
ANSWER.—The water-gauge is used to measure the dynamic force of a current of air. It consists of a U-shaped tube of equal area throughout. The arms are about six inches long, provided with a scale divided into inches and fractional parts of an inch, so that the difference between the height of the water in one arm of the tube, and that of the other may be measured. One arm is placed in connection with the air passing in the mine by placing the tube A through a hole in the brattice or fan casing, while the other is opened to the airway from the mine. The difference in water-level will indicate the drag, or the resistance to the air in the mine.

The weight of one cubic foot of water at 62° F. and 30 inches barometrical pressure is 62·32102 lbs. The weight of one cu. in. is therefore 62·32102 ÷ 1728, or 0·036. When the gauge measures one inch, the pressure is $0·036 \times 144 = 5·184$ or 5·2 lbs. (nearly) to the square foot.

Example.—If a water-gauge read 0·4″, what pressure would it indicate?

$$0·036 \times 0·4 \times 144 = 2·0734 \text{ lbs. per sq. ft.}$$

The water-gauge may be used to show the force of a current produced by a fan or by a furnace, and hence it is very useful as a check to the furnace-man. As it tells the amount of resistance to the air in the air courses, their state or condition may be inferred. If the pressure per sq. ft. exerted by the motive column be known, the height of a motive-column may be determined by dividing the pressure per square foot by the weight of a cubic foot of air.

Example.—What is the height of the motive-column, if the water-gauge reads 0·4″, the temperature is 62° F., and the barometrical pressure is 30″?

The weight of one cubic foot of air at 62° F. and 30″ Bar. is 0·07629 lbs? The pressure is $0·036 \times 0·4 \times 144 = 2·0736$ lbs., and the height of motive column =

$$\frac{2·0736}{0·07629} \text{ or } 27·28 \text{ feet.}$$

To find the velocity we use the equation for falling bodies, which is

$$8·0208 \sqrt{h}$$

This equation is based on the principle that a body falls 16·08, in one second, and that it gains a velocity of 32·16 at the end of the first second. Then the velocity per second equals 8·0208 times the square root of the height of motive-column in feet.

Example.—If the height of the motive-column is 27·28 ft. the velocity per second is $8·02 \times \sqrt{27·28}$ or 41·9 ft.

These formulæ may be arranged as follows:

Let P = Pressure in pounds per sq. ft.

Let h = Height of motive-column in feet.

Let V = Velocity in feet per second.

Then:

$$P = 0·036 \times \text{water-gauge} \times 144,$$

$$h = \frac{P}{0·0763},$$

$$V = 8·02 \times \sqrt{h}$$

These formulæ, it must be remembered, are only theoretically true, on account of the enormous power required to overcome friction. In practice from 10 to 20 times the theoretical amount of motive-column is required to produce the theoretical velocity. To find the horse power expended in the power required for a ventilating current, multiply the quantity of air passing by the reading of the water-gauge, and this product by 5·2; divide the result by 33,000.

The quantity of air passing in an airway is according to the sq. root of the water-gauge.

Thus, if 10,000 cu. ft. is passing per minute with a water-gauge of 1 in., 7,071 cu. ft. is passing with a water-gauge of 0·5 in., or

$$\sqrt{1·0} : \sqrt{0·5} :: 10,000 : 7,071.$$

QUESTION 14.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

If the water-gauge shows a difference of reading of 1·2 inches between the intake and return of a certain portion of a mine, and the anemometer indicates a velocity of ten feet per second, size of entries 6 × 8 ft., what effective horse power has been expended in the ventilation of that part of the mine?

ANSWER.—As the area of the air-way is 6 × 8, or 48 square feet, and the velocity is 10 ft. per second, the volume passing equals $48 \times 10 \times 60 = 28,800$ cu. ft.

Then, according to the rule given in the preceding answer,

$$\frac{28,800 \times 1·2 \times 5·2}{33,000} = 5·45 - \text{H. P.}$$

QUESTION 15.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

Will the velocity of the ventilating current be the greater in the intake or the return, or will they be the same, and why?

ANSWER.—The velocity will be greater in the intake, because there will be a certain proportion of the current lost in leakages, and the velocity will be reduced by friction against the sides of the air courses.

QUESTION 16.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

In a non-fiery mine 500 men are employed, and forty mules, the air course is 6 × 8 ft., give plan, or describe in brief your method for the proper ventilation of such a mine?

ANSWER.—I would ventilate by fan or furnace, preferring a fan. The mine law of Iowa requires a minimum of 100 cu. ft. of air per minute for each man, and 500 cu. ft. per minute for each mule. Making the minimum quantity for the mine $(500 \times 100) + (40 \times 500) = 70,000$ cu. ft.

I would endeavor to have an excess of air above legal requirements, say 50% more, making the total volume 105,000 cu. ft., I would divide this into say six splits, each having a current of 17,500 cu. ft. per minute, which would make the velocity but little over 6 ft. per second, which is safe in non-fiery mines, and I would endeavor to have less than 100 men in each split.

QUESTION 17.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

Explain the use of the anemometer.

ANSWER.—The anemometer is an instrument used to measure the velocity of the air current. Biram's anemometer is in general use in this country. Each revolution of the vanes, which is registered on the dial plate, corresponds to one foot in the linear motion of the air. Then if the velocity per minute is multiplied by the sectional area of the air course in which the anemometer is placed, the result is the number of cubic feet of air passing per minute. These instruments do not measure the actual velocity of the air, especially in feeble currents, but the result is so nearly correct that they answer all purposes. A certain force of air is required to overcome friction and put the instrument in motion. The force varies with each and every instrument. Some anemometers will continue to revolve in a current as low as 30 ft. per minute; but with most of them a velocity of 50 ft. is required, and 40 ft. is recommended as an average allowance to be made to start them. The formula used for true velocities is:

V = ·97 R + 40.

When V = True velocity.

R = Recorded revolutions.

40 = Feet allowed to start anemometer.

QUESTION 18.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

In what part of a mine should observations with the anemometer be taken, and why?

ANSWER.—Observations with the anemometer should be made both in the intake and the return at places of regular sectional area where there are no eddies caused by short bends or turns. The succeeding measurements should be taken as nearly as possible at the same places.

QUESTION 19.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1890.

In the case cited in Question 14, where should the reading of the anemometer be taken, and why?

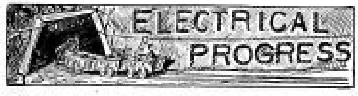
ANSWER.—Both in the intake and the return air courses, so as to get the average velocity, and thus get an average of the quantity circulating.

H. Ward Leonard & Co. have received an order from Wm. Sellers & Co., of Philadelphia, for two 40 horse-power motors for use upon traveling cranes. The motors are to be supplied under rigid specifications, as to dimensions and performance, but the decision as to particular make of motors to be used is left with H. Ward Leonard & Co.

Mr. Leonard is licensing various manufacturing and construction concerns under his recently patented system of motor regulation. The basis of the license is a charge of \$2.50 per K. W. (roughly per horse-power) in the motor. The royalty charge is not an annual charge, but is paid once for all in each case.

Messrs. Wm. Sellers & Co. have taken a license under Mr. Leonard's patent on this basis, they agreeing to use the method upon all electric cranes they build in the future, during the life of the patent.

The royalty is so small that the method will no doubt be rapidly introduced wherever it is applicable.



A Novel Electric Railway for the World's Fair.

October 7th next, the World's Fair Grounds at Chicago will be opened to visitors for the inspection of the progressing work, and for their accommodation there is being constructed an electric railway of a most ingenious and novel character, having a capacity of carrying 30,000 passengers per hour, with the greatest comfort, convenience, and safety. The railway department of the Chicago office of the Thomson-Houston Electric Company has closed a contract with the Columbian Movable Sidewalk Co., of Chicago, for the electrical and steam equipment of the movable sidewalk which is now being installed. The mechanical and electrical plans and details have been carefully worked out by Mr. G. K. Wheeler, of the company, and under his supervision the entire plant will be installed.

By the time named above there will have been nearly completed a large number of buildings, and there will be much to attract and interest visitors. The electric railway, however, will be one of the leading novelties and attractions. This railway will differ from ordinary railways, in that the passengers are transported on a movable sidewalk instead of by cars of the ordinary type. The scheme is the invention of the Columbian Movable Sidewalk Company, of Chicago, and the installation is being constructed under its patents.

The sidewalk is located on the improved and unimproved portions of Jackson Park, and is to be constructed on an elevated structure 25 feet high and 900 feet long, in the form of an ellipse and is to consist of 75 cars, each 12 feet long, connected together, making one solid train. There is to be constructed two parallel sidewalks, one running at the rate of two miles an hour, the other at four, both walks moving in the same direction. The passengers can step from the stationary walk to the one which moves at the rate of two miles an hour, and if it is desired to move at a greater speed they can step from this walk to the one running at four miles an hour. The passengers can safely walk upon either of the movable sidewalks while in motion if desired.

The structure will be illuminated at night by a number of Thomson-Houston incandescent lights, and, as the grounds are to be illuminated with arc lights, a satisfactory view can be obtained during the evening as well as during the day.

Three of the 75 cars are to be equipped, with two 15-H. P. Thomson-Houston railway motors, each mounted upon trucks with wheels 18 inches in diameter. As the car platform, or sidewalk, is arranged it is perfectly level with the stationary walk, allowing the trolley wire to be placed beneath the surface of the platform, and the current taken therefrom by means of small trolleys attached beneath the car floors.

The operation of this train of cars will be arranged in a novel manner, doing away with the use of motor men, the entire train being controlled and operated by one man.

There will be constructed at a central point, at one side of the track, a controlling station, which will contain a main switch, reversing switch, automatic circuit breaker, lightning arrester, ampere meter and rheostats, all arranged so that they can be operated by the attendant from that point who will have the train under perfect control.

The power for the operation of the sidewalk will be furnished by the Thomson-Houston 110 H. P. multipolar compound wound railway generator, located in a power house adjacent to the track. And in connection with said generator there will be placed a suitable switchboard, regulating controlling, and indicating devices of the Thomson-Houston Company's manufacture.—*Electrical World.*

Accumulator Cars at the Hague.

Six accumulator cars, says the *Electrical Engineer*, of London, are now running from the Hague to the Casino at Schevening, a distance of about three miles. The speed of running is 12 miles an hour, including stops. The loaded car weighs 16 tons; it is 32 feet long, carries 68 passengers, and the battery of accumulators weighs 4 tons. The cars constructed at Harlem, have two bogies of two axles each. Only one bogie is driven, having its wheels coupled together. The axles are connected to the motor by solid gearing, and the whole weight is carried by the axles. The motor is supplied by carbon brushes from a battery of 192 Julien accumulators, weighing 40 pounds each. This battery, when charged, provides current for a run of 45 miles, after which the cars return for change of cells. The accumulators are arranged in eight boxes or drawers, weighing half a ton each, placed under the seats. The car is provided with switches and resistances to allow the speed to be varied. The changing of the sets of cells is carried out by the aid of a special mechanical arrangement to allow rapid handling. Two sets of turntables and rolling carriers are placed at the end of a charging bench. The drawers, when taken from the car, slide easily on rollers placed on the bench and turntables, the operation of changing requiring five minutes. The spare sets of cells are always being charged as the others are being used. The connections are made with spring contacts arranged so that no mistake can occur. The charging is accomplished by means of Silverton shunt dynamos, with hand regulators, giving 60 amperes at 100 volts. The machine room contains two condensing steam engines of 210 indicated H. P. each. The condensing water is supplied by a siphon from the canal three-quarters of a mile away. The installation is completed by a small workshop driven by an electric motor, itself supplied by a small battery of 70 cells of 66 pounds each, which are also used for lighting by means of 10 arc lamps. It is intended to settle the question of maintenance by the erection of a small manufactory of battery plates on the spot, with a laboratory.

A New Electrical Carriage.

Electrically propelled vehicles are among the many conveniences which novelists and fiction writers have ascribed to future ages, while practical inventors have given their attention to subjects that bring them more satisfactory results, such as street car work. A departure from this line of thought is afforded in the electrical carriage invented by William Morrison, of Des Moines, Ia. The motive power is obtained from 24 accumulator cells placed under the seats, while the motor itself is on the rear axle. The winding of the motor is so arranged that a reversal of the current will cause the carriage to run backward as easily as forward, while the steering apparatus is arranged simply and effectively.

This carriage has been in practical operation in the streets of Des Moines for some time, and will soon be seen in Chicago.

From the satisfactory results obtained from this mode of locomotion the day does not seem so very far distant when carriages, as well as other vehicles, will be moving around our streets propelled by electric motors that receive their current from concealed batteries, and therefore effect a further emancipation of the millions of animals now performing this service.

Improved Uses of Electricity.

Dr. Louis Bell recently read an interesting paper before the Franklin Institute on "Electricity as the Rival of Steam." The author, in the course of his paper, remarked that we must still look upon electricity not in any sense as a prime mover, but simply as a powerful and convenient means of transmitting power from one point to another. It was also to be inferred that only in exceptional cases could anything but steam be employed as the prime mover. This inference was necessary because, up to the time of the writing of that paper, we had no means of transmitting power by water for any considerable distance, five miles being the longest distance of transmission, and even that at a very great loss of power.

Since that time, however, the Frankfort experiments have shown that electricity may now be transmitted upward of 100 miles, at a less loss than has heretofore been met with in a five mile distance. This fact has added immensely to the possibilities of the uses of electricity. By this increased control over the electric current, it is possible to utilize water power from great distances, and streams which have heretofore been considered of little or no worth are now regarded as of great value. Water power may now be economically and safely transmitted from any of our mountain streams into any or all of our great interior valleys and made to do all that steam can do on the spot. Such power may be made to light cities, run factories or drive trains of cars on our railroads. Power may be "bottled up," so to speak, and sent along a hundred miles of wire or more at a slight expense, divided up to any desired extent, and made to do all the work required of any power at any desired point. By this means, after a plant is once installed, the cost of power will be light—a mere bagatelle of what it is now.

A Word About Coffee.

Much has been written and printed concerning coffee. Cook-books all contain receipts for preparing it in different ways. Every housekeeper considers that coffee is something anybody can make, and therefore she takes no particular pains to make it. It is a fact that on the breakfast table of nine out of ten families, where nice cooking in other respects is the rule, the coffee will be found watery stuff, tasting strongly of chicory, or else so black and thick as to be undrinkable by whoever is used to the better-made article.

In the city the vast majority of housewives buy ground coffee at corner groceries. I think the same rule is good in the country, for most country stores have their coffee-grinder. The grocery man's profit is so large on coffee that of course it pays him well to grind it. And he can, in grinding, adulterate it to so great an extent that he would prefer to sell his "real Java" and "real Mocha" ground, even if he had to sell at a less price than in the bean. The fact that the price is the same, ground or unground, never seems to show people plainly how well it would pay them to grind their own coffee. They may be sure the grocery man does not do it for love.

It is not easy to roast coffee, for it requires much close watching, patience, and experience to bring it just to the proper shade, not burnt, nor yet too light, neither too little nor too much, but just right. It can be bought freshly and perfectly roasted in the larger grocery houses of good repute. It is best to buy not more than two pounds of this at a time, and it should be closely covered until the last grain is used. I have always found that one-third Mocha and two-thirds Java make a good combination. This costs about thirty-two cents per pound at the larger houses.

A coffee-grinder—a good one—is worth fifty cents. The comfort of the good coffee it gives you is worth far more. It is true Bridget will not grind it unless compelled, and if she hasn't any coffee but unground to use; but it should be made a case of "needs must." If she is allowed to grind it over night for use in the morning, it should be put into a tightly covered vessel until used.

I use a coffee-cup full, ground, for a family of five. This makes a pound last about a week. Put in an egg-shell, and fill the pot about a third full of cold water. When it boils hard, add boiling-hot water to the quantity you wish to make. When that boils up once, put in a dash of cold water, and cover the coffee-pot with a folded towel, and set on the back part of the stove until you wish to use it. If you pour into a silver urn, be sure to scald the urn first, that the coffee may not be chilled.

Whoever is used to drinking good coffee, bought and made in this way, will never be content with "grocers' coffee" again.

Always buy a grinder to screw against the wall. It saves time and temper, and is at hand when it is wanted.—*Harper's Bazaar.*

Cures for Warts.

The cures for warts are exceedingly numerous. These which follow are given in the order of their ease and accessibility; but the needle plan, which comes nearly last, bears the palm for speed and certainty: In all cases where a solvent is employed, the hard, insensitive crown of the wart should be previously pared off, but not so deeply as to cause bleeding. And in most cases it is advisable to protect the adjacent skin either with a circle of vaseline or a piece of plaster with a hole in the middle which just fits the wart. Then apply as often as convenient, either the white juice of sow-thistle (*sonchus oleraceus*), which grows everywhere, or the yellow juice of greater celendine (*chelidonium majus*), which prefers the vicinity of human dwellings; or the exceedingly corrosive, creamy sap of sun-spurge (*euphorbia helioscopia*), which likes gardens and cultivated fields. The next few remedies involve going to a chemist, namely: lunar caustic, once or twice a day, glacial acetic acid, salicylic acid and creosote, iodine and carbolic acid, or caustic potash, which is dangerous stuff. A piece of raw beef steeped twelve hours in vinegar and then held to the wart with rag or sticking plaster is pronounced a sure cure in about a fortnight. The needle cure does its work in about ten minutes, of course not counting the healing of the sore. It is done by running a darning-needle through the middle of the wart and holding the end of the needle in the flame of a candle. The heat is conducted along the steel so as to destroy the vitality of the wart, which is not so terrible a process as it sounds, nevertheless, as it demands a little pluck, I have put it last on the list, and advise having some kind of forceps at hand to withdraw the hot needle, if required.—*Hall's Journal of Health.*

Using the Teeth.

The law of deterioration, from disuse obtains with the teeth, as well as with other things. The constant and regular use of them in masticating hard food tends to make them continually grow harder and stronger, and better able to resist the influences that make for decay, while on the other hand, living on soft food and neglect of mastication makes them tender, softens the enamel and renders them easy succeptible to corroding effects. This is sometimes especially shown in the case of people after a long illness who find their teeth tender and sore when they begin to return to a diet of solid hard food. A dentist, speaking on this subject, says: "Some men have healthy teeth all their lives, because they were given good, hard food during infancy. That is the period to begin to save the teeth. Mothers and nurses give children soft food, utterly ignorant in many cases of the result. Crusts and hard stuffs should be given to children as soon as they can eat them. In this way the teeth begin to grow healthy, and gradually harden with time and use. The chewing-gum girl gives her molars plenty of wholesome and unwholesome exercise. But chewing-gum is not especially healthy, because only part of the teeth are used. It is jaw exercise more than anything else. But in eating hard, wholesome food, all the teeth come in contact with the substance. Tobacco chewing is not healthy for the teeth, because the tobacco is generally placed in one location, like chewing-gum, and there remains until thrown out. The Southern negroes have better teeth than most any race because they use them from childhood up in masticating hard food."—*Good Housekeeping.*

Fresh Air in Winter.

Why is fresh air, the very breath of our nostrils, treated by nine-tenths of us as an enemy, throughout the winter? It is as essential to health and life in one season as in another, and yet, from November until May, seven-eighths of us do our best to barricade our dwellings against it. It is impossible to prevent so close a besieger from gaining the advantage now and then, but we do what we can to make our castles impregnable to the outer air. We fortify our doors and windows with contrivances of all kinds to exclude it, and when, through some oversight, it gains admission, we exhaust the intruder with overheated stoves and furnaces. If we cannot altogether keep it out, we can at least poison it when it gets in.

A few hundred of us, congregated in an unventilated room, can soon deprive the air it contains of its vital principle; and were it not that this sleepless enemy outside occasionally makes a plunge into the apartment when a newcomer steps in to assist in the poisoning operation, the coroners would never have a moment they could call their own. As it is, the opponents of fresh air keep them pretty busy.

The occupants of tenement houses, by dint of stopping up crevices with rags and shutting down the dampers of their cracked stoves, so as to prevent the egress of the coal gas from their dormitories, provide the malignant typhus with "all the comforts of a home," and contrive to put a large amount of fees into the pockets of the coroners during the inclement months. Self suffocation is quite an "institution" in this community.

If we cannot have pure milk, pure flour, pure coffee, or pure wine, we can at least have pure air. The Giver of all good gifts provides us with *that* blessing, without money and without price. But ye fall in with the fashons of the time and adulterate it. We poison it and sicken by feeding on its unwholesome corpse. Thirty or forty of us stow ourselves in a horse-car with all its sashes closed, and, having asked the conductor to close both doors, there we sit engendering mutual infection.

Diphtheria, catarrh, lung fever, and consumption are often attributed to draughts of cold air, but they are more frequently caused by stagnant hot air deprived of its oxygen. If we "take cold" in consequence of stepping out of a room heated to a tropical temperature into an atmosphere below the freezing point, the primary cause of the difficulty is the overheated sealed up room, not the healthful open air.

If we were more in the habit of warming our blood in winter with brisk exercise "under the canopy," and less inclined to coddle ourselves in all but hermetically sealed rooms warmed with hot-air furnaces, we should be a healthier people than we are. The winds of heaven are hygeian. They should be permitted to circulate *freely* through every dwelling at least once a day. Warm carbonic-acid gas is not good for the lungs, but cool oxygen is. Let us ventilate!—*New York Ledger.*

Why all Milk Should be Boiled.

A French physician at a seance of the Academy of Medicine dwelt upon the dangers of using cows' milk uncooked. He described the case of a young woman twenty years of age who had tubercular inflammation of the brain. On inquiry it was found that she had been educated in a convent, in which thirteen scholars had been stricken down with tuberculosis during the preceding four years, and evidently this was where she contracted the disease.

Extended inquiry elicited the fact that the cow from which the supply came had been driven every morning to the convent to be milked. When killed she was found to be suffering from advanced tuberculosis, and from her, undoubtedly, the unfortunate girls took the disease that destroyed them.

If the disease has not far advanced it is never easy to detect tuberculosis in a cow, and there is good reason for the belief that very many cows that are in good condition and seemingly sound and healthy are yet suffering from this malady. Considering also the fact that rigid inspection of cows is seldom practiced, it is very evident that safety can only be secured by the observation of one rule, namely, boiling the milk.

If a person keeps an apparently healthy cow, feeds it well and otherwise cares for it judiciously, it would seem that he had nothing to apprehend from the milk. And yet his cow might be ailing and be not know it. Hence milk should always be thoroughly boiled, no matter where it comes from.

Scientific Advancement

University Extension.

There is a new thing under the sun. The thing that hath been is that the universities of all lands have been for the benefit of the few. The thing that is and shall be, in a rapid ratio of increase, is the extension of the resources of these great institutions for the benefit of the many.

The movement is new. Yet it is eighteen years old in England. It is but an infant of months in America, and of days in France. Because it is so new and young its history is interesting, and the promise of its future is derived from its comparatively brief but vigorous life. The seeds of its origin and growth are already sown in Philadelphia and in Boston and in the germinant and springing soil of our own expanding universities. There is every reason to expect that the movement will grow more rapidly here than in the mother country.

That a higher education may become the possession of the people at large may well be the earnest prayer of all who believe in Democracies, and in the solution under American conditions of the problems that confront all the nations. Young men are the leaders in forwarding the movement, and young people are the materials composing it. A definition of its aim, history, and method is desirable. University extension reverses the old way. It takes the teacher to the student in a transient, an itinerary way, instead of bringing the student to the teacher as a resident for a term of years. Since the child cannot come to David for mutual advantage, David goes to the child, and the essential object is secured. Hence the movement aims at universal higher education.

The phrase "University Extension" originated in England and at Oxford as far back as 1850. The movement started at Cambridge at 1873, and its founder was Hon. James Stuart, then a member of Parliament. Oxford and Cambridge, therefore, the two great universities of England, notwithstanding their conservatism, have taken the lead in popularizing their institutions and the education which they exist to promote. The idea has been accepted by all the universities of Great Britain and by many in America. The growth of the movement now covers 18 years. Experience can be given—valuable experience. Results have been attained which demonstrate beyond controversy the feasibility of the scheme, and the development of it in manifold ways. England, Scotland, Ireland, France, Australia, India and the United States are adopting it. The London *Secretary* says: "There are signs that work on similar lines is about to be established in various countries on the Continent of Europe."

The audiences secured have been variable as to sex, age and occupation. Afternoon lectures have been attended chiefly by women. Both sexes and all ages have been secured at evening lectures. Elementary teachers, business and professional men, college graduates pursuing specialties have not been wanting.

The wage earning class have been largely represented. Proofs have been furnished, numerous, pathetic, and gratifying that many toilers are devoting, and are eager to devote, their evenings and their holidays and half-holidays to intellectual pursuits. This is especially true of the labor-reform leaders.

Summer sessions at Oxford and Cambridge have been held in recent years, and those of the present year have been the best of all as regards attendance, interest and profit. This phase of the movement, like the movement itself, originated in an incidental way.

In the summer of 1884, two miners, students at extension centers in Northumberland, were spending three days at Cambridge, on a visit to one of the lecturers. As the visitors were conducted by their hosts through the beautiful library of Trinity College, and the spell of its beauty was upon them, one said to the other, "Oh, that it were possible for some of our students to come up for a short time to work in Cambridge and see all this for themselves!"

