{,}000}{96} = 3{,}750$$

mechanical moments. Now, the water-gauges that are required will be directly in the proportion of the mechanical moments. Then let the water-gauge for A equal one, the water-gauge for B will equal

$$\frac{B}{A} = \frac{3200}{2166{\cdot}6} = 1{\cdot}477,$$

and the water gauge for C will be equal to

$$\frac{C}{A} = \frac{3570}{2166{\cdot}6} = 1{\cdot}6477,$$

therefore, the three water-gauges will be as follows:

A = 1. B = 1·477. C = 1·6477.

Q. 12. Three airways A B C are of the same length, and the other dimensions are as those given in last question, but the velocities in the three cases are different, that in A being equal to 700 feet per minute, B 600 feet per minute, and C 500 feet per minute. If the water-gauge for A be one, what will be the water-gauges for B and C?

A. The resistances will vary as the squares of the velocities, therefore, if the squares of the velocities in each case be multiplied by the rubbing surface per square foot of section, the result will be the proportionate resistances in the three cases. Now, the rubbing surface per square foot of section, or the mechanical moments due to A are equal to 2166·6, therefore, if 2166·6 be multiplied by the square of 700, or 2166·6 × 700 × 700 = 1,061,634,000. Now, the moments in B will be equal to 3200 × 600 × 600 = 1,152,000,000, and the moments due to C will be equal to 3750 × 500 × 500 = 937,500,000, or the water-gauges will be as

$$\frac{B}{A} = \frac{1{,}152{,}000{,}000}{1{,}061{,}634{,}000} = 1{\cdot}085,$$

and the water-gauge for C will be equal to

$$\frac{C}{A} = \frac{937{,}500{,}000}{1{,}061{,}634{,}000} = {\cdot}88.$$

CHEMISTRY RELATING TO MINING.

EXPLOSIVES FOR BLASTING PURPOSES.

In mining three classes of explosives are now in use, first, slow or rending compounds, such as gunpowder for shot firing in coal seams; second, shattering compounds, such as dynamite, for stone blasting in mines; third, flameless explosives, such as roburite, for coal mines. Gunpowder is said to be slow as contrasted with dynamite. This slowness is accounted for in the following way: The nitre known as saltpetre, the sulphur, and the charcoal are ground to fine powder, and mechanically mixed into a paste with water; the paste is granulated and dried. Now as the oxygen of the saltpetre will be given off at points during combustion, it will be clear that some time will elapse between the burning at one point and the burning at another. It will be clear that powder will be relatively slow as an explosive.

Nitro-glycerine is a chemical compound, and not a mechanical mixture; therefore the atomic arrangement of the oxygen and the carbon will be such that if the temperature of the mass is uniformly raised to explosive point, almost instantaneous ignition will take place throughout. Gun-cotton and several other shattering compounds are similar in this respect to nitro-glycerine. During the last fifteen years numerous attempts have been made to displace gunpowder for blasting purposes in mines, but hitherto the great number of explosives thrown on the market have tended to bewilder the miner. This, of course, cannot be avoided during a transition period. Gunpowder shots have generally been fired with a fuse or straw, but the explosive force of gunpowder is nearly doubled when fired with a detonating cap. It would appear that none of the explosives that have been recently introduced have been found superior to powder for a rending compound for coal; but for blasting hard rock, powder has been left far behind by the shattering compounds; and this is not a matter of wonder when we consider that volume for volume the stronger varieties of dynamite are seven times the power of gunpowder; hence holes of smaller diameter may often be used with advantage when charged with shattering compounds, and even with holes of equal diameter the risk and danger of a blown out shot can be avoided.

A primer is used in firing with roburite or dynamite with the object of raising the temperature of the charge suddenly to 360° F. by pressure, because roburite and dynamite will only explode at that temperature. Below 360° F., these compounds only burn at the points where heat is present and do not explode.

We will now proceed and give the composition of the more important compounds now in use, and after doing so we will notice the more important features of the so-called flameless explosives. The blasting force of each explosive will be given bulk for bulk with gunpowder.

First, dynamite—there are many varieties:

Nitro-glycerine	75%
Unctious earth	25%
	100

Blasting force............ 7.