A plan was devised for bringing students to the University for a short summer term. Subsequently the same scheme was adopted at Oxford. Cambridge was invited and welcomed the better students discovered in the winter sessions throughout England. Oxford has popularized the scheme, practically for the benefit of all comers.—*Frank Leslie's Weekly.*

The Moon's Place in Nature.*

Science asserts that the moon shines with a borrowed light—a light reflected from the sun. Science also asserts that the 93,000,000 miles of space between the sun and moon is utter darkness; that the moon is dead, having no atmosphere, no water, no clouds, no life in any form; and that it is a stupendous cinder pitted with countless craters of extinct volcanoes. Contradictory and incongruous as these theories are none the less are they universally accepted to-day.

But science is fallible, and such inconsistencies must lead to the grave result of rendering suspicious all our theories pertaining to the universal space and its contents. To add to the distrust these theories awaken, it is now found that the telescope which hitherto has furnished the basis of our present conceptions of the moon, is not to be relied upon. Prof. Holden, the astronomer in charge of the new Lick telescope, the largest in the world, says of that instrument: "There is no object in the heavens which we must not observe as if viewed for the first time. It has opened a new vista of the creation. It compels us to learn everything anew. Even the most familiar of supposed facts revealed by other telescopes, as of the moon, for example, are found in this great revelator to be not facts but errors."

That the moon receives something from the sun which freely passes through the darkness and cold of space, and which is sent onward to the earth by reflection, is unquestionable, as is also the additional fact that our atmosphere is awakened to its beautiful moonlight effects by this reflected current.

Although scientists make no pretence as asserting the presence of any element or substance in the composition of the moon which is capable of producing actual reflection, yet, nevertheless, it is legitimate to infer that the moon has a medium which possesses reflecting powers adequate to all supposed necessities. The question then arises, what is that reflecting medium? The answer is drawn from analogy.

No one will claim that the dead, dull body of the moon which science depicts is capable of reflecting the currents which it receives from the sun. It is now demonstrable that electrical currents, both instantaneously and incessantly, come from the sun to the earth, and, through the resistance offered by our atmosphere, become awakened into dazzling light and burning heat. Only an atmosphere is capable of thus reflecting the sun's vivifying currents. We may therefore legitimately infer that atmospheres are indispensable to visibility in all worlds; and that a moon without an atmosphere would not be visible. The same is equally true of the sun itself. Inferentially, therefore the moon possesses an atmosphere, with all the constants of an atmosphere, viz.: heat, light animal life and intelligence, vegetable and mineral life, the property of reflection of great cosmical currents, etc.

Direct electrical sun currents come through the darkness and cold of space and develop atmospheric light and heat at the moon, as well as at the earth; and in either case there is reflection, making each a moon for the other. Such electrical sun-currents reflected from the moon to the earth, develop in the earth's atmosphere its beautiful moonlight, therefore, instead of the moon being *dead*, it is undoubtedly another world of activities like unto the earth.

The moon, awakened out of its *Rip Van Winkle* obscurity to which science hitherto has succeeded in relegating it, henceforth should be accorded a more just and honorable position among the members of the celestial family.

*By Henry Raymond Rogers, M. D., Dunkirk, N. Y., read before the Chautauqua Society of History and Natural Science.

A Non-Sinkable Ship.

A Massachusetts inventor has devised a double-hulled ship, with compartments so arranged and constructed that it supplies, he asserts, a mathematical certainty against sinking. Between the outer and inner shells of the vessel is a series of longitudinal compartments, to be filled with water, and emptied by the vessel's pumps for ballast; and about this section, on either side, and rising to the full height of the vessel's sides, is a series of chambers filled with small air-tight tanks, their capacity being figured in excess of the known displacement of the ship and cargo. Thus, a cubic foot of air has a perfect supporting capacity for a known weight. It is claimed that with a supply of air in these tanks of 25 per cent. above that required by the formula, nothing short of fragmentary destruction could sink a vessel. Any probable collision, the penetration of a shot, or the explosion of a torpedo, would injure only a small proportion of the tanks, the rest performing their work easily and safely, thus rendering the vessel non-sinkable, the only sacrifice involved in the arrangement being a decreased carrying capacity.

Useful Information

Effects of the Keeley Treatment on the System.

The effect of Dr. Keeley's treatment for intemperance, or dipsomania, as it is called, is thus described by one who took a course at one of his institutes:

After the acute symptoms of alcoholism had passed away I could recognize and study the symptoms induced by the use of the "gold cure," and by carefully collating the facts given to me by a number of patients I am able to state the effects of the Keeley remedies to be generally as follows:

Marked increase of appetite, improvement in digestive capacity, the functions of the mind became more active, a state of cheerfulness was induced, and a general feeling of "well being" was experienced.

These symptoms were in all probability produced by the bi-chloride of gold. I noted other symptoms that were due, no doubt, to the presence of other drugs used in compounding the medicines. For instance, dryness of the mouth, throat, and larynx, as well as of the lips, increased action of the heart, a rise of blood temperature, a redness of the skin, with a slight rash, not distinctly punctated, dilation of the pupil of the eye, dimness of vision, confusion of sight, slight vertigo, unsteadiness of gait. All these last enumerated symptoms may be accounted for by the use of atropine in the preparation of the "gold cure." So, too, the presence of strychnine may be assumed from the following named symptoms: Increased appetite, increased digestive power, nervous twitchings, dilated pupils, etc. It is well known that strychnine is a valuable remedy in cases of gastric catarrh and morning vomiting common to drunkards; that the poor appetite, the feeble digestion, the nervousness and tremblings which follow the withdrawal of stimulants, are alleviated by small doses of the tincture. There may also be cinchona in the mixture or alkaloid quinine which is frequently used as a remedy in cases of gastric catarrh. The same may be said of arsenic. The fluid extract of coca or even cocaine in some form may account for the feeling of cheerfulness and of well being that takes possession of the mind after using the Keeley remedies. This particular symptom may, however, be due solely to the bi-chloride of gold for as is well known his preparation, or rather the chloride of gold and sodium, is highly recommended by some of the highest medical authorities as a valuable remedy in cases of melancholia, hypochondria, and allied states accompanied by mental depression.

A Visit to Mauna-Loa, in the Sandwich Islands.

I had seen Vesuvius, Ætna, and many of the burning mountains in Central America; but I had an unconquerable desire to see that of which I had heard such wonders, Mauna-Loa. And, after arriving at the Sandwich Islands, I was not long in forming a party for the excursion. The way was toilsome; but the fatigue which it produced was forgotten when I stood upon the edge of the crater, and first cast my eyes into the immense abyss that yawned below.

The view of Vesuvius had affected me deeply, and the crater appeared to me the most gloomy gulf I could imagine, being, perhaps, at the time of my visit, about a quarter of a mile in circumference, and so filled with smoke that the lower parts were concealed from view. The crater of Ætna I found to be two or three times larger; and I contemplated it with greater admiration, mingled with awe and even fear. Can the reader imagine the two objects, in their real and relative magnitudes? Let him then fancy that another opens before him, of double the size of Ætna, then one twice the size of that. Then, instead of a crater two or three miles in circuit, let him imagine one with a circumference of *twelve miles*; and then he has before him *Mauna-Loa!*

The edge or border of that immense gulf, though somewhat irregular and broken, allowed us room to stand and walk from point to point without much inconvenience. I was engrossed with the scene, so numerous and striking were the objects discovered, as I moved from place to place.

Twelve miles in circuit! We could scarcely realize the immense extent of the gulf below us. In one place appeared a cluster of conical heaps, from the tops of which rolled out columns of smoke. Though they seemed not larger than ants' nests they were probably two hundred feet high. The crags which formed the rude wall of the water on the opposite side looking like a low ledge of rocks; but, as we followed it, with the eye, to the left and then to the right, we found it apparently rising in elevation, until we realized that it was equal to the immense perpendicular precipice on the edge of which we were walking.

Although the volcano was comparatively in a state of repose, that is, exhibited no extraordinary phenomena, and gave no symptom of an eruption or emission of lava, it was evident that an immense mass of fire was in active operation in the bowels of the mountain and far down in the earth; for there was a surface of melted lava, extending a great distance across the immense cauldron, in constant and violent undulation, and as red as blood. The heat must have been intense and equal in all parts; for no part of the surface was hardened or of a duller color, except along the extreme edges where the process of cooling seemed to be slowly going on. All the rest was one vast sheet of fluid, red-hot matter, tossed up in waves and whirled in eddies by fresh streams continually thrown up from below. Sounds of a peculiar and indescribable kind rose from one part and another, as the boiling became more violent here and there, or when a new surge rolled over the glowing surface until it dashed at the foot of the awful precipices, which impended over the the gulf at every point of its boundary.

There was a general sound continually in the air, like the roar of a distant cataract, which was caused by the combination of a thousand various noises, made by the cracking and crushing of half-cooled lava, the tumultuous swelling and rolling of the fluid masses, the issuing of steam and the rushing of air in the currents formed by the heat. But now and then one of these noises would suddenly be heard very near us, at the foot of the precipice beneath our feet, or among the rocks just below us; and sometimes a deafening roar would burst from the surface of the boiling lava, which would drown every other sound, arrest our attention, and draw our eyes to the spot where clouds of vapor or jets of shining lava would rise into the air, with shrill whistlings and sullen bellowings, like the most appalling thunder.—*New York Ledger.*

Importance of Parental Authority.

There is a growing tendency among professional reformers and humanitarians to extol kindness as the chief element—as, in fact, the very mainspring of every kind of government. They would suppress all exercise of power, and, instead of firmly enforcing obedience, they would merely solicit the submission of those who are prone to disregard the law and defy authority.

This is a pernicious theory. Unquestionably, the function of government should be pervaded with a spirit of genuine kindness; but kindness alone will not govern lawlessness, nor will it even restrain either children or men from refractory behavior when their passions are aroused.

In order to command the obedience of those whom it is necessary to govern, there must be force, authority, power. There must be in the mind of the party to be governed a full conviction that the power of the other party is superior to his own; that there is in the party claiming obedience an ample reserve of power fully adequate to enforce the claim. The more complete this conviction, the less occasion there will be for the exercise of the power.

The value of kindness should not be underrated in any system of government, whether in the household, the school, or in civil society. But kindness is not the basis of government. Obedience is yielded to authority, and authority is based on right and power. The child who complies with his father's wishes only because his parents have "reasoned" with him, or who has been wheedled into compliance by petty bribes and promises, has not learned that doctrine of obedience which lies at the foundation of all government, human and divine. God has given to the parent the right to the obedience of his children, and the power to enforce it. That parent has failed in his duty who has not trained his child, not only to love him, but to obey him, in the strict sense of the word; that is, to yield his will to the will of a superior from a sense of appointed subordination and rightful authority.

This sense of subordination and of obedience to appointed and rightful authority is of the very essence of civil government, and the place where it is to be first and chiefly learned is in the household. To teach this is a main end of the parental relation. The parent who fails to teach it fails to give his child the first element of good citizenship, and leaves him often to be in after years the victim of his own uncontrolled passions and tempers. The want of a proper exercise of parental authority is, in this age of the world, one of the most prolific sources of those frightful disorders that pervade society and that threaten to upturn the very foundations of all civil government.—*New York Ledger.*

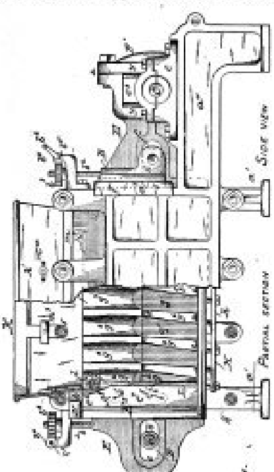
Tobacco as an Antiseptic—Bacilli Succumb to Treatment With the Weed.

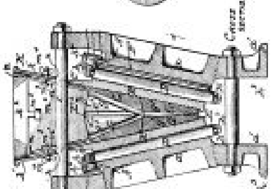
It has long been a popular opinion that tobacco is an antiseptic, and this belief seems to have some basis of fact. Professor Vincenzo Tassinari, of the Hygienic Institute of the University of Pisa, recently made some very interesting experiments on the supposed germicidal virtues of tobacco smoke, which seemed to show that it really had a destructive action upon the growth of bacilli, those minute organisms which are said to be the cause of a vast number of bodily ills that flesh is heir to. Professor Tassinari observed the action of the fumes upon seven different kinds of bacteria—the so-called cholera bacillus, the cattle distemper bacillus, the pus coccus, the Finkler-Prior bacterium, the typhus and pleuro-pneumonia bacillus, and the blue pus bacillus.

Wishing to imitate as closely as possible the processes going on in a smoker's mouth, the professor passed tobacco fumes through a horizontal tube into a receptacle kept moist by damp cotton wool, which contained also a colony of bacilli. The result showed that the smoke retards the growth of some kinds of bacilli, and absolutely prevents the growth of others. The tobacco experimented with was that which is used in making the large Cavour cigar, much favored in Italy, and it was proved that its fumes retarded the growth of pus bacilli by seventy-two hours, and of cattle distemper bacilli by one hundred hours, while they absolutely arrest the growth of the so-called cholera and typhus bacilli. If Professor Tassinari's results may be relied upon, it is evident that not only is tobacco not the deadly enemy of man—and it singular with what eagerness man takes to so many of his deadly enemies—but in many instances it is his great friend, not only by way of solace, but as a warder off and destroyer of deadly germs that insist on colonizing his body and turning it to their own uses.—*All the Year Round.*

CRUSHER AND PULVERIZER.

No. 458,638. ROBERT McCULLY, PHILADELPHIA, PA. *Patented Sept. 1, 1891.* The grinding or crushing is done between two plates E, which are reciprocated lengthways in opposite directions by eccentrics on the driving shaft C. The plates are faced with corrugated jaw plates G. These have large corrugations on the upper half, for crushing; and the lower half is provided with flat faces g^1, separated by square edged grooves g^2 g^2, for pulverizing. The plates E are inclined towards each other as shown in the cross section, and they are supported on rollers b^1 on the heavy

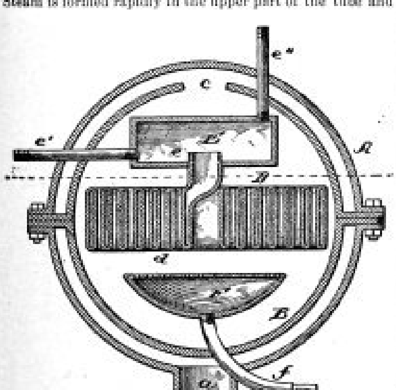




rods b, near each end. These rods are held in brackets B at each end of the machine, and the brackets can be moved up or down in suitable slides, by the screws shown. By lowering the brackets and the main plates E, the grinding faces are brought closer together, and *vice versa*. A gang of rollers D is provided between the back of each plate E and the side of the housing plates A, to relieve the friction. The material to be crushed is fed into the hopper K, and when it is ground it falls out from the lower edges of the grinding faces G.

FLASH STEAM GENERATOR.

No. 461,985. EDWIN REYNOLDS, BROOKLYN, N. Y. *Patented October 27, 1891.* The generator consists, principally, of a spiral coil of iron pipe D, which is flattened, as shown, leaving a narrow space for the passage of water and steam. The pipe is usually lined with copper to prevent corrosion and consequent stoppage of the passages. Water is pumped into the outer end of the coil, and it partly fills the tube. Steam is formed rapidly in the upper part of the tube and

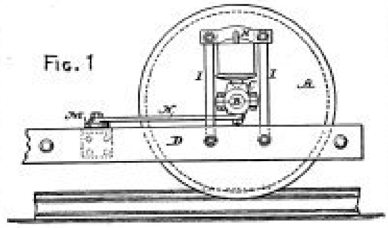


passes out into the drying box E. Here the water carried along by the rush of the steam is separated and runs off by the pipe e^1 and the steam passes out the pipe e^{11}. Heat is supplied by the burner F, which is made to use gas or oil. The casing is composed of two spherical shells, A and B, between which passages are made for the admission of air to the burner, and for the escape of the products of combustion. By this device much of the waste heat is used to heat the air supply, thus adding greatly to the effectiveness of the burner.

CAR TRUCK.

No. 461,680. CHARLES W. HUNT, WEST NEW BRIGHTON, N. Y. *Patented Oct. 20, 1891.* Figure 1 is a side view, and Fig. 2 is a top view of this improvement. The axle boxes C are of any common construction and are suspended by swing links I to the car or truck frame. They are connected by links N to a cross lever M which swings on a king bolt 4. The flanges of the wheels are reversed and are formed on the outer edge of the wheel, contrary to the common practice. When a pair of wheels rigidly fastened to their axle pass around a curve the inner wheel must slide back somewhat, and the outer wheel must slide ahead correspondingly. In the common construction the flange of the outer

FIG. 1



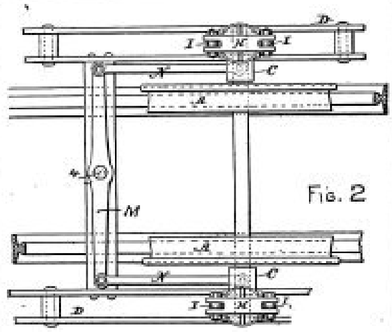


FIG. 2

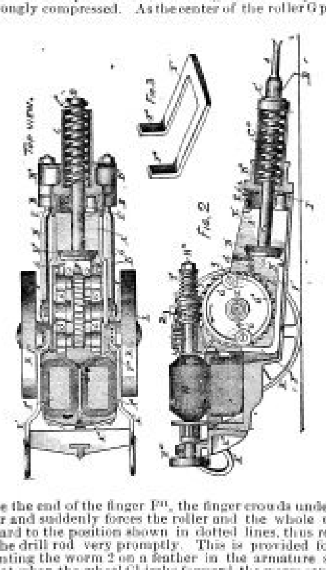
wheel grinds against the outer rail and retards the wheel, but in this invention the flange of the inner wheel grinds against its rail, thus retarding the wheel that should be retarded. The resulting drag of the inner wheel acts through the links N and lever M to crowd the outer wheel ahead. This action helps the axle to assume a position radial to the curve. By this improvement cars of considerable length and of very narrow gauge (24 inches in practice) can be used, and they will pass around curves of very small radius with great freedom.

MINING MACHINE.

No. 459,596. ELMER A. SPERRY, CHICAGO, ILL. *Patented Sept. 15, 1891.* This machine is driven by an electric motor. The armature H carries a worm 2, which rotates the wheel G^1. This wheel runs on a standing spindle 1^2 which is fastened in the sides of the main frame A and it carries four rollers G on two pins 3 and 4, two rollers being on one side of the wheel and two on the other. The drill rod D has a cross head D^2 on its inner end, which carries a U shaped bar F^1 having the ends F^{11} turned up as shown in Fig. 3. These fingers F^{11} are caught by the rollers G as the wheel revolves, and the drill rod is drawn back until the parts are in the position shown in Fig. 2, and the spring C^{11} is strongly compressed. As the center of the roller G passes

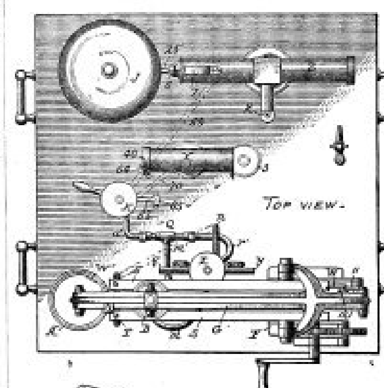


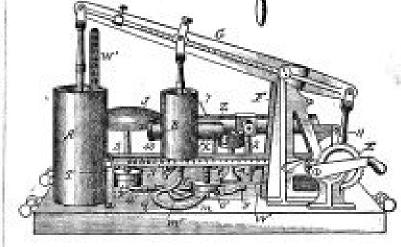
above the end of the finger F^{11}, the finger crowds under the roller and suddenly forces the roller and the whole wheel forward to the position shown in dotted lines, thus releasing the drill rod very promptly. This is provided for by mounting the worm 2 on a feather in the armature shaft, so that when the wheel G^1 jerks forward, the worm can slide along the shaft far enough to accommodate it. The spring I immediately returns the worm to its bearing against the end of the journal box. The drill rod D is provided with a piston D^{11} which enters an air trap or dash pot E, near the end of the stroke and cushions the blow in case the drill does not strike the coal. This dash pot is provided with a pet cock, by which the amount of resistance or cushioning can be easily adjusted. The case containing the spring is attached to a head B^{11} which is fastened to the machine by bolts B^1, shown in the top view. As there are two pairs of rollers G, the drill makes two strokes for each revolution of the worm wheel G^1.

APPARATUS FOR TESTING MINE GAS.

No. 460,683. THOMAS SHAW, PHILADELPHIA, PA. *Patented Oct. 6, 1891.* This apparatus is all mounted on one base which is provided with handles for convenient moving about. It consists of an air pump and gas pump combined so as to work in harmony, and deliver any desired mixture of air and gas; a combustion tube for burning suspected air and comparing it with air carrying a known percentage of gas; also an explosion tube for similar purposes; and a test tube for noting the presence of carbonic acid or choke damp.

The air cylinder A is provided with a piston and a stroke indicator W^1. The cylinder B also has a piston, and serves for pumping gas. The air piston is connected to the end of the beam G, but the gas piston is connected to a sliding block which can be set at any graduation along the beam, thus securing any desired proportion between the air and gas pumped at the same stroke. The valve L which controls the connections to the air and gas supplies is reversed automatically at each stroke of the beam, and the air and gas are brought together in a small injector or mixer Q, from whence they pass to the burning tube X or the ex-



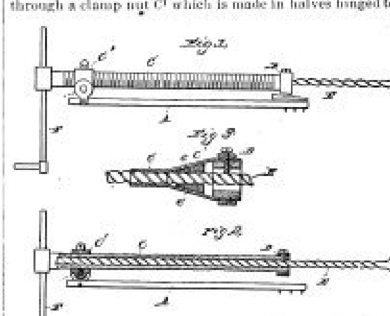


plosion tube Z, as determined by the switch K. When it is desired to pump air directly from the pipes which extend into the working chambers of the mines, the cylinder B and its beam connection are moved back to the fulcrum of the beam so that its piston makes no stroke. Then the cylinder A is connected to the pipes and the mine air is pumped into the tubes X and Y and its explosiveness is noted.

To test for carbonic acid, the air piston is raised to the top of its stroke; then the delivery tube is connected to a glass tube containing lime water. The air piston is moved slowly downward and as the suspected air bubbles up through the lime water it becomes milky. By noting the stroke of the air piston necessary to produce a certain degree of milkiness in the lime water, the percentage of choke damp is readily ascertained.

COAL DRILL.

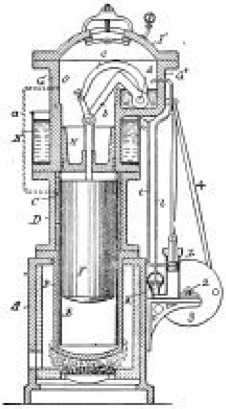
No. 462,109. WILLIAM BULLUCK, CENTRALIA, PENNA. *Patented Oct. 27, 1891.* Figure 1 shows a side view of the drill and wedge bar, Fig. 2 shows a section lengthways, and Fig. 3 shows an improved clamping device. The feed screw C is made of gas pipe, threaded on the outside, and it feeds through a clamp nut C^1 which is made in halves hinged to-



gether in the usual manner. The drill or auger E passes through the inside of the pipe C, and is held firmly by a clamp D at the front end of the tube, so as to turn with it. When the auger has penetrated the coal until the clamp D strikes the face, the clamp is loosened and the nut C^1 is opened, thus permitting the feed screw to be drawn back over the auger as far as desired. The nut and clamp are then closed and the boring is continued. The auger is thus virtually lengthened, and a deep hole can be bored with a comparatively short drilling apparatus.

HIGH PRESSURE HOT-AIR MOTOR.

No. 459,501. August J. Ventzki, Graudenz, Germany. *Patented September 15, 1891.* When at work this engine has compressed air at high pressure on both sides of the working piston. By compressing the air the same results are got as would be obtained by using the same air at atmospheric pressure in a correspondingly larger cylinder. By this means the dimensions of the machine are brought within convenient limits. The power piston H is attached to the lever b and rock shaft d, and outside the casing another arm on the rock shaft (not shown) drives a crank and fly-wheel by an ordinary connecting rod. On the other end of the fly-wheel, shaft 2, is a crank 3, which is suitably connected to move the shifting plunger F. This plunger fits closely but does not touch the lining E, which is composed of copper netting. A small space is left between the lining E and fire-pot B, through which the air passes to and through the regenerator C. At the beginning of the stroke the air in the fire-pot B is expanded by the heat, and the power piston



is forced upwards, but just before it reaches the top of its stroke the plunger F is moved rapidly downward, thus shifting the air in the fire-pot to the space under the piston H. In passing through the regenerator C, which is composed of a great number of thin metal plates, the air parts with a great part of its heat to the rege erator plates and is thereby contracted. It is further cooled by contact with the sides of the power cylinder, which are cooled by a water-jacket K. The compressed air contained in the space O above the piston was compressed still more by the rise of the piston, and when the air below the piston is cooled by the regenerator, it helps to drive the piston in its downward stroke. The working charge of air is quickly shifted to the fire-pot by the quick rise of the plunger F, and as it passes down through the regenerator it takes up the heat it left behind in its upward passage, thus partly expanding it preparatory to the next stroke. Where the rock shafts pass out of the casing through stuffing boxes the shafts are submerged in oil, which is much easier to retain than compressed air.

COAL CONVEYOR.

No. 460,643. Theodore H. Lewis, Boston, Mass. *Patented Oct. 6, 1891.* The common conveyors when lowered into the hold of a vessel will burrow in the coal in one spot, just under the hatchway, and shoveling must be resorted to in order to bring the coal lying near the sides of the vessel to the conveyor. In this apparatus three conveyors are

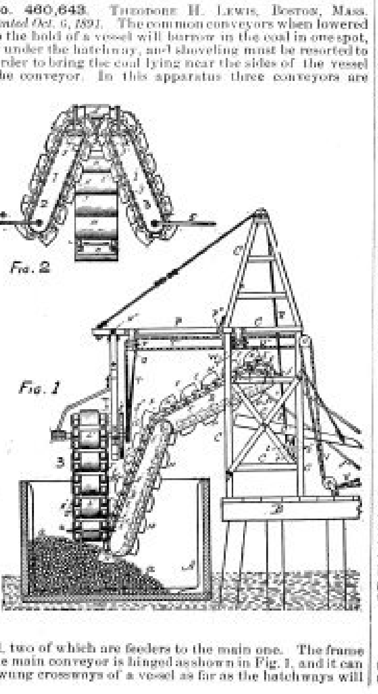


Fig. 2

Fig. 1

used, two of which are feeders to the main one. The frame of the main conveyor is hinged as shown in Fig. 1, and it can be swung crossways of a vessel as far as the hatchways will permit. The two feeders 2 and 3, in Fig. 2, are hung in a frame which is swiveled on the end of the boom P, Fig. 1. The sprocket wheels of both are geared together, and they are driven by a rope belt from an engine on the dock. Both have handles 4 and 5 at the lower end by which they may be extended sideways as far as desired. The feeding conveyors being hung on a swivel may be turned partly around, and be made to gather up the coal in almost any direction, and they may be raised or lowered by means of the hinged boom P, which is operated by the rope and windlass shown.

PUMPING ENGINE.

No. 462,061. James Pollock, Wilkes-Barre, Pa. *Patented October 27, 1891.* The object of this invention is to equalize the driving power of the steam throughout the entire stroke, in an ordinary direct acting pump. B is the steam cylinder, which may be compound if desired, and C is the pump barrel. An extra cylinder E, called the compensating cylinder, is attached as shown, and its piston is attached to the main piston-rod. Both ends of this cylinder are connected by suitable valves with a supply tank, and also with a reservoir or receiver filled with air or steam at a constant pressure, or with water under a suitable head. When steam is used expansively in the cylinder B and is cut off during the first half of the stroke, the pressure is far more than enough to drive the plunger, but as soon as the steam is cut off the pressure rapidly falls and quickly becomes insufficient to do the work required. The compensating cylinder corrects this trouble. During the first portion of the stroke the compensating cylinder draws water from the open tank and forces it into the receiver

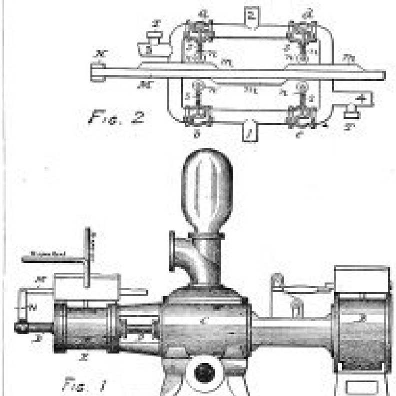

Fig. 2

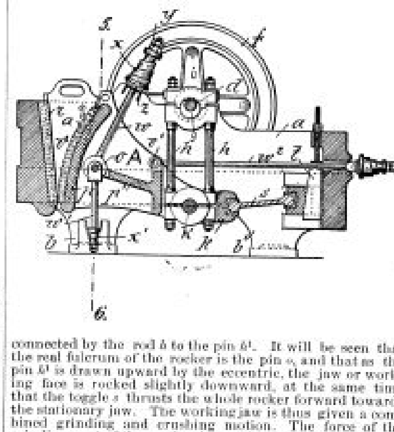
Fig. 1

under pressure, thus storing up the excess of power developed in the steam cylinder. During the middle portion of the stroke both ends of the cylinder are in communication with either the receiver or the open tank, and the piston is in equilibrium, and during the latter portion of the stroke the excess of power stored in the reservoir or receiver is utilized by admitting water from it to the rear of the piston and permitting the water in front of the piston to pass into the open tank. Thus by properly regulating the pressure in the receiver the variation in steam pressure may be compensated for and the pressure on the pump-piston or other resistance rendered substantially uniform. The valves a, b, c, d, Fig. 2, which connect the compensating cylinder with the tank and pressure reservoir, are operated by cams m, which are attached to a sliding rod M. This is moved by an arm N on the piston-rod. The pipe 1 goes to the tank, pipe 2 to the pressure reservoir, and 3 and 4 go to the ends of the cylinder E.

CRUSHER.

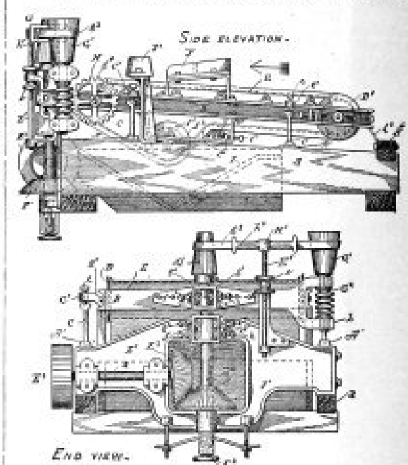
No. 461,050. Wilhelm Schranz, Laurenburg, Germany. *Patented Oct. 13, 1891.* The moving jaw of this crusher is curved, and is carried by a rocker A. This rocker is supported on spring rods a, a^1, at the pin o, and is held back by another spring rod a^2. The rear end of the rocker bears against a toggle S, which is provided with an adjusting wedge and screw, as shown. The rocker is worked by an eccentric on the driving shaft d, which is



connected by the rod h to the pin b^1. It will be seen that the real fulcrum of the rocker is the pin o, and that as the pin b^1 is drawn upward by the eccentric, the jaw or working face is rocked slightly downward, at the same time that the toggle s thrusts the whole rocker forward towards the stationary jaw. The working jaw is thus given a combined grinding and crushing motion. The force of the grinding part of the motion is regulated by adjusting the tension of the springs x and x^1.

ORE CONCENTRATOR.

No. 459,884. Andrew Fraser, San Francisco, California. *Patented Sept. 15, 1891.* The belt E runs over end rollers D and D^1 and under washing rollers I^1 and i and it is also supported by small rollers under the top side. The head roller D is driven by a worm G^2, and worm wheel H on the end of the roller shaft. The worm is driven by a belt on the cone pulleys G and G^1. The belt E, rollers D, D^1, pulp box J, and the driving worm G^2 and pulley G^1 are all carried on the frame B. This frame is supported on swinging posts C, and on a spring b^2 at the rear end. The front end of the frame has an eye or bearing through which the upper end of the driving shaft F passes. The upper part of this shaft is made eccentric to the main body of the shaft, and it serves as an eccentric to swing the end of the frame B in a circle. The rear end of the frame moves back and forth lengthways, but has little or no side motion. The pulp or ore containing the metal to be separated is distributed upon the belt while in rotary motion, by which it is



Side elevation.

End view.

carried forward and exposed to the action of the water-flow which, in connection with the oscillatory motion of the belt and frame, causes the separation of the lighter particles from the heavier. The heavier particles remaining upon the belt are carried beneath the flow of water over the front roller, while the lighter or worthless particles are carried to the rear by the downward flow of the water. As the motion imparted to the rear end of the frame and belt is very slight, whatever of the sulphurets may be contained in the lighter particles will fall and settle upon the belt, and adhering thereto, will be carried forward beneath the water-reservoir over the forward roller.

All material adhering to the belt is washed off in the wash-box I, which is fixed in the main frame below.

PULSOMETER.

No. 462,069. Henry Snooks, Jersey City, N. J. *Patented Oct. 27, 1891.* This pulsometer differs from others now in use, in having double sets of working chambers. The steam valve ball V rocks from side to side and closes the inlet ports to A or A^1 alternately, as in the ordinary pulsometers. But the steamports are branched so as to supply two chambers simultaneously. Fig. 2 is a cross section on the line 7, 8, just above the suction valves. D, D^1 are the discharge chambers. By duplicating the working chambers, the cooling surface is increased relatively to the volume of the steam, and condensation takes place quicker, thus increasing the speed of

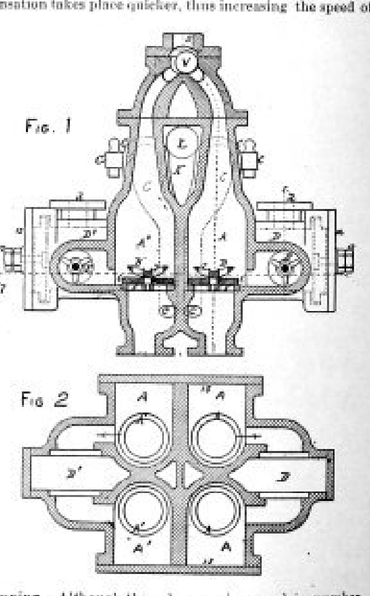


Fig. 1

Fig 2

pumping. Although the valves are increased in number, an advantage is gained from the fact that the failure of one valve will stop only one chamber, and two valves on the same side must fail to work, before the pump will stop. The chambers C shown in dotted lines are vacuum chambers, and they open into the suction pipe below the valves. The discharge branches d are connected by pipes (not shown) to the space K between the working chambers, so that the water on its way to the column pipe helps to cool the chambers and facilitate condensation.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 7. SCRANTON, PA., FEBRUARY, 1892. WITH WHICH IS COMBINED THE MINING HERALD

PENNSYLVANIA COAL AND OIL.

As seen from the stand-point of a Scottish Expert.

(A paper read before the November, '91, Meeting, Mining Institute of Scotland. By Henry M. Cadell, B. Sc., F. R. S. E., Member of International Geological Congress, Washington, D. C.)

The Appalachian Basin.

Before coming to details, it may be of interest to take a general view of the distribution and characteristic features of the vast carboniferous formation of Pennsylvania. The Appalachian Basin, as it is called, contains the largest coal field of any known carboniferous area. On the map it rudely resembles a canoe, lying in a N. E. and S. W. direction, and extends from the north of Pennsylvania south-westwards through West Virginia, South-Eastern Ohio, Eastern Kentucky, and Central Tennessee, to Western Alabama, a total distance of 900 miles from its northern extremity. The general structure of the field is that of a great trough, the strata in which are nearly flat in its western parts, but begin to undulate towards the east, where they finally become bent into the great anticlinal and synclinal folds of the Allegheny Mountains.

The Carboniferous System of this part of America is very variable in thickness, and it would be difficult to give anything but the most general vertical section to indicate its chief divisions. Generally speaking, it may be divided into:

Upper Barren Coal Measures or Permo-Carboniferous thickness unknown, as top not seen say,	1000 ft.
Upper Productive Coal Measures, extending from the Waynesburg sandstone and coal down to the Pittsburgh seam, its most important coal bed, thickness variable, say	450 ft.
Lower Barren Measures, shales and sandstones, say,	500 ft.
Lower Productive Coal measures, extending downwards from the Upper Freeport coal seam to the pebbly sandstones and Brookville coal bed, thickness say,	400 ft.
Pottsville Conglomerate Measures, including beds of shale, oil-bearing sandstone, and conglomerate, thickness very variable, say, Mauch Chunk Red Shale and Mountain Limestone series, with oil-bearing conglomerate.	400 ft.
Pocono Sandstone, shales and oil-bearing sands, forming base of Carboniferous system,	450 ft.
Giving a total thickness of Carboniferous rocks of say,	3200 ft.

Although no coal is found below the carboniferous series of rocks, the economic hydrocarbons are not confined to this formation, but extend far down into the underlying Devonian system, whose upper 2,000 feet contain many valuable oil and gas-bearing sandstones,

The Standard Colliery.

On reaching Pittsburgh, the chief center of the Bituminous coal, oil, and gas region, I first visited the Standard Colliery, situated at Mt. Pleasant, about thirty-five miles south-east of that city. This great colliery is the largest in America, and belongs to the H. C. Frick Coke Company, who own no less than 10,000 of the 16,000 coke ovens in the Connellsville coke district. The Standard property comprises 4,500 acres of land, under which the celebrated Pittsburgh seam exists; and of this area only 400 acres have been worked out, so that the colliery has a long life to look forward to.

Mr. Robert Ramsay, the manager of the Standard Colliery, is, I was glad to find, a native of Fife, and my letter of introduction was not needed to gain for me a cordial reception by a "brither Scot" from the old country.

The Pittsburgh, or Connellsville seam, has here a workable thickness of seven to eight feet. It is entirely used for coking purposes, and is very soft and easily worked. The colliery has two shafts and a slope or mine, by which the coal is raised. One shaft is a downcast, and is entirely used for ventilation. It is fitted with a 25-feet Guibal fan, which is directly worked by a 20-inch diameter by 36-inch engine, running at fifty revolutions per minute. Most of the coal is drawn up by the other shaft, which is 303 feet deep from the surface of the ground, the total height of the hoist from the bottom to the rail on the bank being 334½ feet.

The arrangements on the bank are very complete, and skillfully designed for a large output by Mr. Ramsay, who got his main ideas from some of the large Scottish collieries, and introduced several important improvements of his own. The usual output in the nine hours' working day is 2,000 tons of 2,000 lbs., but once to test the capacity of the arrangements for raising and handling the coal, no less than 3,021 tons were hoisted in 8½ hours from this one pit.

The coal, as I have said, is very soft and easily worked, so that each miner can produce a good darg. The seam is worked on the double-entry pillar and room system, and, as the field is very regular and free from the "troubles" and faults with which we are so well acquainted, and the dip very slight, there is no difficulty in having a very complete and regularly laid out system of underground workings.

The face men, who are mostly foreigners, are paid 1s. per ton, and they have no difficulty in putting out eight or nine tons a day, so that they can make an average wage of 8s. or 9s. —not much different from that of our

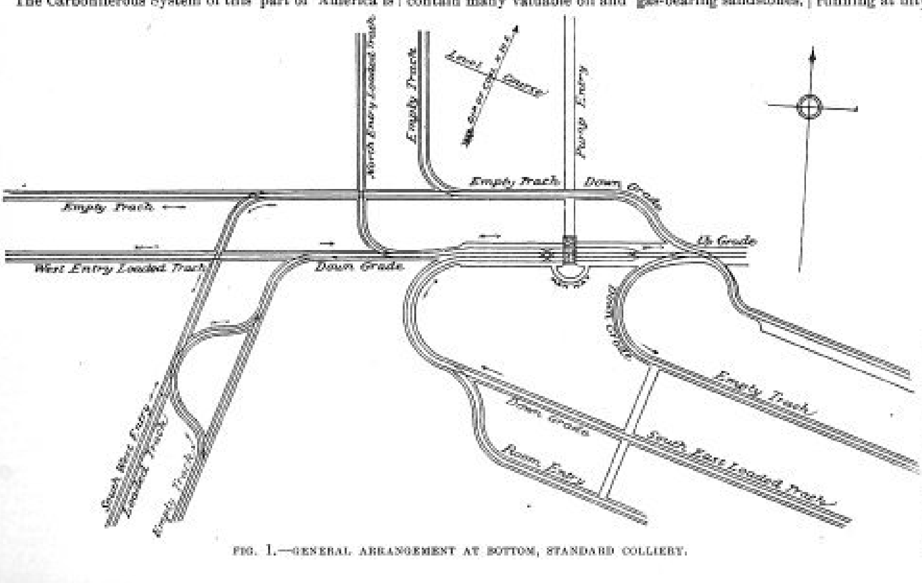

FIG. 1.—GENERAL ARRANGEMENT AT BOTTOM, STANDARD COLLIERY.

own miners here at present. I made a good many inquiries as to the relative financial position of American and Scottish miners, both here and in the Anthracite districts, of which I shall speak afterwards, and I came to the conclusion that, taking the cost of living into account, the workmen in the old country are just now much better off than their contemporaries "across the water." The Pennsylvania miner works nine hours a day and six days a week, buys his coals at market price, and lives, according to the custom of the country, in a three or four-roomed wooden cottage, for which he pays from £11 to £22 per annum. Indeed, I met a workman at Pittsburgh (who had escaped from Russia, and had been waiting for sixteen years till the expected revolution should allow him to return), who told me he had a house with three small rooms for which he paid £36 per annum, and could not keep his small family under £3 12s. a week. Of course, there is no physical necessity for an American miner occupying a larger house than a Scottish collier, but in such a case the custom of the country becomes a necessity that must be satisfied. Again, the price of food in America is not much different from that which prevails here, but the style of living is generally more expensive, as the Americans are high livers and like plenty of delicacies. Protection has raised the price of manufactured goods, and hence clothing generally costs at least double its price here, while the quality is often inferior. Taking all the circumstances of the case into consideration, I do not think that any miner from the old country, working eight hours a day and eleven days a fortnight, and making say 8s. a day, would better his condition by going to America, where, for 12s. a day, he would require to work far harder and longer for his money, and would be obliged to spend it freely on the necessities of life, and on expenses and luxuries that the laws of society in the West render necessary to respectable existence.

The Standard Colliery employs below ground altogether about 535 men and boys. Among them there are many foreigners from the south of Europe, such as Austrians, Poles, Hungarians, and Italians.

The coal is hauled from the face to the pit bottom by horses and mules, and instead of hutches, wagons holding $2\frac{1}{2}$ tons are employed. The loaded wagons from the different parts of the workings, on nearing the bottom, run down by their own weight to the shaft, and the empties run off from the cage on the opposite side, so that the minimum of labor is required in handling them.

The shaft, clear of timbering, measures ten by twenty-four feet. There are two hoisting ways, each seven by ten feet, and the remainder with a cross-section of some ninety square feet, is used as an upcast airway, and contains the steam pipes for the larger pumps, a manway, three feet wide, passes round the foot of the pit in a semi-circular direction, and no one, under any circumstances, is allowed to cross straight through the bottom of the shaft. A general plan of the pit-bottom arrangement is given in Fig. 1.

The pumping plant below ground consists of two Yough mine pumps, with twenty-six inches diameter by forty-eight inches steam cylinders, and fourteen inches diameter by forty-eight inches water cylinders, having a capacity of 1,200 gallons per minute. Besides these there are several smaller pumps for local dips, some of which are driven by compressed air.

The cages, which are very simple and strong in design, are fitted with safety-catches, which are regularly tested once a fortnight by slacking the winding rope suddenly from the drum.

Perhaps the most interesting and ingenious device in the colliery is that at the bank for taking off and tipping the full wagons and putting the empties on the cage, a general sketch of which is given in Fig. 2. On reaching the bank the full wagon is pushed off the cage by an empty one, which in turn is moved by the piston-rod of a steam ram, worked by an operator at X, who turns on the steam by means of a lever attached to a rod with a handle at *p*. The loaded wagon then gravitates down to the "tipple," situated about eight yards from the shaft, the descent being four inches. After being emptied into a hopper below, from which the coal goes direct to the ovens, the wagon is returned by a second operator at the tipple along another set of rails which run past the side of the shaft with a descent of eight inches further, and is landed just opposite the side for empties going on to the cage, but one foot lower. The part of the track on which the wagon now rests is really a traveling carriage, called the "transfer truck," which moves at right angles to the direction of the rails, and at the same time travels up an incline so as to bring the empty wagon exactly opposite its place on the cage. The transfer trucks, of which there are two, one for each line of rails, are worked by a second steam ram, and the movements of all the wagons, loaded and empty, are under the control of one man, who rules supreme at the pit-head, and has only one assistant to help in disposing of the great output. By another arrangement, not shown on Figure, it is impossible for the operator at X to work the ram except when the cage is at the top and ready to receive a wagon. After reaching the hopper or bin below the tipple, the coal is dropped into "larries," or iron hopper charging trucks, each having a capacity of seven tons. The trucks are drawn away by light locomotives and emptied direct into the ovens, which are of the Beehive pattern, and hold each 100 bushels. The average yield of coke per oven each week is $10\frac{1}{2}$ tons, and 905 ovens are supplied from this one shaft. No attempt is made to utilize the heat or gas, and at night the whole region with its long terraces of blazing ovens has a very striking and weird appearance.

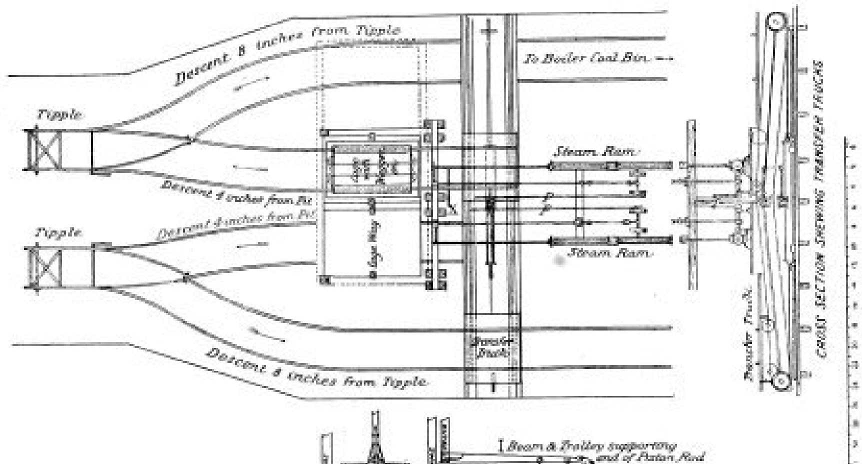

FIG. 2.—ARRANGEMENT AT BANK, STANDARD COLLIERY.

OIL WELLS.

Next day I made my way to the Forest Oil Company's office, in Pittsburgh, where Mr. Young, the Vice-President, kindly sent me out with a party of three others to see some new wells belonging to the Company. We took train to Oakdale Station, in North Fayette Township, Allegheny County, about 12 miles W.S.W. of Pittsburgh, where oil has been recently discovered in large quantities. As the Company's well is a few miles from the station, we got a buggy and drove through the country to visit it. The road, like most American country roads, was execrable, and every few minutes I expected to be pitched out when we jolted over an unusually large stone or into a particularly deep hole. At one place the road ran right along the stony bed of a river, along the sides of which some of the wells are situated. The water was covered with a film of oil, and had we dropped a light into it the results might have been disastrous. As we got into the oil belt, where the productive wells are situated, the tall lattice work "derricks" began to appear over the trees and along the sides and bottom of the glen. All the boring is done by means of a heavy tool on the end of a manilla rope. This is lifted and dropped by a primitive-looking wooden rocking beam worked by a crank, which in turn is attached to a shaft with a large wooden pulley, over which passes a belt worked by a small steam-engine going at a good speed. There is generally a considerable quantity of gas, even if there is no oil in the rocks to be pierced, and a pipe in the bore-hole conveys the gas to the grate of the steam boiler, placed perhaps 20 or 30 yards away so as to avoid the dire consequences of setting the well on fire. There is thus no need of coal, as the well supplies its own fuel.

It is of course necessary to have the bore tightly tubed, as the gas and oil come up at enormous pressures, 400 to 500 lbs. per square inch being quite common. In order to allow of boring to be done after the oil has begun to flow, an ingenious device has been adopted. The tube at the mouth of the well is fitted with a horizontal branch to carry off the oil or gas, while the rope passes straight down through a stuffing box fitted into the cap, which is secured to the vertical prolongation of the tube. As a manilla rope is rough, and could not be made to work tightly through a stuffing box, the rubbing part is surrounded tightly with a short length of smooth tube, which works up and down in the stuffing-box like the piston-rod of a steam-engine, and thus prevents the oil escaping by the wrong outlet. As the bore deepens this tube is shifted further up the rope, which is thus preserved from friction at the orifice of the pipe. The oil, and the gas which always accompanies it, are conveyed to a wooden tank made with staves and hoops like a vat, on the top of which are two square wooden ventilating pipes, through which the gas escapes into the air.

When we reached the Wright Well, where the oil had recently been got at a depth of some 1800 feet, the boring operations were still in progress. We were however, fortunate in seeing the cap taken off and the tool hauled up. As the massive rod and tool at the bottom of the rope emerged, the pressure of the oil was so great that it lifted the rod right out of the hole and shot it a few feet into the air, and the orifice being thus clear, the oil spouted upwards in a solid jet 100 feet in height. Had any of our industrious Scottish oilworks' men, who earn their hard won profits by laboriously distilling petroleum and its products from the heart of the rock, been witnesses of this wonderful spectacle they might well have fallen down to worship. The sight is one I, at least, shall not soon forget. I was told that the well was yielding 500 barrels a day, and that for the following 30 days 300 to 500 barrels might be still expected. At the end of 90 days a yield of 150 barrels daily was all that could be hoped for, and in 6 months this would probably decline to 100 barrels, while for the next 4 or 5 years only from 5 to 25 barrels a day were to be looked for, after which the well would have no commercial value.