Second, nitrated gelatine:

Nitro-glycerine	86%
Soluble gun-cotton	10%
Camphor	4%
	100

Blasting force............ 4.

Advantages—It can be stored for long periods without danger of chemical change.

Third, litho-fracteur:

Nitro-glycerine	70%
Nitrate of barium	5%
Coal dust	2%
Unctious earth	23%
	100

Blasting force............ 5.

This is a very dangerous explosive to use, as it explodes at a temperature very little above the boiling point of water, and it is rapidly falling out of use.

Fourth, tonite or cotton powder: This is a peculiar preparation of gun-cotton, which is granulated and made up into cartridges. Gun-cotton and tonite each have an explosive force of 4.

The following flameless explosives are compounded as follows:

First carbo-dynamite, a mechanical mixture of:

Nitro-glycerine	80 parts.
Cork charcoal	10 parts.
Water	10 parts.
	100

This mixture does not, when immersed for long periods of time in water, part with its nitro-glycerine. The blasting force is about 8.

Second, bellite, a binary compound of:

Denitro-benzine	15%
Nitrate of ammonia	85%
	100

Blasting force, about............ 4.

Third, roburite, a binary compound of:

Chlorinated dinitro-benzine	30%
Nitrate of ammonia	70%
	100

Blasting force, about............ 3.

The following four binary compounds have been found to give excellent results:

First,

Gun-cotton	15%
Nitrate of ammonia	85%
	100

Second,

Dynamite	20%
Nitrate of ammonia	80%
	100

Third,

Dinitro-benzine	10%
Ammonium nitrate	90%
	100

Fourth,

Gelatinized nitro-glycerine	12%
Ammonium nitrate	88%
	100

The blasting force for each is about 1. Considerable uncertainty and doubt prevails about the behavior of the *so-called* flameless explosives, such as roburite, arising from chemical changes that take place during the storage of the material. Sometimes on firing, the front of the cartridge is exploded, sometimes the middle, while the other portion of the cartridge remains unaffected. It undergoes such a chemical change that sometimes on handling it is absorbed by the skin, and impairs the health of the miners. These facts have been taken from actual cases. It would appear, however, according to the evidence we have been able to collect, that the two flameless explosives, viz., 15 per cent. gun-cotton and 85 per cent. of nitrate of ammonia, and 20 per cent. dynamite and 80 per cent. nitrate of ammonia, promise to be the most satisfactory in use.

It is remarkable that the dilutants of flame used in these binary compounds render them difficult to explode; hence roburite requires a very powerful detonator. So much is this the case that we neutralize flame in the shot and intensify it in the detonator. Notwithstanding these remarks we believe a flameless explosive is now within easy reach.—*Tate's Chemistry.*

SCIENCE RELATED TO MINING.

PERCENTAGE OF CLAY IN PAPER.

In the manufacture of paper a kind of pipe clay is used as an adulterant, and if it be interesting for us to determine the percentage of clay in the paper, we should first determine the percentage of earthy matter such as lime and potash common to pure vegetable fiber, when it will be easy to determine the percentage of clay present in the paper. Now let us for a moment or two look the matter simply in the face: take in your hands a piece of paper whose weight, after being thoroughly dried at the temperature of boiling water, is found to be equal to half an ounce. If this piece of paper be set on fire, intense chemical action will be the result, the carbon and hydrogen elements will be burnt off, when the ashes only will remain; and if the ashes be now weighed, they will be found to be only a small fraction of the weight of the original paper if the original paper consisted of pure fiber. Let us suppose that the ashes weighed ·01 of an ounce, the percentage of ashes in the paper may now be determined as follows:

$$\frac{{\cdot}01 \times 100}{{\cdot}5} = 2 \text{ per cent. of ashes.}$$

Before proceeding further in this investigation, let us say that it is not possible to burn a piece of paper without observing that the residue consists of a tinder; further it will be noticed that the tinder is exceedingly light when contrasted with the unburnt paper. But in determining the percentage of ashes in a piece of paper it is not difficult to burn off the hydrogen elements, but the carbon requires time and great heat, and the use of a suitable crucible for its perfect combustion. To make this more plain, burn a sheet of paper with printed characters on it, when, on the tinder, the black marks of the printed characters will be so distinctly seen that the subject matter of the printing may be distinctly read. The reason of this is to be found in the circumstance that printers' ink is made up of oil and lamp black, the carbon element of which is not completely burnt, and requires for its complete combustion the use of the crucible.