On the average, the life of a productive oil well is said to be from 5 to 8 years. The cost of drilling is one dollar, or 4s. per foot, and a good borer can drill a hole 6 or 8 inches in diameter at the rate of from 50 to 60, or even 100 feet in 24 hours. Of course it is plain that in such cases the rock is very soft and easily pierced.

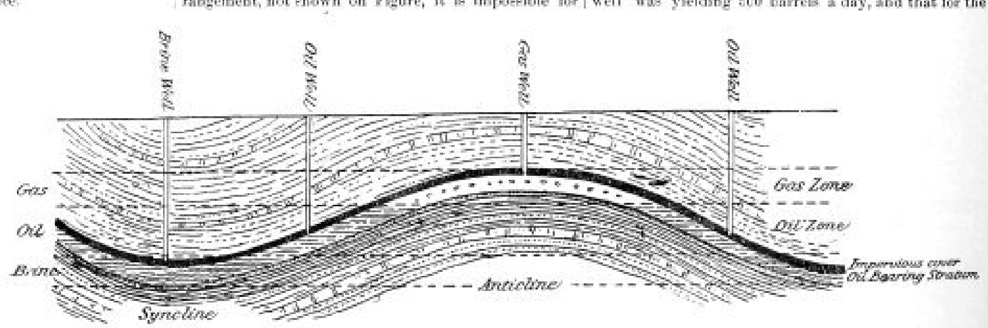

FIG. 3.—ILLUSTRATING RELATIVE MODES OF OCCURRENCE OF OIL AND GAS.

The discovery of oil greatly enhances the value of land, as about one-eighth of the production goes as royalty to the owner of the ground. There is in the old country a great outcry in certain quarters against the royalties paid by mineral tenants to the proprietors of mineral estates. In America, the land of free popular institutions, the minerals go along with the land, and there is no talk of abolishing royalties to private owners, and making them national property. In Colorado the lessees pay from 15 to 40 per cent. of the net profits of the mines after smelting the ore, as royalty to the owners, and the State makes no claim in the matter.

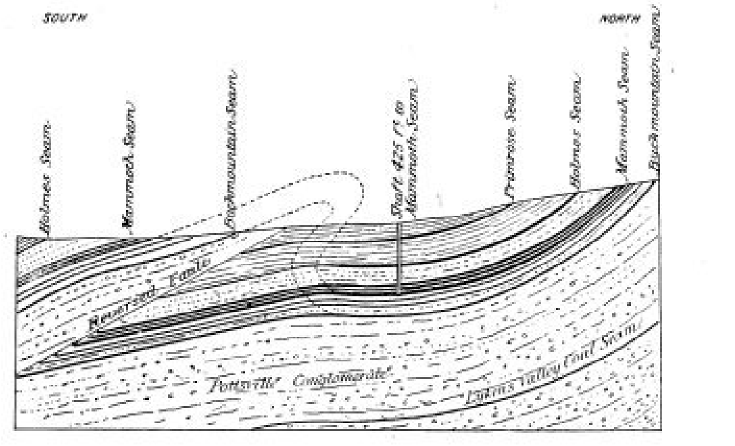

FIG. 4.—SECTION AT KOHINOOR COLLIERY, SCALE 1 INCH = 800 FEET. ILLUSTRATION OF THE EFFECT OF A REVERSED FAULT OR THRUST PLANE IN ALTERING THE STRUCTURE OF A COAL-FIELD.

After seeing a spouting well, which is by no means a common sight for a casual visitor, my curiosity was satisfied, as I had no expectation of seeing anything "bigger" that day at least. Before returning to Pittsburgh, we drove to McDonald, a small town a few miles off, where oil had been found quite lately. Like many other American townships, it is an ugly collection of two-story wooden houses with small gardens, and broad belts of ground running at right angles to one another that pass for streets, but have not yet been constructed with the help of any other tools than the theodolite at first and the cart wheel afterwards. The so-called streets are straight in plan but like a saw in section. The whole place was covered with a forest of derricks, and everyone seemed to have begun drilling in his garden, however small it might be. The sludge from the bores was being emptied out in such volumes that at one place where an unusually deep ditch ran across the street it had become filled with the gray mud to such an extent that we could not venture across for fear of being swallowed, horses, buggy, and all. There were in the town about 120 wells in course of drilling, and the engines were all driven by steam raised by the natural gas, which occurs in great abundance here and is used for lighting the town at night. Like other good gifts it is recklessly wasted, and we passed several jets blazing at noon, as it does not pay to have the gas stored against the fast approaching evil day.

Another interesting feature in the development of the great oil industry is the immense system of pipe lines that convey the oil from the productive wells to the market, perhaps several hundred miles away. The pipes are of malleable iron with screwed joints, and lie on the surface of the open ground or along the roadsides. At one place I counted six pipes from 3 to 6 inches in diameter, all running along the same track, one on the top of another. As the ground is hilly the oil cannot gravitate the whole distance to the central market. There are therefore convenient pumping stations placed at intervals along the track, where it is forced onwards by specially constructed pumps or rams driven by steam and natural gas.

The subject of the geological nature, distribution, and mode of occurrence of oil and gas is one of great interest and importance, and a short consideration of the matter may not be without its value here.

As I have already mentioned, these substances occur chiefly in the lower part of the Carboniferous, and the upper part of the Devonian formation, which lies below, and occupies the same place as the Old Red Sandstone of Scotland. This is to us interesting, as the Scottish oil shales are also chiefly found among the Lower Carboniferous rocks under the Mountain Limestone and the lowest productive coal measures. Our Lower Carboniferous rocks below the Hurlet or Mountain Limestone were, however, chiefly deposited in fresh or brackish water, while the American oil-bearing rocks are chiefly marine deposits, as is proved by the salt water which is found in many of the strata.

Oil and gas—in this case, marsh gas or light carbureted hydrogen—are secondary products, due to the slow distillation of vegetable and mineral matter embedded in the strata, which have found their way into the most open rocks in their vicinity, where they have accumulated in large quantities. It is clear that, if a quantity of salt water, oil, and gas be mixed together in a bottle, the brine, being heaviest, will sink to the bottom, and the oil will float on its surface, while the gas will accumulate in the neck. After long experience, it has been found that the occurrence of oil and gas is generally regulated on these principles, and that their distribution is not absolutely uncertain and without a law. It is true that a dry hole is often found beside a productive well, but it is also true that, outside of certain belts, there is no chance of getting oil at all. The oil and gas occur in certain course open sand-stones, in the interstices of which there is space for fluid matters to accumulate. Now, if we suppose an oil-bearing stratum to be bent into an anticlinal arch and a synclinal trough, in course of time the gas will rise through the oil, and collect at the top of the arch, where it will remain, provided the overlying bed be impervious. The oil will be found below the gas, and any brine that may originally have been mixed with the oil will sink to the bottom of the basin. This is what has actually been proved to occur over large areas. The strata where the best wells are found lie in long, low anticlinal and synclinal folds, and, generally speaking, the holes drilled through the crest of the arches to the oil sands get gas, while those in the basins get brine, the oil being found between these two limits. A reference to Fig. 3, will make the matter clear. The oil sands are not always uniformly porous, and there are spots where the texture is too close to permit of the passage of fluids through them. Hence it is, that in these spots, the wells are "dry" and unproductive. The field is, morever, practically free from faults, so that the fluids can move from one place to another without interruption, which could hardly be expected in our much faulted and irregular formations.

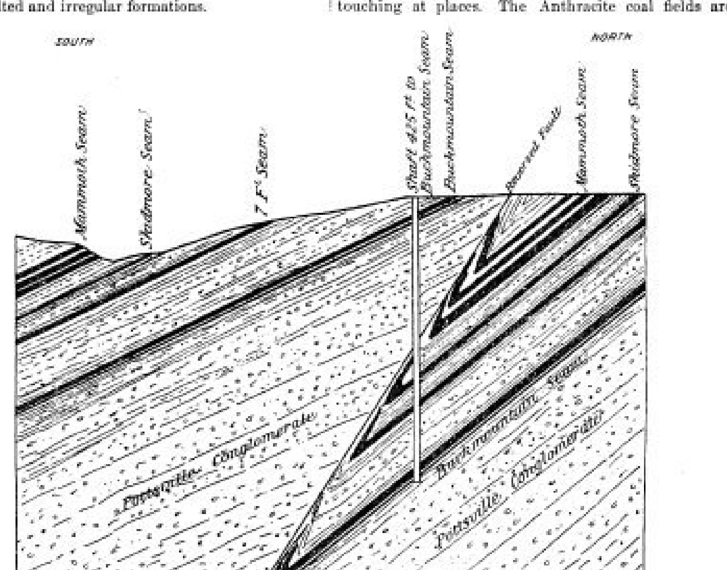

FIG. 5.—SECTION AT SHENANDOAH CITY COLLIERY. SCALE 1 INCH = 200 FEET. ILLUSTRATION OF THRUSTING OR REVERSED FAULTING OF COAL STRATA AS PROVED IN THE SHENANDOAH ANTHRACITE COLLIERIES.

The production of the American oil wells has been enormous; and, as the oil is not being manufactured in nature's laboratory at anything like the rate at which it is being consumed—if, indeed, it is now being thus manufactured at all—it is clear that, sooner or latter, the supply will begin to give out. No oil well has yet been found that goes on producing perennially, and the production is solely kept up by the discovery of new "pools." The natural gas which, for several years, supplied Pittsburgh with a clean and cheap fuel, and greatly added to the wealth and prosperity of that important manufacturing center, is already diminishing in quantity, and the city is again returning to its original smoky condition.

The following table, taken from the Annual Report of the Second Geological Survey of Pennsylvania, 1890 (by Mr. John F. Carll), shows that the total production of the oil wells of Pennsylvania and New York reached the first maximum in 1882, and declined irregularly till 1888. There has, however, since then been a rapid recovery, and the production for 1891, taking the average of the first seven months of the year, will probably be not much below that of 1882. My data for the last two years are from "Stowell's Petroleum Reporter," for August, 1891 (published monthly in Pittsburgh).

TOTAL PRODUCTION.

Years.	Barrels of 42 gals. capacity.	Years.	Barrels of 42 gals. capacity.

ANTHRACITE COAL FIELDS.

After visiting three of Mr. Carnegie's great iron and steel works at Pittsburgh, as well as other places of interest, where, until quite recently, natural gas has been the sole fuel for raising steam, I left on the 20th of August for Pottsville, in the celebrated Anthracite region of Pennsylvania.

Pottsville is situated among the picturesque forest-clad ranges of the Alleghenies, 200 miles east of Pittsburgh. It is located in an isolated basin of Carboniferous rocks, which have been bent and twisted into great folds with steep sides, by the tremendous forces which ridged up this part of America into the Appalachian mountain system. When coal beds have been much squeezed by such movements, it is usually found that they have undergone more or less metamorphism, and have lost a great part of their hydrocarbons, becoming converted into blind coal or Anthracite, which contains over 90 per cent. of pure carbon. Had the crumpling and metamorphism been carried further, the coal beds would have passed from the condition of Anthracite to that of graphite, which consists of pure carbon, and is found in many old and much altered formations.

There are four tolerably distinct Anthracite coal fields, all of which are situated in the extreme eastern portion of Pennsylvania. Each coal field consists of a series of long, narrow, synclinal folds, either join ed together so as to form a single trough with a highly corrugated bottom, or isolated from one another like a collection of long thin canoes laid side by side, and sometimes touching at places. The Anthracite coal fields are entirely isolated from the great Bituminous coal fields to the west by the high forest-clad ranges of the Appalachian mountain system, along which older Paleozoic formations rise from beneath the Carboniferous strata in a series of long ridges, with a highly complicated geological structure.

The Anthracite seams are situated chiefly above the great Pottsville Conglomerate bed, which, as already stated, lies beneath the Lower Productive Coal Measures in the Bituminous coal region to the west, so that, roughly speaking, they may be regarded as the representatives of the lower coals in the Pittsburgh district. It is, however, as yet quite impossible to correlate any of the thick beds of Anthracite with any of the thin Bituminous coals of the Lower Productive measures, as they seem to have been formed under quite a different set of physical and topographical conditions. The thicknesses of the various seams of Anthracite and of the intervening strata are exceedingly variable, so that it is not possible to give a general section which can be applied over any very extensive area. The following section, however, which is taken from the Pennsylvania Geological Survey Report for 1885, p. 320, will show the great thickness and value of the formation in the Southern or Pottsville coal field :

On reaching Pottsville, I made my way to the office of Mr. E. C. Luther, the General Superintendent of the Philadelphia and Reading Coal and Iron Co., which owns some of the largest and most important Anthracite collieries in the region. Mr. Luther kindly sent me on to Shenandoah, ten miles north of Pottsville, in the Western Middle, or Mahanoy and Shamokin field, where some of the best developed collieries are situated within a short distance of one another, having supplied me with a letter of introduction to Mr. John L. Williams, the Division Superintendent. On nearing my destination, the train moved upwards along the bottom of a valley, the sides of which had formerly been thickly wooded, but were now to a great extent bare or covered with tree-stumps and copsewood, only a few of the old trees having been left standing. The hill sides were thickly studded with pits, mines, coal dressing and breaking works, and huge heaps of culm, and coal dirt, which was washed down the slopes at many places and spread over the bottom of the valley in hideous black mud flats, through which the blighted trunks of dead pine trees rose gaunt and grim, while the waters of the Mahanoy Creek in the center of the glen had the color of ink from the fine refuse of the coal washing carried on at every colliery along its banks.

The Western Middle Coal field has a length of about forty miles, and a maximum breadth of about five miles, while the general direction of strike and outcrop of the seams is a little north of east. Shenandoah is geologically in a basin, the thickest coal in which is the Mammoth seam, which is extensively mined in the neighboring pits, and crops out steeply on the north and south sides of the town where it is at places worked opencast. I found Mr. Williams ready to show me round, as Mr. Luther had very kindly telephoned in advance, so that my letter of introduction was not necessary. Mr. Williams is a Welshman by birth, of great experience and ability, and spared no time or trouble in explaining the system and working of the large collieries under his charge, and rendering my visit both interesting and instructive. We drove round and spent a long day in examining the surface and underground arrangements at some half-dozen of the shafts in the vicinity of Shenandoah.

The seams in the mines are thick. The Seven-Foot seam has at places a thickness of seven feet, and the Buck Mountain seam a thickness of twelve feet, while the Mammoth Bed has, with the two thick bands of dirt that it here comprises, a total thickness of over fifty feet. These dimensions, however, are very variable, and the thicknesses of the seams and intervening strata alter very rapidly within comparatively short distances. The coal is worked on the pillar and breast or pillar and room system, and the size of the pillars and percentage of coal removed vary according to the dip, thickness, and character of the roof of the seams. In some districts the proportion of coal removed where the dips are high has been as low as 51 per cent., while in other districts with flatter dips, and under the more modern improved systems of mining as much as 80 or even 85 per cent. of the original seam is said to have been taken out. These percentages, however, do not represent the amount which is converted into commercial fuel, as the coal has to be broken and separated from the large proportion of blaes and dirt it contains before it can be sent to the market. This preparation for the market is attended with great waste, as the huge culm and dirt banks round all the collieries testify. The improved methods of screening, breaking, sorting, washing, and classifying the coal which now obtain, have greatly tended to diminish this waste, and indeed, in some cases it pays to turn over the older rubbish heaps and take out much coal that could not be sold under the more wasteful methods that were in vogue ten years ago. From 1820 to 1883, of the 59 per cent. of the original contents of the coal seams which were brought to the surface, more than half was thrown on to the waste heap. Since then, of the 70 per cent. taken out, only one-third has been lost in the dressing, a circumstance due not only to better methods of cleaning, but also to the demand for small sizes of coal, which were formerly of no economic value. At the St. Nicholas Colliery there are two slopes or mines where the Mammoth seam is worked downwards from the crop. The large breaker supplied by these slopes puts through in an ordinary day of ten hours some 2,000 to 2,500 tons, and the breaker at the adjoining Ellangowan Colliery usually puts through 1,800 tons a day, but has for a month dealt successfully with 2,000 tons every working day during that period.

The huge Mammoth seam has been mined to its full thickness under the town of Shenandoah, and the reckless way in which the pillars were robbed when the workings were in progress, some twenty years ago, I was told, began to terrify the inhabitants who thought the whole place was to be engulfed. It will, I have no doubt, astonish the members of the Mining Institute of Scotland when I tell them that at one part of these old workings the present operators, under Mr. Williams, discovered that their predecessors had left a gigantic room between the pillars, 700 feet in length and no less than 300 in breadth, spanned by an arch of rock sixty feet high, at a depth of 400 feet below the surface. This extraordinary fact is perfectly well substantiated, as the breadth of the cavity is mentioned in one of the reports by Mr. William Stein, the mining inspector of the district. Mr. Stein, by the way, is another example of the successful Scot abroad, and I was glad to learn that as a young man he used to know my father. This vast cavity was found to exist just under one of the best houses in Shenandoah belonging to a Mrs. Grant, the widow of another of our thriving countrymen, who lost his life while doing his duty in one of the collieries.

The plan adopted for preventing a general subsidence was both original and effectual. An eight-inch borehole was drilled in Mrs. Grant's garden down to the highest part of the roof of the cavity below, and into this was conveyed from a neighboring waste-bank a thick stream of culm and water. The culm, when dry, packs closely together into a solid mass, while the small quantity of water required to transport the bulky volume of its light particles, filters away through the deposit, and can readily be pumped out at the nearest shaft. In this way not only has the threatened calamity to the town been successfully averted, but a good "free toom" for the colliery waste has been found. But more than this. It has been ascertained that the culm below packs so well together that headings can be driven through it, and the roof being thus held up the remaining pillar coal can be taken out with safety and profit. I went into part of the workings which had been thus silted up, and saw a heading in the dry culm, the walls of which were wonderfully steep and solid.

This system of filling up old coal wastes in thick seams has been extended to other places where the necessary conditions are present, and several holes had been drilled and were still in process of drilling at other collieries I visited. Of course, it is not everywhere that the necessary conditions for the success of the system are to be found. I bethought myself, however, of the old Wester Main coal pillar workings below Bo'ness, where the roof of a seam some eight feet thick or more, which was worked about a century ago, has within the last two years fallen in suddenly and caused some very alarming and costly subsidences. We have in Scotland, it is true, no Anthracite culm to dispose of, but I think that the idea is a brilliant one, and might in certain circumstances be well worth the consideration of our Mining Institute.

Another point that interested me greatly was the existence of a large reversed fault, or small "thrust plane," which has now been clearly proved to run through part of the Shenandoah coal field. With us ordinary or "normal" faults are, unfortunately, phenomena of every-day experience, but in the Anthracite districts they are, I believe, almost unknown. In fact, faults of any sort are so rare in that region that their nature seems to be but little understood. Of late, however, clear evidence has been obtained that at least one reversed fault, such as are common in highly crumpled and compressed mountainous regions, has been instrumental in altering the lie of the Anthracite beds, and for want of the requisite geological knowledge much money has been lost to some of the former colliery owners of the district. The section (Fig. 4), which is drawn to a true scale of 800 feet = 1 inch, from published mining plans and from information supplied by Mr. Williams, will make the matter clear. In the Kohinoor Colliery, west of Shenandoah, the shaft, 425 feet deep, is sunk on the Mammoth seam, below which, at a distance of about 160 feet the Buck Mountain bed occurs. The beds rise steeply from the bottom of the pit, on the north, and crop out on the hillside above the level of the pit, as shown on the section. South of the colliery the Buck Mountain seam has been long known to crop out, with a dip to the south however, while the Mammoth bed occurs above in its proper place. The existence of a large reversed fault or thrust not being thought of, it was formerly supposed that there must be a return outcrop, as shown in dotted lines, between the shaft and the Buck Mountain seam, and that, in fact, there must be a so-called overturned basin, the strata in the southern part of which, being steep and upside down, were not adapted for convenient working. Instead of this, it has been ascertained that the seams which are flat at the shaft do not really begin to bend up to the south and form part of a basin at all, but at a distance of 60 yards from the pit bottom they again begin to resume their southerly dip, and whereas the former operators thought the colliery practically exhausted, the present company have opened up a fine set of dip workings which run 500 yards down the seam, whose angle of inclination is about 15 degrees. It is quite clear from the figure that there must be here a large reversed fault, as there is no room for an overturn of the strata such as was formerly supposed. The actual plane of fracture has, so far as I heard, not been found in this colliery, but in the Shenandoah City Colliery, three quarters of a mile farther east it has been passed through in the shaft and proved clearly in the workings of several seams, as is shown in the accompanying Fig. 5. The Buck Mountain seam was passed through twice in the same vertical section, both times dipping to the south, and the workings in the overlying seams clearly show that there is here no overturned basin, such as is shown on the geological maps and sections of the district, but a true plane of thrust, the edges of the strata and coal beds being curled up and crumbled just below it. I have gone into some detail on these points as their significance is considerable from a miner's point of view. If, as Mr. Williams said, the life of a colliery has been increased 20 years by the discovery of a thrust plane, then the more we know about these and other out-of-the-way phenomena, the more likely are we to keep our eyes open in the future and be on the lookout for things we would not otherwise have expected to find.

The mines and breakers give employment to a large number both of men and boys. The miners get on the average 8s. a day, and laborers 6s. 6d. Boys of fourteen (the age when they go below) get for attending the doors and switches about 19s. 4d. a week of fifty-eight hours. After one or two years they get for driving one mule 24s. to 28s., and for driving two mules 32s. When they can drive three or four mules together they get about 40s. a week, which is equal to the wages of laborers working inside the breakers. The boys, twelve years of age, who pick the dirt from the coal at the breakers, get 10s. per week.

The total cost of labor in connection with the breaking and cleaning the coal is 1s. per ton, and at present, I was told, the selling price of 7s. per ton barely leaves any margin of profit over the cost of production.

The United Colliery.

Mr. Wm. West, superintendent of the United Coal and Coke Co.'s United Colliery, at United, Westmoreland Co., Pa., writes us as follows:

"We use locked safety-lamps exclusively now, and you would be surprised at the difference it makes in the sanitary condition of the mine, and we are now making about as good time as we did with the carbon oil torches. We have made many important changes and improvements inside, among which were five brick stoppings each 3 ft. thick near the bottom of the shaft. (All permanent stoppings in the future are to be brick walls 3 ft. thick.) We also rebuilt one overcast, and built a brick feed room in the inside stables, and a brick oil house in which to store car grease.

"The bottom of the shaft has all been retimbered, the double timbers on the turnouts having collars 8″ × 16″ bolted to the legs. The collars are 16 ft. long, and the spread is 18 ft., and the turnouts are 10 ft. high. The pump room has been enlarged and is now 50′ × 18′ inside of timbers. We have put in four new pumps, three of them No. 12 Cameron pumps, 18 ins. diameter, 38″ stroke, and one Yough pump, 2 ft. diameter 4 ft. stroke, manufactured by Boyts, Porter & Co., of Connellsville, Pa. The hoisting engines are first motion, 24″ cylinders, 36″ stroke, and were built at the Vulcan Iron Works, Wilkes-Barre, Pa. The cages are self-dumping, and the coal is carried 60 ft. to the bins by machinery. The hoisting ropes are 1¼″ diameter. The engine house is a brick structure 31′ × 40′, and the boiler house is 41′ × 70′. Four new tubular boilers 5′ diam., 14′ long each, with 46 tubes in each, were added to the steam plant. The smoke and gases are carried to a 70′ iron stack. The whole plant, including the stables in the mine and on the surface and the fan house is lighted by electricity."

The United plant is certainly a well equipped one, and we congratulate the United Coal and Coke Co. on its success in making it so, and trust that the coal business of the ensuing year will be such as to yield profits to the company in proportion to the enterprise and good judgment displayed in the selection and arrangement of the improvements just added to the plant.

Among the many handsome calendars sent us with the beginning of the New Year, was a remarkably handsome one sent by Mr. A. H. Christy, Cashier of the Scranton Savings Bank and Trust Co., and issued by that institution. It contains a very fine steel engraving of the D. L. & W. Co.'s Sloan Breaker, located in this city, and is a work of art.

NOTES ON FANS.

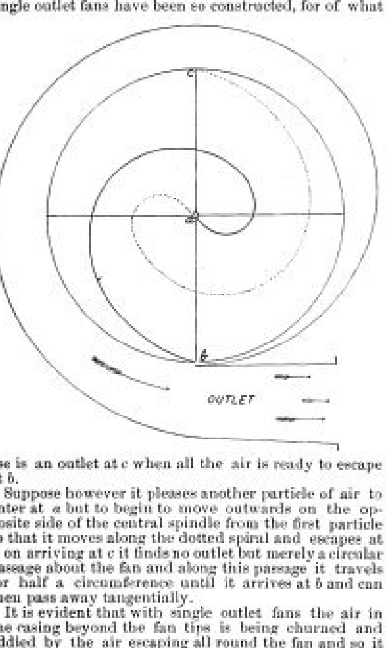
BY W. H. BOOTH, LONDON, ENGLAND.