PERCENTAGE OF COKE.

To find the percentage of coke produced by a sample of any coking coal, proceed as follows: Take a slice off the face of the seam, that is, take an even proportion of the whole section, break it up on an iron plate into small particles, and then mix it well with a shovel; out of this mixture take about 14 pounds, and still further beat the last sample very small, thoroughly mix this pulverized sample, and out of it take one pound, grind it very fine and mix well, and out of this carefully weigh 4 ounces. For the reception of this 4 ounces make a shot case with brown paper, into this case place the 4 ounces of carefully weighed coal, then close the upper end of the case; having done so, procure 18 inches of iron piping, 1½ inches in diameter, with an iron plug welded into the bottom end. The iron tubing being properly made may be used for thousands of experiments. Pour a little sand into the bottom of the tube, then drop in the cartridge case, which we will suppose to be about 1 inch in diameter, now fill up the tube and cover the case with sand, then with a pair of tongs place this tube with the closed end downward in a bright hot fire such as may be obtained in a house by putting up a draught plate. After the tube and its contents have been raised to a red heat and allowed to remain so for one hour the tube should be lifted out of the fire with a pair of tongs and set to one side to cool. After it has cooled to a black heat teem the sand out, when there will be a plug of coke, which, when carefully weighed, may be about 2 ounces and 12 drams. Bear in mind this weight is only imaginary, but suppose it to be correct, the plug of coke will then weigh 2·75 ounces; now 2·75 multiplied by 100 and then divided, by 4, the weight of the coal, the result will be the theoretical percentage of coke that the coal can produce, which in this case will be

$$\frac{2{\cdot}75 \times 100}{4} = 68\tfrac{3}{4}.$$ Now this theoretical percentage will always be in excess of what is obtained from the coke oven, but by means of the theoretical percentage you are at all times able to check the waste of the coke burner.

TO FIND THE PERCENTAGE OF ASH IN COAL OR COKE.

To determine the percentage of ash in a given sample of coal or coke it is necessary to describe the process of burning off in a platinum crucible about 30 grains of powdered coke or coal. Very few of our readers will have at their disposal an expensive chemical balance, a bunsen burner, and a platinum crucible, we will therefore show how to ash, or determine the percentage of ash without this expensive apparatus. Obtain a common fire clay crucible (a charcoal crucible is better), which will answer for ordinary purposes. Weigh off carefully five ounces of coal or coke, according as you require to find the ash in either coal or coke. It must next be finely powdered and passed through a sieve of about sixty lines to the inch. If you are going to find the percentage of ash coal, the powdered coal must be well stirred with an iron stirrer, when the application of heat will convert it into porous cinders. The coke only requires occasional stirring, but if it is not stirred a film of ashes will cover the top of the coke in the crucible, and prevent the oxygen of the air from acting on it. Either coal or coke is quickly ashed by stirring, but take care that none of the coal or coke adheres to the stirrer. Now to find the percentage of ash proceed as follows: Place a crucible in the heart of a hot cinder fire, having a draught plate partly covering the top of the crucible, to prevent the draught from carrying off any of the coal or coke. When the coal or coke is all burned off, no black specks will appear in the ashes. The crucible must now be covered up and set off at one side to cool, after which the ashes can be carefully weighed. The five ounces of coal will be equal to 80 drams, and let us suppose the ashes to weigh 5 drams,

Then

$$\frac{5 \times 100}{80} = 6{\cdot}25 \text{ per cent. of ashes.}$$

Now under the best conditions, with a very hot fire, it will require two hours to burn off. By this process the quickest way to ash is to inject through the lid of the crucible a very small stream of oxygen gas, but this involves the use of suitable apparatus. The way first described answers very well for persons in pursuit of useful knowledge. A nickel crucible can be purchased for less than a platinum one.

PERCENTAGE OF VOLATILE MATTER IN COAL.