[Written for The Colliery Engineer.]

In The Colliery Engineer for May, 1891, Mr. Wm. M. Morris, of Arkansas, sends a sketch of a fan in which the outlet is double one-half the fan discharges to one passage and the other half to the other passage, or, more correctly, one passage takes the air thrown off the fan in one-half the circumference of the casing and the air from the other half of the casing passes away by the second opening.

Mr. Morris does not, however, tell us why his improvement is an improvement, though there appears good ground for supposing that it should be.

To understand the action of the second passage we want to consider just what it is a fan is called on to do and it is simply this: to set in motion at the same velocity as the tips of the fan blades a certain quantity of air which as soon as it gets beyond the fan circumference will cease to have any radial component of motion but will move wholly tangentially. To prevent this the fan is placed in a casing which compels the tangentially moving air to travel in a circular path until it arrives at the outlet which is tangential to the tip circle. In the sketch is shown the tip circle of a fan. Let us suppose there enters this fan at the center a particle of air *a* and that as it travels to the circumference of the fan it moves in a spiral path (relative to a fixed external object) and escapes at *b* after one revolution of the fan has been made. This would tell us that no air entering the fan was thrown off sooner than after the fan had made one revolution. On this supposition single outlet fans have been so constructed, for of what



use is an outlet at *c* when all the air is ready to escape at *b*.

Suppose however it pleases another particle of air to enter at *a* but to begin to move outwards on the opposite side of the central spindle from the first particle so that it moves along the dotted spiral and escapes at *c*, on arriving at *c* it finds no outlet but merely a circular passage about the fan and along this passage it travels for half a circumference until it arrives at *b* and can then pass away tangentially.

It is evident that with single outlet fans the air in the casing beyond the fan tips is being churned and eddied by the air escaping all round the fan and so it would appear reasonable to expect Mr. Morris' idea to be productive of economy. We may calculate the angular motion of the air passing through a fan if we know the outlet volume and area in fan. In the sketch the angle is taken at 360° quite arbitrarily as an assistance in illustrating a principle, not as a hard fact.

This angle will of course vary greatly but will not vitiate the reasoning.

A fan resembles the converse of an inward flow turbine of the Thomson or Vortex type. Now we should not make such a water-wheel without guide blades to regulate the water entrance, and its flow in the vortex casing and yet with a far less solid substance, air, we make fans without guide blades on the outside, and it is a mistake to do so and though one must not carry the principle too far, there appears reason to suppose that advantage would follow three or even four outlets. Especially should this be the case with fans supplying blast to forge fires often in opposite directions from the fan.

The outlets could easily be brought more directly in line with the final direction of flow of the air and the loss due to bends and branches diminished or avoided, and these, it is so well known, are such serious factors in diminishing fan outputs. Every eddy in the outflowing stream of air means loss of forward energy and heat; the heat is a dead loss in many cases and though recovered or utilized in case of a forge fire it is expensively manufactured heat. For economy and efficiency it may be laid down as a general rule that in dealing with fluids in motion they must not be allowed to flow in two large masses or thicknesses. There is, of course, a limit to the amount of control and this of course comes at that point where gain arising from better guidance of the working stream is counterbalanced by loss arising from skin friction of guide-plates and vanes, and it becomes important therefore that the guides and vanes of fans and turbines should have the smoothest of surfaces, an item too little appreciated, but one which will enable Mr. Morris' system to be carried as far as possible.

THE PROGRESS IN MINING.

Reviews of Important Papers Relating to Mining in the Proceedings of the Mining and Scientific Societies, and in the Mining Journals of Europe, United States, and Canada.

Safety Explosives. The following is the text of a paper recently read by Mr. William Foggin before the North of England Branch of the Colliery Managers' Association.

It was not until the issuing of the Report of the Royal Commission on Accidents in Mines in 1886, that direct attention was given to the necessity of obtaining an explosive which could be used with impunity in coal mining. Previous to that date two attempts had been partially successful in solving the problem; but in both cases the objections were such as to preclude the general adoption of the explosives suggested. I allude to lime cartridges, and to the method of exploding dynamite enclosed in water invented by Professor Abel.

The first experiments which came under my notice in connection with blasting with lime were carried out at Usworth Colliery; but the results were so discouraging that nothing further at the time was attempted in this direction. The method adopted was to ram the lime well into the bottom of the hole, tightly stemming the outer end with clay, the water for slacking the lime being poured down the pricker-hole, which was afterwards stemmed. From half-an-hour to four and five hours were wasted in waiting for the results, and in about 10 per cent. of the cases no results whatever took place. A great advance was made upon this method in the introduction of compressed lime cartridges, which were manipulated somewhat similarly. These were used to a considerable extent in blasting coal at some of the large Midland collieries about ten years ago; but the time occupied (from 10 to 40 minutes) by the cartridge in doing its work was the great obstacle to its general adoption, and no doubt tended to discourage the more enthusiastic of its users.

So far as safety is concerned, the water cartridge recommended by Sir Frederick Abel really left nothing to be desired theoretically, but when submitted to numerous practical tests its weak points were found to be too objectionable to be overcome. In the first place, the unusual diameter of the hole 2½ inches added greatly to the already high first cost of the explosive and its accessories. Secondly, in spite of the extra care bestowed by the workmen in stemming the holes, my experience warrants me in stating that quite 30 per cent. of the water cartridges were burst before the firing of the enclosed shots.

These methods of securing immunity from explosions in shot-firing are, however, rapidly giving place to the more popular high-class explosives introduced to the mining world during the last half-dozen years, and it is more especially upon the qualities and capabilities of the latter that it is proposed to deal in this paper.

In passing judgment upon an explosive the following four points should be considered: 1, safety; 2, strength; 3, convenience; 4, cost.

In order to satisfy myself upon the point of safety, I carried out a series of experiments in the following manner: A cylindrical boiler 17 feet 10 inches long by 3 feet diameter, with eight apertures along one side (9 inches by 6½ inches) fitted with 1 inch plate glass, was fixed horizontally upon the ground, one end being closed with strong sheet-iron, in the center of which a hole 11 inches diameter was left in order to admit the end of the firing mortar. This latter consisted of an iron block 4 feet 7 inches long and 11 inches in diameter, with a 1½-inch hole 18 inches long drilled in the middle. A tram set upon iron rails supported the mortar, so that after each experiment it could be run back, and the process of charging and tamping the shot hole witnessed without inconvenience.

When the mortar was fixed in firing position, the outer end of the boiler was closed with a sheet of thick paper securely held in its place with an india-rubber ring.

Gas to the percentage required to form a highly explosive mixture was then let into the boiler through a 50 light meter, coal dust being sprinkled in from above, and the mixture kept in agitation by means of an iron flapper worked from the outside.

When it was thought that the mixture was thoroughly uniform, the charge was exploded electrically, and the result noted from a protected standpoint at the side of the chamber.

In designing and arranging the above apparatus, the primary object kept in view was to reproduce as nearly as possible an underground working place in its most dangerous and critical condition. And that the result was successful may be concluded from the fact that the North of England Explosive Committee, after viewing the apparatus, cancelled their previous arrangement, and adopted this plan for carrying out their experiments.

The great danger to be dreaded in underground blasting operations is undoubtedly a blown-out shot, and if this could be guarded against by any mechanical means the necessity for safety explosives would be to a considerable extent obviated; but so long as the possibility of this danger exists we shall have to depend upon one or other of the high class explosives at our disposal.

As a blown-out shot is most frequently the result of inefficient tamping, it was therefore assumed that the explosive requiring the least amount of tamping to ensure safety in the event of a blown-out shot, was the one which could be most relied upon. And on this line the experiments in connection with the gas chamber were carried out.

COMPOSITION OF EXPLOSIVES TESTED.

Dynamite consists of 75 parts by weight of nitro-glycerine uniformly mixed with 25 parts of infusorial earth, known as kieselguhr.

Tonite is a nitrated gun-cotton, the nitrate usually employed being that of barium.

Securite is a mixture of about 26 parts of meta-dinitro benzol and 74 parts of nitrate of ammonium.

Roburite consists of 7 parts of nitrate of ammonium, with 1 part of chlorinated dinitro benzol.

Ammonite is a mixture of 90 per cent. of ammonium nitrate and 10 per cent. of nitro-naphthaline.

Carbonite is composed of 25 parts of nitro-glycerine and 75 parts by weight of a pulverized preparation, consisting of not less than 40 parts of wood meal, and not more than 34 parts of nitrates of potassium and barium, with about a half per cent. of carbonate of sodium.

SAFETY.

Experiments with blown-out shots to ascertain the minimum amount of tamping required to ensure safety. Four ounces of explosive were used in each experiment.

Gunpowder was found to be unsafe in every case, irrespective of the amount of tamping employed.

Dynamite with 16 inches of wet clay stemming was safe, but shots fired with less than this amount exploded the mixture.

Tonite.—Eight shots were fired with this explosive with 16 inches and less of dry clay stemming, and each shot produced an explosion.

Securite.—Sixteen securite shots were fired, 11 with dry clay stemming from 1 to 16 inches, resulting in an explosion each time. But proved to be safe with 16 inches of coal dust or wet clay stemming.

Roburite.—Twenty-six shots were fired with this mixture, which proved to be comparatively safe with 1 inch of dry clay stemming, and absolutely safe with 1½ inch.

Carbonite.—Twelve carbonite shots were fired, with the result that 1 inch of stemming was found to be its margin of safety.

Ammonite.—Fifty-four shots were fired with ammonite, giving results more favorable than the above, inasmuch as a minimum of 1 inch of dry clay tamping, or ½ inch of wet clay were sufficient to secure safety.

It will thus be seen that out of these explosives three only can lay any claim to safety, namely: Ammonite, carbonite, and roburite. And when we can assure ourselves that an inch, or an inch-and-a-half, of stemming is all that is required to shield us from the worst effects of a blown-out shot, it must be admitted that we have every reason to be satisfied with the advance we have made in the direction of safety.

STRENGTH.

The same explosives were tested in the following manner, in order to ascertain their comparative strength.

A cylindrical shot, weighing 29 lbs., was fired from a steel mortar, and set at an angle of elevation of 45 degrees.

The following results represent the average of six shots with each explosive, a charge of five grammes (1 gramme = 15·432 grains) being used in each case:

	Range in feet.	Comparative Strength.
Ammonite	310	100
Roburite	294	94
Dynamite	264	85
Tonite	222	71
Securite	182	58
Carbonite	168	54
Gunpowder	142	45

It will thus be seen that of the three safe explosives carbonite falls a long way down in the scale of strength, being only one remove from gunpowder, and little more than half the strength of ammonite and roburite.

CONVENIENCE.

Under this head should be considered—1, susceptibility to climatic changes; 2, safety in handling; 3, resulting fumes upon explosion.

As carbonite contains 25 per cent. of nitro-glycerine, the uninterrupted use of it in the winter months cannot be relied upon. Again, should the magazine in which it is stored be at all damp, the explosive becomes perfectly useless by reason of the moisture absorbed.

Roburite is even more susceptible to moisture than the foregoing, and should be used as soon after being manufactured as possible, or kept at a constant moderate temperature.

Ammonite, on the other hand, by reason of the air-tight metallic case surrounding each cartridge, is impervious to either frost or damp, and can be kept and fired in a block of freezing ice, or used under water with impunity.

With a view of arriving at the comparative merits of these various explosives in regard to their "safety in handling," the following experiment was carried out:

A steel block, 59 lbs. weight, was hung by a rope over a pulley and allowed to drop upon the explosive, which was placed upon an anvil. In order that the block should fall evenly upon the explosive, two rigid wires were fixed perpendicularly to act as guides. A disconnecting hook was attached to the end of the rope nearest the block, so that, upon the block being wound to the requisite height, the hook could be operated by means of a light cord laid to a safe distance.

Roburite, dynamite, tonite, securite, carbonite, and gunpowder, with a fall of 5 feet, exploded in each case. Ammonite was tested at different heights, from 5 to 23 feet, without exploding.

Upon the third condition, "resulting fumes," much more has been said than can be repeated in this paper. It is a point which cannot be experimented upon in a day or a week. Much abuse was heaped upon high-class explosives in this respect shortly after their introduction, but with what amount of reason may be gathered from the recent report of the North of England Committee, which inquired into the matter, and exonerated them from the charge that any danger resulted from inhaling their fumes. The writer's experience leads him to the belief that the presence of objectionable fumes is entirely a matter of fancy.

COST.

On the score of cost, the considerations are so obvious as to scarcely require mentioning.

However, taking other points as being equal, it is only reasonable to expect that an explosive which is barely half as strong as its competitors should only be half the price.

Again, in buying an explosive, it is somewhat disappointing to have included 10 per cent. of cartridge paper, which can be bought at one-fifth of the cost.

A Method of Removing Deposit from the Inside of Column Pipes in Shafts. A paper descriptive of the above was read at the December meeting of The North of England Institute of Mining and Mechanical Engineers, by Mr. R. T. Swallow. The pipes in question formed the delivery column 1062 feet in height, of the force pumps at Hebburn Colliery. The pipes were originally 9 inches inside diameter at the bottom of the column widening out to 10½ inches at the surface and the water had a flow at first of 203 feet per minute. The pipes had been tested at the foundry previous to being put in place, to a pressure of 715 lbs. to the square inch. After having been in use 5 years one of the 9 inch pipes split down one side, and on examination the internal diameter of the pipe was found to be reduced by sedimentary deposit to 6½ inches, or little more than half their original area, so that the velocity of the water was increased very considerably. It was then decided to clean the column in position, and the following was the method adopted:

Two small pulleys were hung to the head gear at the pit mouth so that a rope passing over them hung directly over the center of the column. To the end of this rope a specially constructed cutter was fixed. This consisted of a piece of bar iron hung horizontally fitted with steel springs on each of its sides to each of which two knives were fixed, from the bottom of this cutter a length of chain weighing 448 lbs. was hung to give weight. The horizontal pipe, in the pit, leading to the foot of the rising main having been removed, the cutters were lowered to the bottom of the column and gradually chopped up and down until they reached the top of the column. After this was done the cutter was withdrawn and the knives set to the full diameter of the pipes and the operation repeated until all the pipes were apparently cleared. By this means five tons of deposit was removed at a cost of 11½ hours work and with the services of an engineman, two men on the surface and two in the pit.

Mine Ropes. The following is a summary of a report made to the French Government on the above subject for which we are indebted to the last issue of *The School of Mines Quarterly*: Iron wire rope should be strong, hard, pliable, and not galvanized. Steel wire rope should be of very homogeneous and comparatively hard quality, and suitably annealed; it should have a tensile strength of 70 to 76 tons per square inch, and should stretch from 3 to 5 per cent., and be pliable. The wire should be in all cases tested for tensile strength, stretching, bending, and torsion; and all the wires should be as closely alike as possible. Experience proves that the very material itself of every rope changes in course of working and gradually diminishes in strength until it is no longer safe. The wires become harsh and brittle. Large diameters of drums and pulleys are essential for the longevity of a rope. The smallest diameter of these should be from 1300 times the diameter of the wire for iron ropes to 2000 times the diameter of the wire for steel ropes, or from 80 to 100 times the diameter of the rope. The rope should wind smooth on the drum or pulleys without rubbing sideways, and so as to run free of jolts and flapping. The grooves of the pulleys should be lined with wood. In doubling back the rope end for attaching to the cage the loop should be kept as large as possible by inserting an iron eye or wood disc. The attachment should be made with springs to ease the strain at starting.

Ropes should be greased regularly with a grease soft enough to work into the strands right through the hemp core, but stiff enough to stick to the outside of the rope. Where the mine water is impregnated with acid, steel ropes will wear quicker than iron.

The rope should be examined every 24 hours, and this should be done by running it through the operators hands so that if he does not see all the broken wires he will feel them. Occasionally the rope should be thoroughly cleaned so that its condition may be more minutely ascertained. When broken wires are found the longest should be tucked in and the shorter ones cut off to prevent further damage by catching. When a rope is used for winding men, the shackle should be cut off regularly every two or three months, the rope thoroughly examined and the shackle re-set.

The Manufacture of Patent Fuel. A paper on this subject was lately read before the members of the Mining Institute of Scotland, by Mr. James Grant, and as the ever-increasing production of coal causes a proportionate increase in the amount of small coal sent out and the consequent call for some means of using this small coal to profit the subject is worthy of careful attention.

There are three methods of fuel making:

(1). Processes requiring drying in an oven after compression.

(2). The dry process, consisting of passing coal and pitch through hot cylinders over a furnace.

(3). The steam process which effects the melting of the pitch by hot dry steam.

This last process is the one which is now almost universally adopted.

The patent fuel is generally produced in blocks called *briquettes*. These *briquettes* are of various sizes to suit local requirements. Some works also produce egg-shaped pieces for shoveling into furnaces, these are called *ovoids*.

Patent fuel can be stowed into 31½ cubic feet per ton. Coal requires 41 cubic feet. The heat given off by

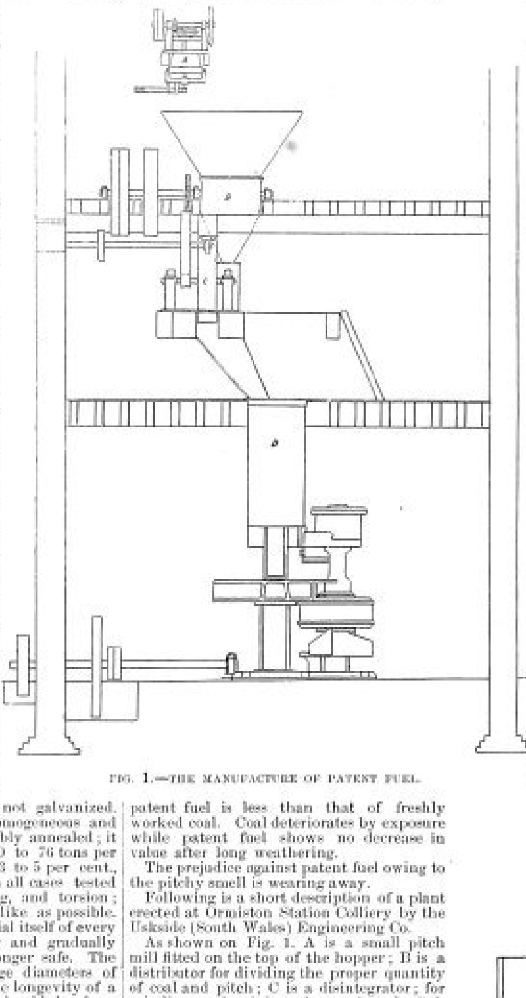


FIG. 1.—THE MANUFACTURE OF PATENT FUEL.

patent fuel is less than that of freshly worked coal. Coal deteriorates by exposure while patent fuel shows no decrease in value after long weathering.

The prejudice against patent fuel owing to the pitchy smell is wearing away.

Following is a short description of a plant erected at Ormiston Station Colliery by the Uskside (South Wales) Engineering Co.

As shown on Fig. 1. A is a small pitch mill fitted on the top of the hopper; B is a distributor for dividing the proper quantity of coal and pitch; C is a disintegrator; for grinding and mixing the coal and pitch together, D is a pug-mill where the coal and pitch are stirred and heated to the proper consistency for compression. B² Fig. 2, is a pan-mill to receive the coal and pitch, with revolving arms in it to fill the moulds; C² is the press cylinder for pressing the blocks; D² shows the amount of compression, 2½ inches on each block, which equals 1,344 lbs. pressure to the square inch of block surface. D³ is where the block is tilted off after it is finished; E is a section of the stamper that presses the block; F is the lever on the end of the piston-rod that lifts the stamper by means of what is called a hammer resting on the center of this lever. When the moulds are filled the table is turned round horizontally, a tooth at a time, by a kicker on the upright shaft that passes through the pug-mill to the top of it; and they are passed round to the top of the hammer where the blocks are pressed. After they are pressed they are passed on with the stampers rising on an inclined plane, and when the moulds get to the opposite side of the press from the hammer, the blocks are above the level of the table and are tilted off there; then the stampers are passed along on a descending plane into the pan-mill for filling. Immediately above the pan-mill, and on the bottom of the pug-mill on this upright shaft, there is an eccentric that works the slide-valve of of the press cylinder and causes the piston to give the blow. The whole of this machinery is driven by a pair of coupled engines, 10-inch cylinders and 20-inch stroke, supplied with steam at 40 lbs. pressure. The speed of the engine is sixty revolutions per minute; the speed of the main shaft of the full plant is ninety-five revolutions per minute. The pug mill and press cylinder are supplied with steam at 70 lbs. pressure from a small multitubular boiler, seven feet long by three feet six inches in diameter with twenty-eight tubes of three inches internal diameter. It requires one man on the top to fill in the coal, one boy to fill in the pitch, one pressman on the bottom floor to attend to the press and pug-mill, two laborers to take away the blocks and load or store them, and one boy to fire the boilers; in all four men and two boys. The machine turns out three tons of fuel per hour. The quantity of pitch used is from 9 to 10 per cent. of finished fuel. The principal things to attend to in making good fuel are to see that the proper quantity of pitch is filled in along with the coal; that they are both properly ground and mixed in the disintegrator; that the steam from the pug-mill is kept up to the proper pressure, and that the nozzles conveying the steam into the pug-mill are in order. There are two nozzles into the pug-mill; one about twelve inches from the bottom of the mill, and another about six inches further up on the opposite side of the mill. The diameter of these nozzles is from ⅜ in. to ½ in., screwed, into a ¾ in. tube. The height from the bottom floor to where the coal is filled into the hopper is twenty-three feet. The small coal, as it comes from the coal miners is emptied by the pit-head man into a well, made to receive it from the screening platform. The pitch is hoisted up an inclined plane in cars to the same platform, and emptied on the opposite side of the hopper.

Before this plant was erected hundreds of tons of this small coal was stowed in the workings; now it is all drawn, and whatever is left over after supplying the colliery with steam is made into patent fuel. The coal is so soft and drossy that an arrangement was entered into with the coal miners when the colliery was first opened out to screen all the coal over a ⅝ in. screen, and that enabled them to make a better job of screening it into pea and nut for the market.

The size of the briquette is 6 inches by 4 inches by 3½ inches, and it weighs four pounds.

In course of a discussion which followed the reading of the paper, Mr. Clark stated that the best coal for briquette-making was a good free-burning non-coking coal.

If the proper consistency of pitch is not used the briquettes fall in pieces after being made. One machine, such as described, made three tons per hour, or thirty four-pound briquettes per minute. The coal used was not washed. It was passed through ⅝-inch hand screen in the pit.

A New Form of Coal-Washing Machine. We are indebted to the Mining Institute of Scotland, for the following synopsis of a paper by Max Everard, on the above subject.

This is a modification of the piston-jigger, having an arrangement for scraping the surface and removing the top of the washed layer under treatment. It consists of a sieve-plate 10 feet long by 3½ feet in width, the apertures being largest next the feed end—fixed on a pyramidal hutch, having a plunger box attached to one of the long slides, and an opening variable by adjustable slides for the discharge of the heavier waste on the other. The piston is a circular wooden dish moved by an eccentric and communicating motion to the water

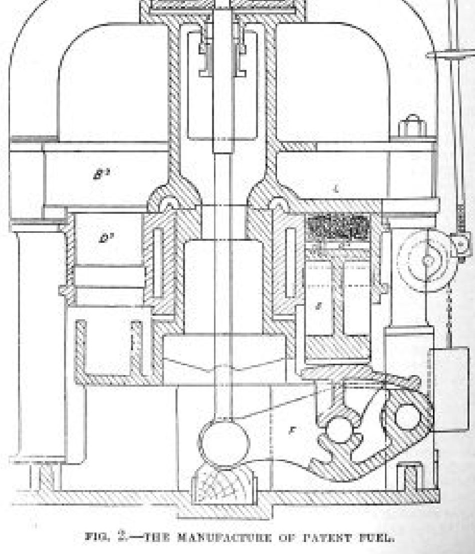

FIG. 2.—THE MANUFACTURE OF PATENT FUEL.

in the hutch through a cushion of air confined above the water in a piston box. The scraper is a harrow-like frame suspended by a system of jointed rods above the sieve-plate, and receives motion from a cam acting upon the counterpoised arm of an angle lever, which gives a slow forward and quick return motion. The frame is connected with a slide opening the feeding hopper so as to allow a fresh portion of material to be dropped upon the plate at the coarse end, at the commencement of each stroke, where it is subjected to the most energetic action of the water, while the finer portions of previous charges brought to the surface are drawn forward by the teeth projecting from the frame, towards the discharge end. Usually the frame is so suspended as to pass clear of the charge on the return stroke. The length of the stroke of the frame is 20 inches, so that the surface of the washed material is broken up six times in its passage over the 10 feet length of plate.

The machines weigh about 6 tons each, and are worked in pairs, each pair requiring a motive power of 4 to 6 H. P., and one man to attend to them; and the average produce is 15 tons per hour for the two machines.

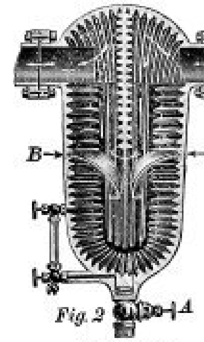
COAL-DUST AND COLLIERY EXPLOSIONS.