To find the percentage of volatile matter in coal, we proceed as follows: Having ground up into powder a section of the seam from top to bottom, it is repeatedly ground and mixed until at last 5 ounces is taken, then after being carefully weighed, this is put into a cartridge case about 1 inch in diameter, the case being properly closed is put into an iron tube; a little sand is put into the tube, the cartridge case is dropped onto this sand, and more sand is then poured in upon the cartridge case until it is completely covered, having a clear depth of 3 inches of sand above the top of the case. The iron tube is then put into a hot fire when the tube and its contents are raised to a red heat, it is then set to one side to cool, and if the sample under notice is that of caking coal, the coke is weighed. Now let us suppose that the coke weighed 3½ ounces, one and a half have therefore been expelled as volatile matter, therefore

$$\frac{1{\cdot}5 \times 100}{5} = 30.$$

The volatile matter of the coal is therefore 30 per cent.; should the coal however, not be coking coal, the 5 ounces of coal are placed in a small iron tube with a loosely fitting lid to allow for the escape of the volatile matter; the small tube and its lid are now dropped into the large tube and covered with sand as before, and raised to a red heat, and when cool the sand is poured off and the inner small tube carefully emptied and the residue weighed, which will chiefly consist of carbon, when the percentage of volatile matter may be determined as before. To find the percentage of moisture in the coal, carefully grind to powder a sample of the section, and after being repeatedly mixed and passed through the meshes of a sieve of 50 or 60 lines to the inch, carefully weigh 2 ounces or 32 drachms in a saucer or small plate, the weight of which has been previously ascertained; place this in an oven for one hour, subjected to a temperature of about 220 degrees F., then weigh the saucer and its contents, next place the saucer in a moderately cool place (taking care not to expose the contents of the saucer to a draught) for about 5 or 6 hours, then weigh. Now let us suppose the difference in the weights is equal to one drachm, it follows then that

$$\frac{1 \times 100}{32} = 3{\cdot}125$$ the percentage of moisture in the coal.

THE BAROMETER AS A MEANS OF SECURING SAFETY IN MINING.

In a coal mine there are certain places called goaves, which are formed when the coal is taken out, when the roof of a seam is allowed to fall. The roof in falling does not entirely fill the space previously occupied by the coal, but falls irregularly, and the mass of rock, etc., composing the roof is heaped up in an irregular manner. These spaces form reservoirs of gas, because the currents of air cannot ventilate them internally, but simply passes by their edges. The barometer is used to measure the pressure of the atmosphere, and the higher the reading of the barometer the greater is the pressure. It is also well known that the volume occupied by a gas is inversely as the pressure which it bears, the temperature remaining the same. When the barometer falls, the pressure of the atmosphere is lessened, and hence the gas in the goaves expands and pours over the edges of the goaf, so to speak, into the places where the men are working, and is liable to be ignited by a naked light or a defective safety-lamp. Gas being elastic, it follows that small variations of pressure will show themselves on the gas sooner than they can be detected on the barometer. I hope these reasons will make it clear why warnings to miners should be issued in good time, and before any lowering in the height of the barometer takes place. The pressure at which gas exists in the coal itself is generally so very high that the variations of the pressure of the atmosphere (about ½ lb. per square inch for an inch variation in the height of the barometer) will not appreciably affect the quantity flowing into the workings of the mine. Hence the indications of the barometer in such cases are of little value to the miner. However, the state of the mine as regards ventilation to cope with the extra gas in times of low pressure, and discipline to ensure due precautions being taken by the officials and workmen, should not depend on such unstable quantity as the atmosphere, but should be such that in all cases it will not affect the general safety of the mine.

THE SIMPLEST GAS DETECTOR.

The gases met with in mines may be experimented with in a very simple manner. If the reader procures an india-rubber bung with two holes through it for the insertion of pipettes, one of the pipettes having a funnel on its top, and both of them being made capable of opening and closing by means of small cocks, having procured a bottle of any kind with a neck that an india-rubber bung will exactly close air-tight, armed with this simple apparatus the most fascinating experiment may be performed, if the cocks of the pipettes be shut and the bottle filled with water you carry the apparatus into the mine, and to obtain a sample of fire-damp the bottle is held in a cavity in the roof where gas is known to exist, and as the water runs out fire-damp enters the bottle, and by this simple proceeding the bottle becomes filled with the gas, before lowering the bottle the bung should be pressed tight in, and the bottle and its contents may now be carried home for experiments; when by pouring water into the funnel in one pipette the water will press out the gas through the cock of the other pipette, which may be lighted and the inflammability of the gas may be clearly proved.

Carbonic acid gas can be collected with the same bottle, and the same mode of proceeding should be followed, only the air charged with carbonic acid should be collected near the floor of the seam, unless it was required to determine the percentage of carbonic acid gas in the return current of the ventilation, when the bottle, should be filled at the mean height. That is to say, a bottle filled with water is taken down the pit with an india-rubber bung, having two pipettes with taps passing through it, to fill the bottle the taps should be shut, and where it is intended to collect the sample of mine air, the water is poured out, and as the water exhausts from the bottle, the air to be tested enters and takes its place, at this moment the bung must be tightly pressed in and the sample brought out. If the taps and the bung are perfectly airtight a very interesting experiment may be tried at once, on opening one of the taps it will be found that a portion of the air will rush out with great force, proving that the air in the mine is more dense than the air at the surface, or that the pressure of the atmosphere in the mine is greater than the pressure of the atmosphere at the surface. Now if a strong or saturated solution of caustic soda be provided in a large jug, and the bottle of mine air with its neck downward be lowered into the solution, and the bung withdrawn with the neck below the surface of the liquid, the bottle may be set aside for a few hours, when the caustic soda will absorb the whole of the carbonic acid in the air, and the watery liquid will have risen in the bottle to occupy a space equal to the volume of the carbonic acid previously present. Care must be taken to reinsert the bung before the bottle neck is withdrawn from the liquid, now weigh the bottle and its contents, next fill the bottle with the caustic soda solution and weigh that, next empty the bottle and weigh it, subtract the weight of the bottle from each of the former weights, then multiply the smaller weight by 100, and divide by the greater weight, the result will be the percentage of carbonic acid in the mine air that has been experimented on.

To make the matter still more clear, let us suppose that the solution that filled the bottle weighed two pounds, and let us suppose that two ounces of the liquid entered the bottle after the absorption of the gas. Now two pounds are equal to 32 ounces, therefore, two multiplied by 100 and divided by 32, would give the percentage of carbonic gas present in the air as by the sample, or in figures,

$$\frac{2 \times 100}{32} = 6{\cdot}25$$ per cent. of carbonic acid gas in the sample of air that has been tested.

MECHANICS IN MINING.

MAIN AND TAIL-ROPE HAULAGE.

John Cowie, an English miner, thus describes main and tail-rope haulage:

This system of haulage is very suitable for seams having a varying inclination, where two roads cannot be cheaply maintained owing to the nature of the roof or floor, and for working branch roads. It may be described as follows: A single line of tram-rails is laid down in the main road, but two lines of tram-rails are required at the junction of the branch and main roads, one for the full the other for the empty cars. The cars in large collieries are coupled in trains of from forty to ninety, and in small collieries may be as low as twenty or even less, the number of cars in a train being regulated by the output, size of cars, speed of haulage, and length of road. For hauling these trains of cars two ropes are required, a main and a tail rope, the tail-rope being usually from one-half to three-fourths the circumference of the main rope. The main rope is attached to the first car and the tail-rope to the last one. The rope is carried from the engine and along the plane, either on rollers slung from the roof, or on rollers on the floor; steel rollers are preferred, and are fixed at intervals of not more than ten yards apart to avoid unnecessary friction and damage to the ropes. The duty of the main rope is to haul the full train outbye, with the tail-rope attached to the inbye end, and the duty of the tail-rope is to haul the empty cars inbye with the main rope attached to the outbye end of the train. An independent tail-rope is required for each branch road, and when the train arrives at each branch road, or as is sometimes done before the train starts from the shaft, the branch tail-rope is attached to the main road tail-rope by a short length of chain and a shackle to allow of a train of cars being taken out of the branch way. Two drums are used on the engine, one for the main rope and one for the tail-rope, each drum being mounted on a movable carriage so that they can be thrown out of gear with the engines when required, if the engine is required to haul along two main roads, two pairs of drums are put in, all on movable carriages, and each drum is supplied with a suitable brake to allow of the speed of the cars being regulated when descending an incline, either when going inbye or coming outbye. When the cars are going in a branch road or round a curve, suitable sheaves should be put to deflect the cars into their proper course. The average speed of these trains of cars is from eight to ten miles an hour, and the road requires to be well laid and packed to prevent accidents. The kind of rail used has a great deal to do with the success of the system, and flat-bottomed rails weighing 36 lbs. per yard, with fish-plates at the joints and secured to ties by "dogs" or "spikes," the ties being not more than three feet apart, are found to give excellent results, and are now universally employed. The defects of the system may be summed up thus: A large number of stations are required to work branch roadways, more rope is required, there is a greater liability to accidents and damage, through the quick speed at which the trains are run, greater power is required as the engine has the whole work to do in one-third the working day, with a consequent increased consumption of fuel owing to the friction of the rope on rollers, the brakes, and drums, occasioned by the loss of compensatory action of gravity on undulating and inclined roadways.