A series of short public lectures on "Coal and Coal Mining," in Manchester, England, was brought to a close recently by Prof. Dixon, who lectured on the action of finely divided coal-dust either in promoting or aggravating the intensity of explosions produced by fire-damp, or, on the other hand, by igniting itself and causing an explosion in mines.

Prof. Dixon believes that coal-dust of itself, under certain conditions is explosive, and the following synopsis of his lecture, from *The Colliery Guardian*, of London, is worthy the attention of American colliery managers. Attention, he said, was first directed to this question by Lyell and Faraday in the year 1845, when they found portions of charred coal-dust on the props and other articles in the pits after an explosion. The dust found by them corresponded with the dust found in the latest explosion that was attributed to the ignition of coal dust—in the Apedale Colliery, Staffordshire—but until a few years ago, although attention had been called to the *role* which dust might play in explosions, no one had attributed to dust the power of carrying on an explosion by itself, or of being the main factor of an explosion in mines. It was in connection with the explosion at Seaham Colliery, Durham, on the 8th September, 1880, that this view was first urged. Professor Dixon briefly recapitulated the circumstances of that accident and the evidence that was adduced at the time and a year afterwards—a portion of the mine having been locked up for about twelve months. It was the miners themselves, he remarked, who brought forward the theory that dust had played the principal part in the explosion, and since then particular attention had been directed to the subject, and experiments had been made, not only in this country, but also in France, Germany, and other parts of the Continent. The question which was being considered was this: "Is dust capable of producing a flame when it comes in contact with a large flame such as may be produced by a blown-out shot or produced by an explosion of gas and air?" It was not supposed that an ordinary naked light in a mine would suffice for an explosion of coal-dust and air. There must be first a great disturbance to raise the dust and mingle it with the air to make it an explosive mixture, and there must be great heat locally applied to initiate the explosion; but once that had been set up a flame might extend so far as there was the coal-dust lying on the floor or sides, and the damage done by it was comparable, at all events, with the damage done by an explosion of fire-damp and air. This was a view frequently urged, and in support of it the lecturer tried a few experiments. He showed that fine dust falling on a flame will give off flame and sparks, and that when mixed with oxygen an intense flame is produced. The difficulty, he added, was, happily, to get the requisite proportions of coal-dust and air to make an explosive mixture. The gentlemen appointed to inquire into the circumstances of the Seaham explosion came to the conclusion that there was great danger in small quantities of fire-damp in dusty mines, but they did not state that dust would explode by itself. They did not regard it as being capable or as likely to carry an explosion from end to end. From this point the lecturer went on to speak of the causes and results of the explosions at Altofts and Elemore in 1886, at Hyde in 1889, and at Llanerch and Morfa in 1890. He spoke of the inquiries which the Royal Commission are making with a view to determining the question as to whether coal-dust may be the chief factor in mine explosions. By experiments in imitation of those attempted by Mr. Hall, H. M. inspector of mines for the Liverpool district, the lecturer demonstrated that coal-dust brought into contact with flame will sometimes explode. The fact, he said, that the dust did not always explode was urged by some people as a proof that dust of itself would not produce an explosion. They said there were dusty mines that had been worked for fifty years without an explosion, and that was a stronger argument than any experiments. The lecturer, however, did not think that such an argument was sound. He hoped the Royal Commission would be able to conduct experiments on a large scale, a scale equal to the ordinary conditions of mining, so that the question might be settled. He mentioned, in conclusion, that the Austrian Commission had confirmed the German Commission in the opinion that dust could cause an explosion, and that they suggested that the danger might be met by watering the dust or by attempting to sweep it up, which of course presented great practical difficulties, or by using a particular kind of cartridge which would not produce a flame that would ignite dust or gas. If this could be done it might be possible, said Professor Dixon, to go on using shots in dusty mines.

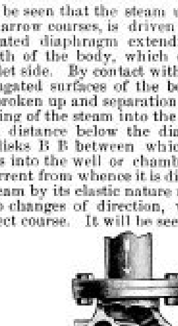
HINE'S ELIMINATOR.

We herewith present sectional views of the two forms in which this device is constructed. The Hine Eliminator is not new to the market, it was brought out in 1888, and over seven hundred of them are now in use. The exceedingly high merit it has been demonstrated to possess as a separator of water from live steam and the importance of such a device throughout the mining districts has prompted the publication. As will be seen, it is made for steam-pipe running either horizontally or vertically, and by inverting the vertical form the course of the steam, be it up or down, is immaterial. Scientific investigation has demonstrated that, to obtain complete mechanical steam separation, provision must be made for carrying the water out of and away from the action of the steam current before they can be again taken up and carried forward by the rapidly moving steam, which continually surrounds it. By reference to the horizontal style,



HORIZONTAL.

Fig. 2, it will be seen that the steam upon entering, as indicated by arrow courses, is driven against a transverse corrugated diaphragm extending vertically to half the length of the body, which divides the inlet from the outlet side. By contact with this diaphragm and the corrugated surfaces of the body the steam is thoroughly broken up and separation accomplished before the turning of the steam into the outlet side, at the proper aerial distance below the diaphragm are two converging disks B B between which the water instantly passes into the well or chamber below, out of the steam current from whence it is discharged through valve A. Steam by its elastic nature readily accommodates itself to changes of direction, while water will pass in a direct course. It will be seen, therefore, that



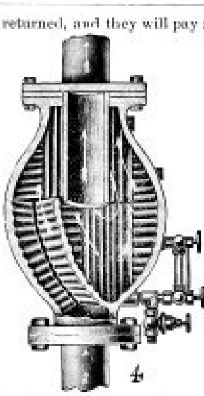
VERTICAL WHERE COURSE OF STEAM IS DOWNWARD.

the water being at once deposited in the lower chamber out of the current, the dry steam passes under the diaphragm thence upward and out, being deflected by an inward extending pipe at the immediate point of outlet.

Figure 3 (vertical). At the side on one end, a corrugated deflecting partition extends half the length of the body, forming the inlet. At the opposite end a vertical pipe, cast with a flange and standing out from the body, forms the outlet. The steam in passing through the deflecting partition obtains centrifugal action, and by contact with the inner corrugated surfaces is broken up, the water, eliminated, readily flows down the vertical corrugations and out, while the steam diverted from its direct current passes through the vertical pipe to point of delivery.

In 1891 a test of steam separators was made at Sibley College, Cornell University. The object being to determine the principle involved, the conditions necessary for the most efficient separation, and the efficiency of the best forms of separators known to the market. Suffice it to say that in twelve trials the Hine Eliminator with steam under varying conditions demonstrated an average efficiency of $98\frac{7}{10}$ per cent. dry steam, defeating in a marked degree *all* competitors.* The Eliminator is compact in construction, positive in action with nothing to get out of order, requires no attention, and is cheap.

As a manifestation of the confidence held by the manufacturers in the efficiency of the eliminator they propose to send it, in either of its forms, to any responsible party on a month's trial, with the understanding that if it fails to give entire satisfaction the same can be returned, and they will pay freight charges



VERTICAL WHERE COURSE OF STEAM IS UPWARD.

both ways. Full particulars may be had from the Hine Eliminator Co., 106 Liberty Street, New York.

*The Hine Eliminator Co. will send free the complete report of the Cornell steam separator test to any addressing them for the same.

MISSOURI'S COAL RESOURCES.

At a recent meeting of the Board of Managers of the Bureau of Geology and Mines of Missouri, a report by State Geologist Winslow was submitted, entitled: "A Preliminary report on the Coal Deposits of Missouri." It consisted of about 300 type-written pages, and was accompanied by 131 illustrations of coal beds and other subjects. An edition of 5,000 copies was ordered printed. The report contains four chapters and two appendices as follows: Chapter 1, The Coal Measures; chapter 2, The Coal Beds; chapter 3, The Coal Industry; chapter 4, A Systematic Description of Coal Beds now operated; appendix A, Notes on Coal Mining in Thin Coal Beds; appendix B, A List of the Coal Operators of Missouri.

In chapter 1 a brief outline is given of the distribution and topography of the coal measure formations, and the nature of the various rocks which exist there are described, as well as the manner in which these rocks occur. Following this is a discussion of the process by which these rocks were formed, which is especially valuable as an exposition of the laws governing the distribution of coal beds and other strata of this formation.

Chapter 2 consists of a description or the various conditions which restrict the distribution of coal and of those which restrict its availability. The general character of Missouri coals is also described here.

Chapter 3 is introduced by a few remarks on the coal production of the State, in which it is shown that Missouri ranks second among the coal producing States west of the Mississippi River and sixth among those of the whole union. Following this is a description of the geographical and geological conditions affecting the market of the coals of Missouri and adjacent States. The present uses and adaptabilities of the coals are then briefly discussed, though the lack of exact knowledge concerning these questions is deplored. An answer to the questions of the available coal in the State and the duration of the supply is dismissed as premature with the present state of our knowledge. It is estimated, however, that less than two square miles of coal land are annually exhausted in the State, and, inasmuch as there are 23,000 square miles of coal measures in the State, a small fraction of this containing workable coal would suffice to maintain the present rate of production for a thousand years. Some interesting figures are given concerning the value of coal lands, and, after recommending the coal lands of Missouri as fields for investment, the chapter concludes with the statement that we may look forward, in the march of events, to a large increase in the coal industry of the State, to profitable returns to those who invest their money sagaciously in coal lands and in the support of the dependent industry, and to an enhancement of the value of such lands now largely held and used purely for agricultural ends by private citizens of the State.

Chapter 4 contains the bulk of the report and consists of descriptions of the occurrences of coal in the State in fifty-seven counties. It is liberally illustrated by sections showing the thicknesses of the various coal beds and associated rocks, and the general character of the coal in each locality is described. The results of deep drilling and shafting in many parts of the State are included in this chapter, and the prospect of further discovery of coal in various counties is stated. A small block map showing the area of the coal measures and the general distribution of mines accompanies the report. The occurrences of isolated coal deposits or "coal pockets" in the State are also described.

In Appendix A is given an interesting description of the methods of mining thin coal beds in the State, which is an important addition, inasmuch as it demonstrates the entire availability of coal beds here, which elsewhere might be considered too thin to work.

In the preface to this report and elsewhere, the value of reliable drill-hole records for determining the extent and distribution of coal in the state is emphasized. The lack of authentic results from much drilling that has been done in the past is deplored and a plan of co-operation is suggested which deserves wide consideration, and which, if followed, will be productive of much good. It consists, in brief, of the following offer: To any private individual or community desiring to have a deep drill hole sunk, the survey offer first to recommend reliable men whom the individual or community can employ to do the work of drilling; second, it offers to supervise this drilling, and last, it offers to furnish an official statement of the results of this drilling, all free of charge, in return for this service, all that is required is that the survey be allowed full and free use of the results for the benefit of the State.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.*

Fans in Mining.

Editor Colliery Engineer:

SIR:—Please publish the following in answer to "E. R.," of Hopwood, Pa.

(1.) The fan on a certain mine has an equivalent orifice of 37·81 square feet, the mine's equivalent orifice is 19 square feet; the size of the fan is 12 ft., making 90 revolutions per minute. What is the fan's efficiency?

The theoretical head due to the fan's velocity,

$$H = \frac{v^2}{g} = \frac{(12 \times 3{\cdot}1416 \times 15)^2}{32} = 99{\cdot}93',$$

h, the effective head equals

$$\frac{H}{1 + \frac{o^2}{o^2}} = \frac{99{\cdot}93}{1 + \frac{19^2}{37{\cdot}81^2}} = 79{\cdot}79';$$

$h\ o$ = the head lost = $H - h = 99{\cdot}93 - 79{\cdot}79 = 20{\cdot}14$.

The efficiency of the fan will be as

$$79{\cdot}79 + 20{\cdot}14 : 79{\cdot}79 :: 100 : 79{\cdot}84\%.$$

The quantity passing $= 8\sqrt{79{\cdot}79} \times {\cdot}65 \times 60 \times 19 = 52{,}937$ cu. ft.

$$\text{Proof, } a = \frac{{\cdot}000385 \times q}{\sqrt{w.g.}} = \frac{{\cdot}000385 \times 52937}{\frac{\sqrt{79{\cdot}79}}{60{\cdot}4}} = 19.$$

(2.) What size fan, giving an efficiency of 50%, would you apply to the ventilation of a mine 500′ deep, the quantity of air required being 40,000 cu. ft. per minute and the equivalent orifice of the mine being 20 sq. ft.? The effective head

$$\left(\frac{40{,}000}{8 \times {\cdot}65 \times 60 \times 20}\right)^2 = 41{\cdot}088,$$

as this is only 50% of the theoretical head

$$H \text{ will equal } 41{\cdot}088 \times 2 = 82{\cdot}17 = \frac{v^2}{g}.$$

$\sqrt{82{\cdot}17 \times 32} = \sqrt{2629{\cdot}44} = 52{\cdot}46$ = velocity per second and as the number of revolutions is not given we will assume it to be 90 per minute, or 1·5 per second, then

$$\frac{52{\cdot}46}{1{\cdot}5} = 34{\cdot}97' = \text{the circumference of fan,}$$

$$\frac{34{\cdot}97}{3{\cdot}1416} = 11{\cdot}13' = \text{diameter of fan.}$$

Yours etc.,
T. S. C.

Gardner, Ill., Dec. 21st.

Arithmetic.

Editor Colliery Engineer:

SIR:—I submit the following in reply to question by "A. A.," in the December issue:

[The solution sent is the same as that of "J. S. K.," of Canon City, Col., published in the January issue.—ED.]

Yours, etc.,
BEGINNER.

Riverton, Ill., Dec. 21st.

Mensuration.

Editor Colliery Engineer:

SIR:—In the December issue "H. L. D. W.," of Buffalo, N. Y., solves the tree question for "Trackman," of Reynoldsville, Pa., but according to the figures given his work does not prove itself. I hope he will work it out in detail so as to enlighten a mining student.

Yours, etc.,
BEGINNER.

Riverton, Ill., Dec., 21st.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to question (1), asked by "A. B.," of Hanna City, Ill.:

An air-way 8′ × 8′ × 1000′ is passing 40,000 cu. ft. of air, what diameter should a circular air-way 1200′ long be to pass one-half the quantity, the pressure remaining the same?

In solving we use the formula

$$p = \frac{k\,s\,v^2}{a},$$

substituting their values

$$p = \frac{{\cdot}0217 \times 32{,}000 \times {\cdot}39062}{64} = 4{\cdot}23 \text{ lbs.}$$

The length of first air-way is found thus, when q = 20,000, and p, a, and o remain the same. Since q varies inversely as $\sqrt{l}$, we have

$$20^2 : 40^2 :: 1000 : x, \text{ or}$$
$$400 : 1600 :: 1000 : 4000, \text{ or length.}$$

Next, we find the size of equivalent air-way 1200 long,

$$l \text{ varies as } \frac{a^3}{o} = 8195',$$

then

$$4000 : 1200 :: 8196 : \frac{a^3}{o},$$

working out we find

$$\frac{a^3}{o} = 2430,$$

therefore

$$a = 37{\cdot}5', \text{ and } o = 21{\cdot}7'$$

for the circular air-way, the diameter of which would be 6′ 11″.

Proof

$$p = \frac{k\,s\,v^2}{a},$$

or substituting

$$p = \frac{{\cdot}0217 \times 26040 \times {\cdot}284089}{37{\cdot}5} = 4{\cdot}28 \text{ lbs.}$$

Yours, etc.,
N. S.

Dagus Mines, Pa., Dec. 19th.

Algebra.

Editor Colliery Engineer:

SIR:—I submit the following in answer to "A. B. C.," of Pittston, Pa.:

[The solution sent is similar to that of "T. S. A.," of Anita, Pa., inserted in the October issue.—Ed.]

Yours, etc.,
JAY.

Nanticoke, Pa., Dec. 26th.

Ventilation.

Editor Colliery Engineer:

SIR:—In reply to question on ventilation by "S. U. P.," in the October issue, which was answered by "L. P. H.," in the November number, and corrected by "S. U. P." in your December issue, I submit the following:

Suppose a volume of 64,000 cu. ft. of air per minute is passing through a rectangular shaft 8′ × 16′ and 500′ deep, what is the pressure?

If the shaft is partitioned off, *i. e.*, a brattice run from top to bottom making two 8′ × 8′ shafts, or air passages, what volume may be expected, pressure to be the same in both cases?

I think the "correction" by "S. U. P." is also wrong, and therefore work it out as follows:

$$8' \times 16' = 128 \text{ sq. ft.} = a.$$
$$64{,}000 \div 128 = 500 \text{ cu. ft.} = v.$$
$$8' + 8' + 16' + 16' = 48 \text{ ft.} = p.$$
$$500' \times 48' = 24{,}000 \text{ sq. ft.} = s.$$

Then by formula

$$p = \frac{k\,s\,v^2}{a},$$

we have by substituting and working out

$$p = \frac{{\cdot}0000000217 \times 24{,}000 \times 250{,}000}{128} = 1{\cdot}017.$$

To find volume of divided shaft we find the velocity by following formula:

$$v = \sqrt{\frac{a \times p}{k \times s}},$$

substituting values

$$v = \sqrt{\frac{64 \times 1{\cdot}017}{{\cdot}0000000217 \times 16{,}000}} = 432{\cdot}9 +,$$

Then

$432{\cdot}9 \times 64 = 27705{\cdot}6$, and $27{,}705{\cdot}6 \times 2 = 55{,}411{\cdot}2$ cu. ft. volume, and $64{,}000 - 55{,}411{\cdot}2 = 8{,}588{\cdot}8$ difference in cu. ft. lost.

Yours, etc.,
A. G.

Falls Creek, Pa., Dec. 21st.

The Siphon.

Editor Colliery Engineer:

SIR:—Will you please publish the following question in your next issue:

A siphon 550′ long and 2″ in diameter has a lift of 8′ from sump to summit, and 25′ fall from summit to discharge. What will be the volume of water discharged per minute?

The water is allowed to accumulate 14 hours, and the siphon will run off this head in addition to the water made while running in 4 hours, thus making 18 hours water run off in 4 hours. Now, what is total amount of water conveyed in 18 hours? This being 75% of water made, what will be the total amount for 24 hours?

Yours, etc.,
S. U. P.

Lawsonham, Pa., Dec. 9th.

Ventilation.

Editor Colliery Engineer:

SIR:—Will you please insert the following in reply to "Miner," of Middleport, Ohio:

If "Miner" will examine my reply to "Inquisitive" he will find I gave the figures shown as the relative quantities and not as cu. ft., the cu. ft. were given further on. I also gave a rule "As the total relative quantity is to the relative quantity in each shaft so is the total actual quantity to the actual quantity passing in each shaft."

I will assume the "Dutchman's" right and keep on till I get it right. The formula given is

$v^2 = \frac{p\,a}{k\,s} \times a$, except that p and k being common to both are cancelled and the formula becomes

$v^2 = \frac{a}{s} \times a$, or the area divided by the rubbing surface gives the square of the velocity, the square root of which is the velocity itself; when p and k are cancelled the relative velocity is found.

Then for the 11′ shaft we proceed as follows;

$a = D^2 \times {\cdot}7854 = 95{\cdot}0334$, area; circumference $= D \times 3{\cdot}1416 = 34{\cdot}5576$, and circumference multiplied by depth, or

$34{\cdot}5576 \times 800 = 27{,}646{\cdot}08$, s, and

$95{\cdot}0334 \div 27{,}646{\cdot}08 = {\cdot}003442$, the square root of which will be

$$\sqrt{{\cdot}003442} = .059.$$

Then,

${\cdot}059 \times 95.0334 = 5{\cdot}60697$, which is the relative volume for the 11′ shaft.

Proceeding in the same way for the 10′ shaft, we find the relative volume to be 4·39824.

Then

$4{\cdot}39824 + 5{\cdot}60697 = 10{\cdot}00521$, this being the total relative volume, by proportion we can determine the actual volume, for as the total relative volume is to the relative volume in each shaft, so is the total actual volume to the volume in each shaft, or for 10′ shaft

$$10{\cdot}00521 : 4{\cdot}39824 :: 100{,}000 : x, \text{ or } 43{,}959.$$

For the 11′ shaft, we have.

$$10{\cdot}00521 : 5{\cdot}60697 :: 100{,}000 : x, \text{ or } 56{,}040,$$

then,

$43{,}959 + 56{,}040 = 99{,}999$, which is within one cubic foot of 100,000.

"Miner" requests that I show how I obtained the figures given in the August issue. In working the problem over, I find that the figures given were not absolutely correct, the error arising from dropping decimals. If "miner" will work the problem out, as I have shown he will find it is correct, or near enough, when it comes within one cubic foot. If he will furnish his address I will cheerfully forward the manuscript I have used in working it out.

Yours, etc.,
S. U. P.

Lawsonham, Pa., Dec. 21st.

The Nanticoke Disaster.

Editor Colliery Engineer:

SIR:—My views regarding the Nanticoke disaster are simply that there was an insufficiency of ventilation instead of an increased amount. Undoubtedly, in this case, the ventilation was diminished one-fourth and, perhaps, one-third by the wagon left standing in the air-way. The increased resistance to the fan, with the removal of stoppings and the liberation of gas helped to increase the temperature in the mine until it overcame the pressure and friction in the downcast, assisted, no doubt by the pressure through the bore-holes at the inside shaft. Then came the reversion of the ventilation and with it the explosion and loss of the twelve unfortunate men. It was an unlucky mistake of some one to have left the wagon standing there as the mortar should have been shoveled out and the wagon removed. It ought to be one of the rules at all mines that the air passages must not be contracted by leaving any obstructions in them longer than can possibly be avoided.

Yours, etc.,
ROBERT ROCHESTER.

Robbins Station, Pa., Dec. 27th.

Mathematics.

Editor Colliery Engineer:

SIR:—Please insert the following question in your journal:

A shaft 12′ in diameter was measured by a rod the exact depth of the shaft, and on leaning it over against the other side, thereby forming the hypothenuse of a right-angled triangle, it lacked one inch of reaching the top, what is the depth of the shaft? Please explain fully.

Yours, etc.,
F. W.

Duncan P. O., All'y Co., Pa., Dec. 30th.

Mechanics.

Editor Colliery Engineer:

SIR:—I submit the following question for solution in your journal: If the pressure of an engine is 44 lbs. per sq. in., diameter of cylinder 1′ 8″, length 6′, and paddle-wheel makes 20 revolutions per minute, what is its power?

Yours, etc.,
THOS. M. BROWN.

Pinckneyville, Ill., Jan. 2d.

Methods of Working.

Editor Colliery Engineer:

SIR:—Please insert the following question for solution by some of your able correspondents:

In a vein with 4′ of solid rock between top and bottom coal, the top coal being 3′ 8″ and the bottom coal 2′ 6″ thick and with a pitch of 63°, it is proposed to work the coal out, leaving the 4′ of rock intact. Please state how you would drive the gangway and air-way and how you would open and work the breasts. Also, how would you ventilate the same?

Yours, etc.,
J. T. HOWLAND.

Hazleton, Pa., Jan. 5th.

The Practical Work of Engines.

Editor Colliery Engineer:

SIR:—I quite agree with "R. M. H.," of Denver, Colo., that a discussion of the subject of the work of engines would be highly entertaining to your readers for it is an important one and is also very extensive. As he criticises the formula I gave in the August number of your valued journal I beg leave to ask space in which to offer the following in the hope that some of your readers may in like manner contribute to a much neglected branch of mining work.

The fundamental principles of mechanics involve two conditions depending upon the theory of the conservation of force and of motion; that equilibrium is established first when action and reaction are equal and, secondly, when the "moments" of the forces are equal to those of the resistances. To state these conditions in plainer terms, if the state of a body with respect to rest or motion is not changed, that body is in equilibrium and the forces acting upon it are not greater than the resistance which that body is capable of offering. The instant that a change does take place—that the body begins to move—then at that instant the sum of the forces is greater than the sum of the resistances offered by the body and its intervening members.

To satisfy the second condition of equilibrium which pertains, not to motion in a straight line as that of the former case, but to rotary motion, two elements are involved. Not only is the force or resistances considered but also its lever arm. When a force acts through a lever arm to produce rotation, the product of the force measured in pounds and the lever arm measured in feet, is called a "moment." Thus a man pulling on a five foot crow-bar with a force of 25 pounds is exerting a tendency to motion called a moment of 125 ft. pounds, (see January issue of THE COLLIERY ENGINEER, page 139). Now according to the "principle of moments"—the second condition of equilibrium—the sum of the moments of the forces must not exceed the sum of the moments of the resistances. If it does, motion takes place and this is true of any form of mechanism. Our muscular effort upon the crow-bar having a moment of 125 ft. lbs., can only overcome a moment equivalent to that. Thus, we can lift a 600 lb. box if it rests not further than $2\frac{1}{2}$ inches from the lower end, because $600 \times 2\frac{1}{2} \div 12 = 125$.