MECHANICAL QUESTIONS ANSWERED.

Q. What is a unit of work?

A. A unit of work is done when one pound of force is exerted through the space of one foot.

Q. How many units of work are performed in raising a weight of 927 pounds through a space of 290 feet.

A. The weight in pounds $\times$ the distance in feet $=$ units of work, then $927 \times 290 = 268{,}830$ units of work.

Q. How many units of work are done in lifting a weight of 65 tons through the space of 20 yards?

A. Tons must be converted into pounds, and yards into feet. There are 2240 pounds in a ton, then $65 \times 2240 = 145{,}600$ pounds in 65 tons; also there are three feet in one yard, then $20 \times 3 = 60$ feet in 20 yards, now $145{,}600 \times 60 = 8{,}736{,}000$ units of work.

Q. What are the units of work in a theoretical horse power?

A. A theoretical horse power is equal to 33,000 units of work per minute.

Q. What must be the horse power of an engine to perform 396,000 units of work per minute?

A. $396{,}000 \div 33{,}000 = 12$ theoretical horse power.

Q. Water has to be pumped from a depth of 200 fathoms at the rate of 165 gallons per minute, what horse power of an engine will be required?

A. 200×6 feet in a fathom $= 1200$ depth in feet, and a gallon of water weighing 10 pounds, then $165 \times 10 = 1650$, also $1650 \times 1200 = 1{,}980{,}000 \div 33{,}000 = 60$ theoretical H. P.

Q. What is the modulus of an engine?

A. The modulus of an engine is the amount of useful work done.

Q. What is the co-efficient of friction of an engine?

A. The co-efficient of friction is the amount of work lost, by friction on the moving parts.

Q. The modulus of a winding engine being ·4, what is lost by friction?

A. $1{\cdot}0 - {\cdot}4 = {\cdot}6$ or three-fifths.

Q. The modulus of a hauling engine being ·7, what is lost by friction?

A. $1{\cdot}0 - {\cdot}7 = {\cdot}3$, or three-tenths.

Q. The modulus of a pumping engine being ·6, what is lost by friction?

A. $1{\cdot}0 - {\cdot}6 = {\cdot}4$ or two-fifths.

Q. The theoretical horse power of a winding engine is calculated to be 650, what will be the useful work done by this engine, its modulus being ·4?

A. $650 \times {\cdot}4 = 260$ H. P.

Q. The theoretical horse power of a pumping engine is 720, what will be the useful effect?

A. $720 \times {\cdot}6 = 432$ H. P.

EXAMINATION QUESTIONS ANSWERED.

QUESTION 2.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

Upon what does natural ventilation depend; is it reliable, and if not, why not?

ANSWER.—Natural ventilation depends on a difference of temperature of the air on the surface, and of that in the mine. It is not reliable, because atmospheric changes on the surface, due to change of seasons, causes the current to reverse, and because on days when the temperature of the air on the surface is the same, or nearly the same, as that in the mine, there will be no current.

QUESTION 3.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

Upon what does furnace ventilation depend; is it reliable as a means of ventilation of mines?

ANSWER.—Furnace ventilation depends on the heating of the air in the upcast, thus making it expand and become lighter. The colder air in the downcast being more dense and heavier, will force the heated air to rise, and thus produce a current in the mines. Furnace ventilation is much more reliable than natural ventilation, but not nearly as reliable as fan ventilation, and besides it is objectionable on account of the great number of accidents, underground fires, explosions, etc., that can be traced to the use of this method.

QUESTION 4.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

Which would you prefer, and why, an exhaust fan over the upcast or a force fan over the downcast?

ANSWER.—This is a question that is still in dispute by leading authorities on ventilation, and the evidence in favor of each kind of fan is about equal, and there is no apparent advantage in one system over the other, though the standard types of fans are now all exhaust fans.

QUESTION 5.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

Describe black-damp, and give its characteristics, how produced, detected, &c.

ANSWER.—Black-damp is a common name for carbonic acid gas (Symbol CO_2). Its composition is two atoms of oxygen combined with one atom of carbon. One thousand cubic feet of it at 32° F. and barometer 30 ins. weigh 128·45 lbs. It is heavier than air and therefore lies next the floor. It has neither color nor smell, but an acid taste. It is found in large quantities amongst the gases occluded in some coals; but is also produced in mines by the respiration of men and animals, by the burning of lamps, and by the oxidation of the coal and other substances. It extinguishes lights and 8 to 10% of it in the air is fatal to animal life. It may be detected by the action of the flame of a lamp. Small quantities of it will cause the flame to grow dim, and as the quantity is increased the light will become smaller, and finally go out.

QUESTION 6.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

Describe white-damp and give its characteristics, how produced, detected, &c.

ANSWER.—White-damp is a common name for carbonic oxide (Symbol CO). Its composition is one atom of oxygen combined with one atom of carbon. One thousand cubic feet of it at 32° F. and barometer 30 ins. weigh 78·305 lbs. This gas is the result of imperfect combustion. When a body containing carbon is burnt in air, each atom of carbon will combine with two atoms of oxygen to form carbonic acid gas; but, if there is not sufficient air to provide two atoms of oxygen for each atom of carbon, that is to say, if the combustion of the carbon is incomplete, carbonic oxide is formed. It has been detected in rare cases amongst the occluded gases; and is also produced by the combustion of coke, charcoal, and gunpowder; and must, in many cases, be one of the constituents of after-damp. It has neither color, taste, nor smell, but is exceedingly poisonous; one-half of one per cent. in the air, if breathed for long, producing fatal results. It does not support combustion, but itself burns with a blue flame forming carbonic acid gas. It is the most treacherous gas encountered in coal mines, as the victim will be overcome with it before it is possible to detect its presence. Mine fires frequently cause large areas of workings to fill with it.

QUESTION 7.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

What is the most effective method of dealing with fire-damp in mines?

ANSWER.—The most effective method of dealing with fire-damp is to provide a sufficiently large current of air to dilute and carry off all fire-damp generated in the mine.

QUESTION 8.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

State some essential points in regard to air-courses.

ANSWER.—Air-courses should be of as large a sectional area as they reasonably can be made, the sides should be reasonably smooth, and they should be as free as possible of short turns, and there should be no obstructions in them.

QUESTION 9.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

State some essential parts in regard to timbering main entries?

ANSWER.—The timbering of main entries should be done in a most substantial manner, if timbering is required. The timber should be sound and of a nature that will ensure long life, so that constant repairing will not be necessary.

QUESTION 10.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

What are the main features of the Longwall system?

ANSWER.—The main features of the Longwall system of working are, the coal is all worked away at once, and there is comparatively no expensive narrow work.

QUESTION 11.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

What are the advantages of the Longwall system over room and pillar workings?

ANSWER.—In seams where Longwall work is practicable, a greater percentage of large coal is obtained, from 15 to 25 per cent. more coal per acre being won. The system is simpler, ventilation easier, and the men work with greater safety.

QUESTION 12.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

In what proportion will the pressure on the head of an air column have to be increased in proportion to the increased length of air-way to force the same quantity of air through an air-way 2,000 yds. long, as through an air-way 1,000 yds. long?

ANSWER.—As the perimeter of the air-way remains the same, the length only being doubled, the rubbing surface is doubled. As the pressure varies directly as the rubbing surface, to pass the same quantity of air through the 2,000 ft. air-way as through the 1,000 air-way, will require double the pressure.

QUESTION 13.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

Describe the water-gauge and its use.