(1). If, on the other hand the 25 pounds operate on the 15 inch crank arm of a windless, the moment is 31·25 ft. lbs. which is only capable of balancing or holding in equilibrium $83\frac{1}{3}$ lbs. of weight suspended from the 9 in. barrel, because

$$25 \times 1\tfrac{1}{4} = 31\tfrac{1}{4} = 83\tfrac{1}{3} \times \tfrac{3}{8}.$$

If now, we measure the friction of the axle in the standards and find it to be 10 per cent., the expression becomes

$$31\tfrac{1}{4} = \tfrac{3}{8}\,(W + 0{\cdot}10\ W) \text{ whence } W = 75{\cdot}7 \text{ lbs.}$$

(2). If instead, of a windlass, we examine a winch and determine the conditions of equilibrium, we find now a complex system of levers. Nevertheless the principle is readily followed. Herein the power works on a crank arm and turns a toothed wheel (A) which engages into another toothed wheel (B) on the axle of which is the barrel carrying the rope and its load. The equilibrium is established when the pendent load (L) from the barrel is just being moved by the muscular effort P on the crank arm l. Now if the crank turns its wheel, A must move in which case the moment P l must be equal to, or greater than, the resistance R acting on the teeth with a lever arm equal to the radius r of the wheel A. Whence

$$P\,l = R\,r \text{ or } P\,l > R\,r.$$

This resistance R is received from the teeth of the wheel B and before B and its barrel can move, we have a similar condition of moments in which case

$$L\,m = R\,n \text{ or } L\,m < R\,n.$$

L m is the radius of the barrel and n, of the wheel B. Whence P l must be greater than R r and R n greater than L m. Or, P l n must exceed L m r. But as the sizes of the teeth in A and B are the same, then the number of teeth is proportional to the length of the circumference of the respective wheels and if x and y respectively represent the number of teeth we have

$$x : y :: r : n.$$

Finally P will balance a load, not to exceed

$$L = \frac{P\,l\,y}{m\,x}.$$

With fairly good castings, the friction of the toothed wheels should not exceed 25% of the pressure in which case

$$P = \frac{m\,x}{l\,y}\,(L + \tfrac{1}{4}\ L) \text{ and } L = \tfrac{4}{5}\,\frac{P\,l\,y}{m\,x}.$$

Let us now apply the same rules to the examination of the steam engine hoister, the pitman rod from the piston being directly connected by crank pin to the hoisting drum. Here we have the first case (1 above). With the area of each cylinder designated by A, the boiler pressure, by p, the length of the stroke by 2 C, and the diameter of the drum by D 2 R, we have P, the steam pressure on each piston as the active force with a lever arm C, giving a moment P C to balance that of the friction and the load with a lever arm R.

If c is the number of cylinders, one or two, and a plain slide valve engine be assumed with an internal friction of 10%, leaving 0·90 P as effective; and if the external friction of the sheave and the stiffness of rope be taken at 4% of the load, we have

$$0{\cdot}90\ p\ A\ c\ C = (L + 0{\cdot}04\,L)\ R$$

If the engine is double cylinder and if the cranks are set "at quarters," then one piston is operating at a dead point while the other is at full lever arm, whence

$$0{\cdot}90\ p\ A\ C = 1{\cdot}04\ L\ R.$$

When, however the crank pins are at 45° from the dead points, the maximum effect of the steam is exerted, in which case we have

$$0{\cdot}90\ p\ A\ c \times 0{\cdot}707\ C = 1{\cdot}04\ L\ R.$$

The relative length of the connecting rod has a very great influence in the calculation, but unless we have an expression for its length we must neglect it. The load L, therefore which a double cylinder direct-acting, cylindrical drum hoister can start will be between

$$0{\cdot}865\ \frac{p\ A\ c}{R} \text{ and } 1{\cdot}223\ \frac{p\ A\ c}{R}$$

according to the position of the crank pin.

(2). For a second motion engine, we have the case already mentioned where P is again $c\,p\,A$ with the similar limitations as to position of pin.

When, however we examine the case of a cut-off engine we are met with the question as to the least steam pressure which the piston exerts, not the boiler or throttle pressure, nor even the mean effective pressure, but the force operating at any given instant as compared with the resistances then operating. Engines in good working order provided with cut-off, allow the expansion substantially according to the law that the pressure falls in inverse ratio with the expansion of the steam. A $\frac{1}{2}$ cut-off gives a $\frac{1}{2}$ steam pressure at the end of the stroke. As a hoisting engine must be capable of starting the load from any point in its stroke, its weakest position must be examined. Then if f indicates the fractional part of the cut-off, the weakest condition of the hoister is at the end of the stroke when

$$L = 0{\cdot}865\ \frac{f\,p\ A\ c}{R}.$$

Here surely it would be advisable for the engineer to endeavor to stop the engine with its crank pins at 45° from the dead points.

If there are 2 cylinders the values for the steam pressure at the 45° points can only be given when the amount of the cut-off is known. For the steam pressure p^1 at any point, k, *beyond the point of cut-off*, is always a fractional part of the throttle-valve pressure p expressed by

$$p^1 = \frac{f}{k}\,p.$$

All of the above calculations were for the purpose of ascertaining the load which an engine can *start*. The operation of starting requires greater energy than is afterwards necessary to keep up the proper mean velocity of the combination. When once in motion, the velocity is more easily maintained. Moreover, the parts of the engine having acquired a certain momentum can thereby assist the piston at such points as its steam pressure is weakened by expansion and also at dead points. Hence the excess of power during one portion of the stroke may be availed of at other points of the stroke. Such consideration introduces the additional element of time, and the *work* (not the *power*) of an engine is measured by the time occupied in its performance.

As this portion of the discussion was so fully treated in recent issues of THE COLLIERY ENGINEER, I would not occupy valuable space by repetition, except to review two cases. The capacity of a plain slide-valve engine to do work, varies with its consumption of steam; and the load it will hoist at a given speed s, increases with the area of the piston, the length and number of strokes and the pressure of the steam.

A direct connection, plain slide-valve hoister with cylindrical drum, offers the following condition of equality of momentum at t strokes per minute.

$$0{\cdot}90\ p\ A\ s\ c\ t = 1{\cdot}04\ L\ v = 1{\cdot}04\ L \times 3{\cdot}1416\ R\ t,$$

whence

$$L = 0{\cdot}275\ \frac{c\ p\ A\ s}{R}$$

allowing for 10% internal and 4% external friction. One book gives an erroneous formula as follows:

$$0{\cdot}90\ p\ A\ c\ t\ 3{\cdot}1416\ s = 1{\cdot}04\ L\ 3{\cdot}1416\ R\ t.$$

A geared slide-valve engine, with 20% internal and 4% external friction gives

$$0{\cdot}80\ p\ A\ s\ c\ t = 1{\cdot}04\ L\ v = 1{\cdot}04\ L\ \frac{x\ t}{2\ y}\ 2\ 3{\cdot}1416\ R,$$

and

$$L = 0{\cdot}245\ \frac{c\ p\ A\ s\ y}{R\ x}.$$

Cut-off engines are not so easily calculated, for we have now to deal with the mean effective pressure of the steam during the entire stroke. This, in the formulæ given by "Equity," in the July number, is represented by $a\,p$. Though it may be calculated, many works on steam give tables for the mean pressure, which value is to be introduced above instead of p. Below is an abbreviated table of this kind in which the initial pressure is represented by unity, 1·00.

Period of Cut-off.	Mean Pressure a.
0·20	0·567
0·25	0·637
0·333	0·726
0·40	0·787
0·50	0·890
0·60	0·913
0·666	0·942
0·75	0·969
0·875	0·992

This discussion has taken more space than I had intended to consume, but it is my understanding of the case, and as I have verified many of the formulæ on large hoisters by indicator cards and otherwise, I believe that whatever discrepancies may appear to exist or become manifest by the use of the numerous formulæ offered for solution arise only from the variation of allowances made for the various frictions, clearance, the effect of position, and length of the connecting rod or pitman, and the friction of sheaves or stiffness of rope—not from any error of principle or theory. I trust that some of our fellow readers will contribute to the general good, as it was this thought that prompted me to offer the present.

Yours, etc.,
THEORIST.

Golden, Colorado, Jan. 17th.

P. S.—The equations given above assume a connecting rod between piston and crank pin, of very great length (in fact, of an infinite length) such that its various positions are parallel, and the steam pressure is always exerted horizontally upon the crank. Strictly speaking, the equations only apply to that condition.

But as the pitman is of finite length and quite short, its several positions are not parallel, but are measured between two convergent positions, each at the angle above or below the horizontal whose *sine* is equal to the quotient of the crank-arm by the connecting rod. Between these two extremes, the rod assumes various angular positions and hence imparts to the crank-arm a driving power which is neither horizontal nor tangential to the crank circle. This force for the instant, is less than it would be in either of the other cases.

The result is that during the period of time while a piston moves through the rectilinear path of its stroke, "at a rate which is gradually increasing until it attains a maximum, and then as gradually diminishing until the piston comes to rest," the crank-pin travels in a circular path with a "velocity which, though actually variable, may be considered as uniform for all calculations possessing sufficient refinement for practical requirements." The work being the same for one stroke as that of the resistance during the same time, but over the semi-circumferential path of the crank-pin, it follows that the mean driving power on the pin bears the same ratio to the total steam pressure as does the length of the stroke to the semi-circumference of the crank circle.

These variations influence the steadiness of driving; for the uniformity depends solely upon the "ratio subsisting between the work imparted to an engine by the steam pressure, and that given out to overcome resistance."

The variations in the effect produced by a finite connecting rod are only spent in pressure downward on the slide-bars and upwards on the crank-shaft journal. No power is lost except that consumed in overcoming the increased friction.

A fly-wheel would regulate this irregularity if it could be applied to a hoister, but that is out of question. Hence the methods must be by the use of duplex cylinders with their "cranks at quarters," or by the compound system which lends itself well to the plan.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to question by "Carbon," of Lemont Furnace, Pa., in your last issue: If we have 6,250 cubic feet of air traveling in a mine through an area of 25 sq. ft., and wishing to have 22,500 cubic feet per minute in the mine with the same power, how large should the area be?

Since the quantity passing is in proportion to the area, other things being equal, therefore

$$6{,}250 : 22{,}500 :: 25 \text{ sq. ft.} : x, \text{ or } 90 \text{ sq. ft.}$$

Again, as the power is the same in both, the velocity is also, and by the formula $\frac{q}{a}$ we find the velocity to be 250 cubic feet per minute. We have by the formula

$$\frac{q}{v}, \text{ or } \frac{22{,}500}{250} = 90 \text{ sq. ft.},$$

the same as before.

Yours, etc.,
L. P. H.

Avoca, Pa., Jan. 13th.

Ventilation.

Editor Colliery Engineer:

SIR:—Will some of your correspondents kindly explain the following facts:

A mine, drift opening, has the inlet and furnace on same level; the diameter of shaft being 6′, and depth 70′; area of inlet 6′ × 9′. Size of furnace: width 6′ from grate to arch 4′, arch 14′ long, and dip 24′ in 1200′. The intake goes down the dip and return air comes back parallel with intake but rising to same level when it reaches the furnace. With a good clear fire a volume of from 10,000 to 15,000 cubic feet is obtained. Another mine, also drift opening, has noa furnace or shaft, but a small fire-place built under a 20′ stack. The area of inlet is 5′ × 7′ and area of return airway 4′ × 5′. The rise being 30′ in 1200′. The intake air rises and return air comes down to same level as inlet. With a very small fire from 2500 to 4000 cubic feet of air can be obtained. Please explain fully why more air in proportion to amount of fire can be obtained in the mine in which the intake air rises. In both cases the air must travel against dips, in the first case the intake goes down the dip, and in the second case the return air comes down the dip.

Yours, etc.,
S. U. P.

Lawsonham, Pa., Jan. 15th.

IMPORTANT INFORMATION FOR STEAM USERS.

How Boilers May be Cheaply and Effectually Protected from Scale, Corrosion and Pitting.

The corrosion and pitting in steam boilers and deposition of mineral in form of scale is one of the greatest evils that steam users in general have to contend with, but more particularly does this problem confront the owners of mines, from the fact that in nearly every case the feed water contains, besides the usual amount of scale forming mineral, more or less sulphur, which at the ordinary boiler temperature is transformed into sulphuric acid. This acid is cumulative and having a somewhat greater specific gravity than water, usually finds its way to the lowest parts of the boiler or in such nooks and corners as have the least circulation. The destruction of steam boilers from this source is often very rapid and frequently takes place under a covering of scale, which hides the mischief until the boiler is nearly eaten through.

Much effort has been expended in devising ways and means to neutralize the effects of the acid. The prevalent idea has been to fight the acid with an alkali, but aside from the excessive cost there are a number of objections to setting up a chemical laboratory in a steam boiler. Foaming and the saponification of the oil used in the cylinders with the result of destroying the lubrication, are two objections of several we might mention. A most successful method of dealing with the problem of scale and corrosion and which has been adopted by many of the largest mining companies in the United States and Mexico, is by the use of a non-chemical compound, the base of which is a heavy natural oil having a vaporizing point in excess of the highest temperature of the boiler, thus preventing its evaporation with the steam. This oil is freed from the residuum products incident to all natural oils, which if allowed to enter the boiler, would unite with the mineral and form a substance resembling putty, infinitely worse in its effects than the ordinary scale.

This compound acts by coating the inside of the boiler in a manner so slight as to be scarcely perceptible, yet sufficient to prevent adhesion of mineral particles contained in the feed water and being proof against the action of the most violent acids, prevents them from attacking the metal. A letter from the engineer of the Paris [Tex.] Compress Co. states that four years ago they put in a new set of boilers, the old ones having been eaten up by the acid in the feed water while using the best known of the alkali compounds, to prevent such a result. The boilers were started with the petroleum compound described above and although the water is so bad as to turn a tin dipper into a sieve in three weeks use, there are no signs of any corrosion or pitting in the four years use and in that time they have evaporated 20% more water than when they were using the old boilers.

The individual atoms of scale forming mineral boiling up through this compound become coated with it and their tendency to crystalize or aggregate in the form of scale is prevented, and they are held in solution until the boiler can be emptied and washed out.

The cost of preserving and keeping boilers clean by this compound is but one third of that by any other method, and the cost is offset several times over in the saving of fuel to say nothing of repairs.

A pamphlet containing further particulars will be mailed free on application to the Pittsburgh Boiler Scale Resolvent Co., Pittsburgh, Pa.

[Among the large number of users of this compound are Carnegie Bros & Co., Oliver & Roberts Wire Co., Dilworth Porter & Co., of Pittsburgh, Pa.; Des Moines Edison Light Co., Des Moines, Iowa; Union Bridge Co., Athens, Pa.; Pottsville Iron & Steel Co., Pottsville, Pa.; etc., etc. These parties use the compound continuously, and the fact that it proves satisfactory to them, and saves them money by saving their boilers should be argument enough to induce all mine owners and superintendents having any trouble from corrosion and pitting of boilers to try a remedy that is so cheap and that has received the indorsement of many of the largest and most prominent steam users in America. Ed.]

The Acme Coal Drill.

One of the most successful hand coal and rock drills on the market is known as the Acme Drill, and is manufactured at the Peoria Coal Drill Works, Peoria, Ill.

Mr. James T. Johnson, the proprietor of the works, is the patentee of the drill. He informs us that he established his works in 1887, and that during the past five years, he has introduced his drill in every mining region of the West. It will drill a hole at any angle, and will do equally well in an 18 in. seam or a 20 ft. seam. It is light and handy, and can be worked easily with one hand. There are three kinds manufactured, and he is about introducing an improved drill with bearings in boxes that can be taken out and replaced, instead of replacing the box, which lessens the cost for repairs more than one-half. He claims this to be the most important improvement in coal drills yet made. He is also manufacturing coal-cutting machines and coal mining machines which will prove both effective and economical. When ready to place on the market, these machines will also be described and advertised in our columns. Descriptive pamphlets fully illustrating the Acme Drills will be sent free on application to the Peoria Coal Drill Works, Peoria, Ill.

The Stratton Separator Company, 32 Cortland Street New York City have recently furnished to the Columbian Iron Works & Dry Dock Co., of Baltimore, Md., several large separators for use in the new cruisers Nos. 9 and 10, which they are now constructing for the government. These separators are of the naval type especially constructed with steel shells and brass heads to meet the requirements of the United States navy.

THE WEATHER AND ANTHRACITE COAL.

A Measure of the Influence of Warm and Cold Winters Upon the Consumption of Anthracite Coal.

BY H. GAWTHROP, PHILADELPHIA.

[Written for The Colliery Engineer].

In every week's report of the coal trade, and every letter from local correspondents to the trade journals, for the greater part of the year, reference is made to the effect of temperature. As the mercury goes up, coal goes

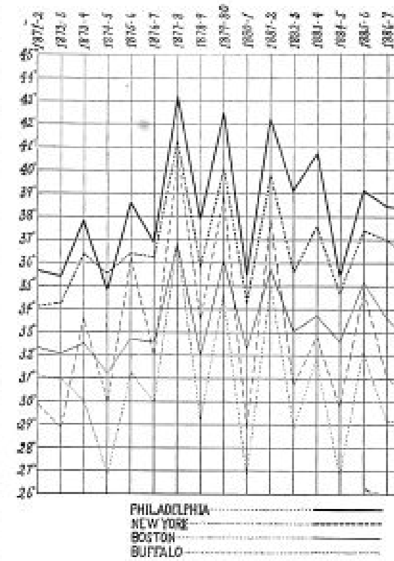

CHART NO. 1.

Mean Temperature of the five largest Cities for the six coldest months—November to April, inclusive.

down, and the reverse. Reference is more frequently made, of late years, to temperature, because buyers are content to let first hands carry the stocks, knowing that the coal can be had when they wish it, and at little difference in prices throughout the year, thus making the trade more sensitive to influences. Every cold wave causes an active demand which quickly falls off during the intervening warm spells. As the vast "areas" of "high" and "low" barometer and thermometer cross our so-called temperate zone many times in a month, the countenances of those engaged in the business are subjected to a lengthening and shortening process which, as most of them become used to it, affords a striking example of human endurance.

When we consider that for twenty years the government has recorded the temperature closer than ever before, it is reasonable that its influence on the consumption of coal should be measured, and at request, the writer will attempt the problem.

The yearly tonnage of Anthracite coal is chiefly influenced by three causes: (1). The increase because of the growth of the country in new houses and new manufactories, and by its substitution for other fuel, all of which for want of a better name, we will call the "normal increase". (2). The fluctuations by reason of the activity or depression of manufacturing industries,

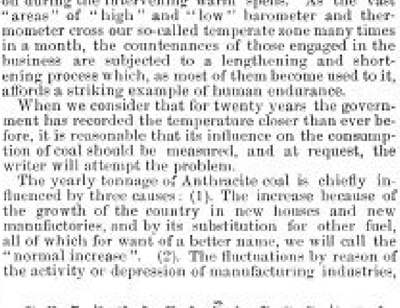

CHART NO. 2.

Average Mean Temperature for Six Months—November to April, inclusive, of Philadelphia, New York, Boston, Buffalo and Chicago for Twenty Years.

and (3) the variations of temperature. It is proposed to examine more particularly as to the influence last mentioned and to measure it, but the others must be considered incidentally.

The quantity of coal carried over on the first of January, from one year to another, is so small in comparison with the years' tonnage, that we are safe in considering the production of the mines, or rather the coal shipped from the mines, as being the same as the consumption, for the *difference* between the stock in first hands at one first of January, and another, is only about half a million tons, or three days production. Moreover we must have in mind, that, as a rule, when stocks are low in first hands, the dealers and consumers bins are full, and the reverse, so that practically there is little difference in the quantity of coal above ground at the close of the years.

Reference has been made to the similarity in the changes of the temperature at the five cities of Boston, New York, Philadelphia, Buffalo, and Chicago in the winter season. This is illustrated in Chart No. 1, and shows that we have to deal with a homogeneous condition of temperature in what may be considered the territory in which Anthracite coal is consumed. It is remarkable that it should be so, and simplifies our problem. Except in case of Chicago, it will be seen that there was only one crossing of the lines in the twenty years. That city was wayward for a time, but of late years, has kept lock step with the others.

The annual, seasonal and diurnal variations of temperature are so countless that it renews one's confidence in the fundamental causes governing climate to see the parallelism of temperatures shown in the Chart.

For our purpose, we will take the average mean temperature of the six coldest months for each of the twenty years, November to April inclusive, in the cities mentioned to see the effect of the changes upon the tonnage of the year following. In the twenty years there were thirteen years in which the winter season alternated cold and warm. At the commencement of the twenty years there was a cold period of four years, and at the close, as we all know, there has been a warm period of three years. In detail, the temperature and tonnage of the ten years, midway of the twenty, divided under head of cold winters and warm winters, as they were below or above the average temperature, were as follows:

COLD WINTERS.

1877.	Temperature of previous winter.....	33·5°.	20,828,179 tons.
1879.	Temperature of previous winter.....	33·7°.	26,142,689 tons.
1881.	Temperature of previous winter.....	31·5°.	28,500,017 tons.
1883.	Temperature of previous winter.....	33·4°.	31,793,027 tons.
1885.	Temperature of previous winter.....	31·3°.	31,623,530 tons.
	Average of five years.....	32·8°.	27,777,488 tons.

WARM WINTERS.

1878.	Temperature of previous winter	39·5°.	17,605,262 tons.
1880.	Temperature of previous winter	38·5°.	23,437,242 tons.
1882.	Temperature of previous winter	38·1°.	29,120,096 tons.
1884.	Temperature of previous winter	35·8°.	30,718,293 tons.
1886.	Temperature of previous winter	35·7°.	32,136,362 tons.
	Average of five years.....	37·5°.	26,603,451 tons.

The difference between the average of the two groups is 1,174,037 tons, but as the warm winters were one year later than the cold winters, there must be added to this the normal or average increase for a year. For our purpose, in this instance, we will take the average tonnage of the last ten years, 1882 to 1891 inclusive, 33,989,926 and deduct from it the average of the first ten years, 1872 to 1881 inclusive, 21,579,972 leaving 12,409,954 as the increase in ten years, the temperature of which we are considering. This method eliminates the influence of general business which, in a period of ten years, may be both good and bad. We thus find that the average for the ten years was 1,240,995 tons. This we add to the 1,174,037 and the result is 2,415,032 tons as the effect of temperature for one year. Fortunately we can test this roundabout process, for we have three other groups of ten years each. By summing up in the same way, the tonnage following five cold winters is found to be in excess of that for the five warm winters as follows:

Ten years 1875-1884..........	1,518,896 tons.
Ten years 1876-1885..........	3,901,107 tons.
Ten years 1877-1886..........	1,174,037 tons.
Ten years 1878-1887..........	3,536,695 tons.

To or from these results we must add or deduct the normal increase to find the effect of temperature for one year, accordingly as the warm winters follow the cold or the reverse, but as one condition offsets the other, the easiest way is to add the figures of the four groups and divide by four. The result is 2,032,661 tons, as the effect of temperature for one year.

We may consider from this that the result of our first process is conservative and proceed with it. The average temperature of the warm winters was 37·5°, and that of the cold winters 32·8°, the difference was 4·7°. If this range of temperature effected the product to the extent of 2,415,032 tons, as shown above, then the effect of one degree would be 513,836 tons. The average tonnage of the ten years, 1877 to 1886, during which we find this effect, was 27,190,470 tons. Hence we find that the influence for one degree of temperature was ·0189 per cent. of the tonnage. From our study of the subject and giving consideration to the result in the other groups, we feel warranted in claiming that the influence of temperature is two per cent. for every change of one degree in the cities named.

Now for the application. In the table below, opposite the year, will be found the average mean temperature of the five cities for the winter (or correctly speaking, the six coldest months); the variation from the average; the percentage at 2% for each degree, and the resultant effect on the tonnage.

nage of those years. Then the times improved until 1882, followed by the reaction which culminated in 1885. The effect of this reaction in business is strikingly shown in the transportation bulletins, recently issued by the Census Bureau. Then occurred the only break in the otherwise steady advance for the 10 years in railroad traffic. Anthracite in that year was evidently saved from serious depression by the previous

TABLE NO 1.—INFLUENCE OF TEMPERATURE.

November to April, inclusive of the years.	Average Mean Temperature of the five cities for six months.	Variation from average temperature.	Percentage at 2% for each degree.	To or from tonnage of years following the periods of temperature given:	
				Add.	Deduct.
1871-2	32·6°	— 2·3°	·046		995,338 tons.
1872-3	32·3°	— 2·6°	·052		1,049,290 tons.
1873-4	34·1°	— 0·8°	·016		317,246 tons.
1874-5	31·7°	— 3·2°	·064		1,185,712 tons.
1875-6	35·1°	+ 0·2°	·004	74,301 tons.	
1876-7	33·5°	— 1·4°	·028		567,304 tons.
1877-8	39·8°	+ 4·9°	·098	1,912,767 tons.	
1878-9	33·7°	— 1·2°	·024		630,390 tons.
1879-80	38·5°	+ 3·6°	·072	1,818,406 tons.	
1880-1	31·5°	— 3·4°	·068		1,814,608 tons.
1881-2	38·1°	+ 3·2°	·064	1,991,118 tons.	
1882-3	33·4°	— 1·5°	·03		926,011 tons.
1883-4	35·3°	+ 0·4°	·008	247,728 tons.	
1884-5	31·8°	— 3·1°	·062		1,846,195 tons.
1885-6	35·7°	+ 0·8°	·016	502,543 tons.	
1886-7	33·9°	— 1·0°	·02		679,236 tons.
1887-8	33·3°	— 1·6°	·032		1,182,833 tons.
1888-9	37·2°	+ 2·3°	·046	1,707,290 tons.	
1889-90	39·5°	+ 4·6°	·092	3,633,916 tons.	
1890-1	36·9°	+ 2·0°	·04	1,685,347 tons.	
Average	34·9°	2·2°	·044		

Attention is called to the fact that the average variation of the temperature was 2·2° and the range from 3·4° below to 4·9° above the normal temperature, or altogether 8·3°; and the average percentage of influence on the tonnage was ·044 with a range of ·166 per cent. This is one-sixth, and if applied to the present product represents an extreme influence from temperature of nearly seven million tons, a factor well worth considering.

In the next table, we give in the first column, the Anthracite product and in the second column the result of correction for temperature, reached by adding or deducting from the production the figures in the foregoing table.

TABLE NO. 2.—ANTHRACITE TONNAGE.

Years.	Production shipped from mines.	Corrected for temperature.
	Tons.	Tons.
1872	19,669,778	18,833,440
1873	21,227,952	20,178,662
1874	20,145,121	19,827,875
1875	19,712,472	18,526,760
1876	18,501,011	18,575,312
1877	20,828,179	20,260,875
1878	17,605,262	19,518,030
1879	26,142,689	25,529,970
1880	23,437,242	25,255,648
1881	28,500,017	26,685,409
1882	29,120,096	31,111,214
1883	31,793,027	30,867,016
1884	30,718,293	30,966,021
1885	31,623,530	29,777,335
1886	32,136,362	32,638,905
1887	34,641,018	33,961,782
1888	38,145,718	36,962,885
1889	35,407,710	37,115,000
1890	35,865,174	39,499,090
1891	40,448,336	42,133,683

In chart No. 2, the average monthly temperature of the five cities given above are shown by the heavy line drawn to the scale of degrees on the margin, and the average for the six months by the dotted line. Chart No. 3 exhibits the tonnage figures given in the table.

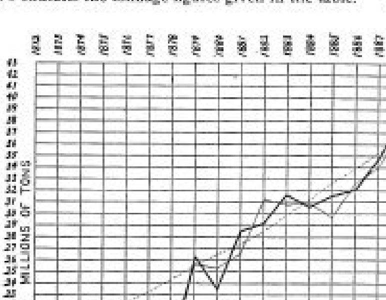

CHART NO. 3.

Glancing from one chart to the other, it can be seen that as the temperature goes up, the output, as shown by the heavy line in tonnage chart, falls off, and as the temperature goes down, the output increases.

If we are correct in our adjustment for temperature, the light line should in a general way, indicate the effect of activity or depression of general business. The long period of depression from 1873 to 1878, as shown by such tests as Dun's report of failures and the statistics of bank clearings, will account for the light ton-

cold winter. Since then the coal tonnage has had the benefit of the general activity only checked by the adverse winters.

Serious objections will be made to a correction for temperature which increases the normal tonnage so much above last year, the tonnage of which is considered so large, but we can make this further test. Early in our calculations we showed that grouping the first 10 years and the second 10 years, one year's average of the actual output was 1,240,995 tons. The last ten years averaged warmer than the first ten years. If the two groups of the output are corrected for temperature, the result of one year's average is 1,300,222 while the column "corrected for temperature," if tested in same manner by groups, shows an average normal increase of 1,308,227 tons.

Moreover the conditions in 1872 were in some respects, not unlike those of 1891. Both were years of steady work compared with other years, and each showed an increase of more than four million tons as compared with the year immediately preceding, but it will be claimed that the utilization of small sizes has swollen the tonnage of 1891. On the other hand in the year 1872, the use of the large sizes of Anthracite by the iron furnaces was much greater *in proportion* than now, Coke and Bituminous having been substituted.

A period of high temperature is a missionary era, when by reason of low price, and active competition, the trade is carried into new fields. No doubt there was some increase last year from this cause, but it, as well as the increase in quantity of the small sizes, is a phase of the normal increase as we have defined it and effects future years as well.

After some disappointment in prophesying as to temperature, we conclude that it is wise to adopt the advice of the philosopher, to predict only *after* the fact. Therefore the rule that we have reached will be available in May of each year. It is as follows:

For every degree of the average mean monthly temperature of the cities of Boston, New York, Philadelphia, Buffalo and Chicago, for the six months, November to April, inclusive below or above 34·9° (the average of twenty years), add or deduct two per cent. from the estimated normal output of Anthracite for the year. This result is subject to the effect of the activity or depression of general business.

There is now left the difficult problem to solve as to what the output will be in normal times and at normal temperature. The average increase of the column "corrected for temperature" is about 1,225,000 tons per year for the 19 years intervening from 1872 to 1891, but this represents the increase midway of the period or about 10 years ago, and will not do for either of the extremes, for there is a gain upon the gain each year to be considered. The above average gain is about four per cent. upon the average tonnage of the period and this is close to the ratio of increase.

In Chart No. 3, the dotted line represents an increase of 4½ per cent. compounded yearly, commencing with 18,833,440 tons in 1872, and ending with a tonnage of 41,028,884 in 1891. We are satisfied however that compounding upon the whole tonnage is not a correct ratio of increase but that it is somewhere between this and the average increase.

As a compromise, we offer a scale increased, one-half at the average of twenty years, and the other half at 4½ per cent. compounded annually. On this basis the estimate of the normal output is as follows:

1891	42,133,683 tons.
1892	43,681,500 "
1893	45,187,500 "
1894	46,773,000 "
1895	48,492,000 "
1896	50,161,000 "

The method may be questioned but the result has the merit of showing less increase than the last six years of actual output.

In the table showing effect of temperature, the calculation is so made that the percentage is upon the corrected-for-temperature tonnage, as being closer to the averages upon which the formula is based, than if taken upon the actual product, so that our rule is more closely applicable to such estimates as above.

The producer gets the credit in popular belief of controlling the business by combination, but it is evident that the struggle is to fit his supply to variations in demand to which no other business is subjected in like degree. Formerly Anthracite was mined primarily for both manufacturing and family use. Now it can almost be claimed that it is produced primarily for the family and secondarily (in the refuse sizes) for manufactures. Our conclusion is that the great uncombined consumer, through demand, regulates the output, and he in turn is largely influenced by the temperatures of the winters.

Mr. L. A. Gabanyi writes us that the first fire was lighted at the new furnace of the Allegheny Iron Company, Iron Gate, Va., on the 12th of January. This company was incorporated in 1890 and controls 3,500 acres of iron ore land (the ores are brown ore and red hematite ore ranging from 45% to 64%). The ore is partly mined and partly quarried. Four miles of three feet gauge railroad and two self-acting inclines are in course of construction. The furnace plant when completed will be one of the largest and best in the State, with an estimated daily capacity of from 150 to 200 tons of pig iron.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED 1881. INCORPORATED 1889.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
ALEX. DICK, MINING ENGINEER, ASSISTANT EDITOR.
THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send upon payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed

CONTRACT LABOR IN THE MINES.

LABOR Inspectors Conkling and Osborne, of New York City, who were recently detailed to report on violations of the alien contract law in the coal regions of Pennsylvania, have submitted their report to Secretary Foster, of the Treasury Department.

If the newspaper summary of this report is true, it is a tissue of falsehoods from beginning to end, and shows that the authors were never in the coal regions of Pennsylvania, or, if they were they are either gullible fools or deliberate falsifiers. No other excuse can be offered for such a report as they have submitted, and it is evident that they are unfitted for their positions and should be speedily replaced by men who will carefully investigate and truthfully report on this and kindred matters. Their statement that nine-tenths of the miners employed in the mines surrounding Scranton are Hungarians, Italians, and Slavs, is a falsehood of the first magnitude. Less that 10 per cent. of the men employed inside the mines, whether as miners or laborers, are of the three nationalities mentioned, and less than 5 per cent. of the miners in the Anthracite regions are Hungarians, Italians, or Slavs.

It is true that there are large numbers of Hungarians and Slavs employed on the surface and around the breaker as laborers, but that is because no other nationality will do the work, which is such that no skill is required. Operators and superintendents do not employ these nationalities from choice. They employ them because no other labor is available for the work they do. They were not brought here by the operators and coal companies, but came of their own accord at the solicitation of friends who had found employment in the mines, and who were sharp enough to see that the scarcity of unskilled labor, and the wages paid made desirable openings for their starving friends in Europe, and they urged them to come.

One statement of the report that particularly stamps the whole of it as untruthful and unreliable is the following:

"At the mines near Carbondale, in 1886 there were 600 miners, all American citizens. While the miners' strike was on in 1889 and 1890, large numbers of Slavs and Hungarians were brought to the mines from Castle Garden under the protection of Pinkerton's detectives. At the last election, out of 787 miners employed there were just 68 entitled to vote."

In the first place the number of miners employed in the mines near Carbondale greatly exceeds 600, and the same statement as to the proportion of Huns, Slavs, and Italians (less than 10 per cent.) applies here as well as at Scranton.

In the second place there was no strike in the Lackawanna region in 1889 and 1890, and no Pinkerton detectives were employed. There has been no strike of any magnitude in the entire northern coal field since 1877.

In this connection it is well to state that the Poles are an entirely different race than the Huns and Slavs. The Poles are naturally intelligent, and when they come to America they come to stay. They soon become Americanized, and it is safe to say that they will in time become as a class equally as prominent in business and politics as have any other race in this cosmopolitan nation.

A fair estimate of the proportions in which the various nationalities are employed in the Anthracite mines may be obtained by taking the classification of the workmen of the Phila. & Reading Coal & Iron Co. This company operates 61 collieries and employs 24,754 men and boys, of whom 9,709 are of foreign birth. Of the total number 4,718 are of American parentage, 6887 are of Irish birth or parentage, 4287 are of Polish birth or parentage, 3,709 are of German birth or parentage, 2,089 are of English birth or parentage, 1,466 are of Hungarian birth or parentage, 1,282 are of Welsh birth or parentage, 210 are of Scotch birth or parentage, 86 are of Italian birth or parentage, and 20 are French.

The above list comprises about 20 per cent. of the employes in the mines of the Anthracite region, and if each nationality's number be multiplied by 5, an approximate estimate of the nationality of all the mine workers in the Anthracite region may be arrived at. It is true that at individual collieries, there will be found wide divergences from these figures, but they are approximately correct for the whole region.

However, this must be said: The number of Hungarian, Slav, and Italian miners will increase each year, owing to the operation of the foolish "Miners' Examination Act" passed by the Pennsylvania Legislature in 1887. This act forbids the employment as miners in Anthracite mines of any man who has not worked at least two years as a laborer in such mines. No English, Welsh, Scotch, or German miner can emigrate to this country, and take employment in an Anthracite mine, no matter how skillful he may be, unless he performs the drudgery of a laborer for a laborer's pay for two years. This he will not do. No intelligent young man of American birth can become a miner, unless he complies with the same conditions. The ignorant Hun, Slav, or Italian, at the end of two years work as a laborer in the mines, can be certificated as a miner, and is certificated as such, even if, as is usually the case, he is fit for no other work than cleaning out ditches. The operators and superintendents, owing to lack of better material to draw from, will in time be compelled to employ them as miners or close the collieries.

A REWARD OF MERIT.

ALMOST every nation has some distinctive medal or cross which is conferred for eminent worth or noble conduct. Such medals of honor are seldom of any intrinsic value, their worth depending on the associations connected with them. The Victoria Cross of Great Britain is the great object of attainment with naval and military men, and any one from the general or admiral to the private soldier or sailor can gain this distinction by the performance of some act of individual heroism in battle.

The French Legion of Honor ribbon is conferred for bravery on land or sea and is also given to distinguished men of science, art, or letters.

It is to Queen Victoria however, that the credit is due of installing an order of heroes of quite another class. As the Victoria Cross is only given to military and naval men, the Albert Medal is reserved to civilians, and there is a large representation of mining men of all ranks in the roll-call of the order. The intrinsic value of this medal is almost *nil*, but it is a pleasing thing to have a distinctive badge for deeds of individual bravery in the industrial ranks. No man is a hero from mercenary motives. He acts generally on the spur of the moment and no money consideration can compensate him. In such a case a medal that can be worn is better than great riches.

Among other persons who enjoy the proud distinction of possessing the Albert Medal received for acts of heroism in connection with coal mining are A. H. Stokes, the Inspector of Mines, Derby, and Reuben Smallman, Mining Engineer, of Nuneaton, England. We should have such a badge of distinction in this country, as the opportunities for the display of heroism are just as frequent, and the number of heroes as great on this side of the Atlantic as on the other. If the establishment of such an order by the Government is contrary to American practice and precedent and therefore not advisable then it might be well to organize a society for the encouragement of heroism in the industrial walks of life and this society might at the same time provide the ambulance service in our mines, &c., which is so greatly needed.

EXTRAVAGANCE AT AMERICAN COLLIERIES.

THE time is rapidly approaching when the production of American coal and coke must of necessity be effected with greater economy than is now exercised. This will not be due to a scarcity of coal in the ground but to increased and aggressive competition in the markets. The time has already arrived when only those miners of coal, who either work under fortunate natural conditions, or who exercise strict economies succeed in securing a fair profit.

Americans are noted for their extravagances in both their domestic and business habits, but in no case is this extravagance more apparent than in our methods of mining coal and manufacturing coke.

In mining coal, entirely too much labor is performed by men and animal power. Mechanical appliances are cheaper in the long run, though their initial cost may seem high to the operator. Our system of conveying power from the steam plant to the machinery is also, as a rule, wasteful.

In the matter of underground haulage alone, hundreds of thousands of dollars are annually wasted at American mines by the use of mules in cases where the use of machinery would reduce the cost of haulage anywhere from twenty-five to seventy-five per cent.

In timbering our mines, valuable timber is wasted by being either poorly placed, placed where not necessary, or wasted in the cutting to sizes required.

Lubricants and oils are wasted by the use of wasteful lubricating appliances and slovenly habits on the part of oilers.

Tools are not taken care of and are rusted and ruined, if not lost, by being carelessly left lying around in out of the way places.

Rails in mine tracks are allowed to corrode and waste away when the use of a shovel in opening the ditch would drain off the acidulated water often covering and flowing over them.

Mules are worn out by being driven over muddy inside roads that could at a trifling cost be kept dry.

Lumber is allowed to rot in old brattices that are of no earthly use, instead of being taken out for use in some other place where brattices are necessary.

Steam pipe lines are put in that are of larger diameter than is necessary and the entire steam plant is larger than necessary because the value of good non-conducting steam pipe covering is not appreciated.

Machinery is allowed to run long after the necessity of important repairs is evident to every intelligent mechanic, and in the end a serious break-down resulting in infinitely more cost than timely repairs, is the result.

Duplicate parts of machinery are not kept in stock, and when an unavoidable breakdown occurs, the whole colliery is shut down until such parts can be secured from the machine shops. Decrepit and worn-out mine cars are sent in the mines, and when on the outward trip, loaded with coal, they give out, vexatious and expensive delays are the result.

The mine tracks are not kept in good order, and the result is frequent delays caused by mine cars jumping the track, and frequently making matters still worse by knocking out timbers.

In fact there are "a hundred and one" places in which economies at American coal mines can be practiced with good results.

Some of these economies may make necessary the initial expenditure of a little money, but they will pay in the long run.

This extravagant method of doing things is the natural result of the phenomenally profitable coal business of a quarter of a century ago, when the producing fields were few and the markets demanded more than could be supplied. But this is not the case now. New fields are constantly being developed and the production keeps well apace with the demand. The coal that can be placed in the market at the lowest price is the coal that as a rule is purchased by consumers. Therefore it is essential that the cost of production must be lowered if profits are to be realized on the mining. This lowering of cost cannot be effected by slovenly management and wasteful habits.

In coke making we are especially wasteful. None of the by-products are saved at American coke works. If they were saved they would materially add to the income derived from the coke plant and thus lessen the cost of the production of coke.

This matter of greater economy at collieries is not a matter for future consideration. It is a matter for immediate consideration, and the operator or colliery manager who first adopts and carries out a systematic plan of economizing in every detail, great or small, is the man who will reap the profits so ardently wished for, but often unreached by the majority of colliery owners of to-day.

THE McALESTER DISASTER.

IN another column we publish a description of the Osage Coal and Mining Co.'s Mine No. 11, which was the scene of an explosion on January 7th that resulted in the death of 56 men, and the injury of 120 more. For the excellent description and drawings illustrating the scene of the disaster, we are indebted to the engineer of the company, Mr. W. Farnham.

Mr. Farnham shows in his article that the officers of the Osage Co. paid more than usual attention to the dangers attending the presence of coal-dust, by damping the roadways. The fact that this was done leads some of the committee, that inspected the mine and inquired into the cause of the accident, to think that the explosion was not extended by dust, because the floors of the entries and rooms were damped. But, the damping of the floors is not sufficient to overcome the dangers incident to the presence of coal-dust in the mine. The danger still remains, unless the dust is either swept from the sides and roof, or thoroughly saturated by water sprayed on it.

That the primal cause of the accident was a blown-out or "windy" shot is certain, and that this was due to disregard of the rules of the company is also certain. But the cause of the explosion extending over so large an area of workings is not so clear, unless the sides and roof contained large quantities of dry dust.

That the coal-dusts containing high percentages of volatile hydro-carbons are explosive is a settled fact. They not only intensify the initial explosion, but they may be the primal cause of the explosion. Therefore, it will pay colliery officials to pay just as much attention to its complete removal or complete damping, as they do to the removal of explosive gas. Till this fact is recognized by colliery owners and colliery officials, in all regions producing Bituminous coal, immunity from widespread and disastrous explosions cannot be obtained.

Indeed, in the light of the investigations made during the past few years, it is doubtful if any of the large explosions that extended over large areas in the coal mines of America or Europe can truthfully be charged entirely to gas. If the gas alone was a factor, the explosions would be confined to comparatively small areas. Dust is the factor that extends them, even when originated by gas, and it should be removed so as to add to the security of both the workmen and the colliery.

This explosion is remarkable in that so many persons who were injured escaped with their lives. As a rule, in extensive mine explosions, those who are uninjured by the explosion afterwards die from the effects of the after-damp which frequently kills many who are not burned or otherwise injured. Many so lost their lives in this instance, but many escaped, and this was probably due to the fact that the ventilation was not interrupted. As appears from the report the fan was not stopped by the explosion and its speed was increased immediately after it occurred. The noxious gasses resulting from the explosion were thus carried off in the ventilation and the injured had pure air to breathe until they were rescued or escaped from the workings themselves. The officers of the mine merit commendation because they had provided an extra fan to use in case the other should be disabled. Fortunately, the running fan was not disabled on this occasion, but if it had been, there was one in place to do its work. Mr. Cameron, the superintendent, did the right thing at the right time when, after the explosion occurred, he at once increased the speed of the fan, and we think the precaution taken to provide against accident previous to the explosion and his conduct when the disaster occurred proved him to be the right man in the right place.

EDITORIAL NOTES.

THE difficulty experienced by the mine inspectors in enforcing the mine law has again been illustrated in the Lackawanna County courts, by the disagreement of the jury in the case of the Commonwealth vs. James Smith, on the 29th ult. Smith was prosecuted by Inspector McDonald for firing a shot in a narrow pillar without warning the men employed in the adjoining chamber, one of whom was killed and the other injured. A clear case was made against him, and his own evidence showed his guilt, but the jury failed to agree after being out twenty-four hours, and it was accordingly discharged. If a few such violations of the mine law as Smith was guilty of, could be punished, the law would be found much more effective in saving life in the mines. A false notion of sympathy prevents the average jury from convicting the *poor miner* guilty of a violation of the law, but it forgets the hundreds of other poor miners whose lives are jeopardized by such actions as Smith's was.

MR. Wm. Griffith, Inspector of Mines for the Second Mining District for the State of Washington, sends us the following statistics for his district for the year ending December 31, 1891: Amount of coal produced, 287,513 tons; number of men employed, 674; number of boys employed, 20; number of persons killed by accidents in the mine, 6; number of persons injured, 1.

THE COAL TRADE

The Anthracite Trade.

During the past month, the Anthracite trade had several days of demoralization due to the cut of fifty cents per ton in prices, made by the Lehigh and Wilkes-Barre Coal Co. The other interests immediately met the reduction, but none seemed anxious to secure orders at the cut rate. On the 28th ult. the sales-agents of the various companies met in New York, and harmony was restored by an advance of twenty-five cents on the Lehigh and Wilkes-Barre circular prices, making them f. o. b. tide water as follows, with twenty cents per ton added alongside in New York: Broken, $3.45; egg, $3.60; stove, $3.75; and chestnut, $3.25. The output for February was placed at 2,500,000 tons. The allotment question will soon come up, and this may make some trouble. It came up at a meeting of the sales-agents during the month, but was laid on the table as a question with which that body was not competent to deal. It will be settled by higher powers if settled at all, and that in the near future.

The new prices took effect on the 28th, immediately after adoption, and they will be strictly adhered to. The action of the agents meets the approval of everybody in the trade, except the retailers who failed to profit by the low prices prevailing for the week previous to the meeting.

A meeting of the general freight agents of the Anthracite carrying roads, called by the Lehigh Valley Railroad Co., was held on the morning of the 28th to consider the question of east bound freights on Anthracite coal. The meeting was called to consider a reduction so as to enable the individual operators, who claimed to be oppressed, to realize a profit on their shipments. But as the meeting evidently had some knowledge of the subsequent action of the sales-agents, nothing was done in the way of a reduction of tolls, and the meeting adjourned for two weeks. The general outlook for the Anthracite trade is very fair and, if there is no war over the allotment question, the prospects are that business will be comparatively brisk for this season of the year.

The Bituminous Trade.

The Bituminous trade is dull. The new business offering is light and the supply on hand is comparatively large. The cold weather has not had much effect on the demand and what little extra demand there is can be easily supplied from stocks on hand. Prices, however, are about as low as they will go, and there will, no doubt, soon be an increased demand and prices will advance. Most of the demand now is for coal contracted for some months ago.

The Coke Trade.

The coke trade shows no change and prices remain the same as they have for months past. In the Connellsville region about 83% of the ovens are in blast, and they are running on an average of about five days per week. Prices are well maintained at the same figures as have been quoted for the past year. *The Connellsville Courier*, which makes a specialty of local coke news states in its last issue that "the outlook for a good business in 1892 grows brighter."

MINING ENGINEERS OF OHIO.

The Annual Meeting of the Ohio Institute of Mining Engineers.

The Twelfth Annual Meeting of the Ohio Institute of Mining Engineers was held in Celtic Hall, Columbus, Ohio, January 21 and 22, 1892. The meeting was well attended and the following papers were read:

1. The Coal Seams of Jackson County, by Hon. Andrew Roy.
2. The use of the Prismatic Compass in Mine Surveying, by E. D. Wileman.
3. The Necessity of Making Break-throughs Even and Uniform at the Mines, by James W. Haughee.
4. Mining Limestone by Underground Instead of Open Quarry Work, by E. B. Willard.
5. Comparison of the Composition of Certain Coals with their Evaporating Powers in Locomotive Boilers, by Prof. N. W. Lord.
6. The Original Members of the Institute, by J. L. Morris.
7. Improved Methods of Mining, by Mr. Jos. W. Blower.
8. Split Air Courses vs. Continuous Currents in Mine Ventilation, by Prof. F. W. Speer.
9. The Harrison County Oil Fields, by Wm. B. Hanlon.
10. The Wasteful Methods being Practiced in Mining Coal in Ohio, by Inspector R. M. Hazeltine.

A resolution was adopted tendering Dr. Edward Orton, State Geologist, the sympathy of the Institute in his present affliction.

The summer meeting of the Institute will be held in West Virginia.

The following officers were elected for the ensuing year:

President, Mr. A. Howells; Vice-President, Prof. N. W. Lord; Secretary, and Treasurer, R. M. Hazeltine; Executive Board, Hon. A. Roy, Prof. F. W. Speer, and Capt. J. L. Morris.

The meeting was one of the most interesting ever held by the Institute. Profs. Lord and Speer, of the School of Mines of the State University, gave the students a holiday on Friday afternoon and many of them were present at that session of the Institute. The members of the Institute also visited the Mining School and many of them expressed much satisfaction at its growth and development. There are more students studying mining in the University of Ohio now than any other branch of education.

ANTHRACITE COAL STATISTICS.

Statement of shipments of Anthracite coal for month of Dec., 1891, compared with the corresponding period last year. Compiled from the returns furnished by the Mine Operators.

	December, 1891.	December, 1890.	Difference.		For Year 1891.	For Year 1890.	Difference.	
From Wyoming Region,	1,885,041·05	1,672,748·12	Inc.	212,292·13	21,325,239·18	18,657,694·14	Inc.	2,667,545·04
From Lehigh Region,	581,389·12	487,209·15	Inc.	94,179·17	6,381,838·08	6,329,658·07	Inc.	52,180·01
From Schuylkill Region,	1,121,540·16	905,249·19	Inc.	216,290·17	12,741,258·05	10,867,821·18	Inc.	1,873,436,07
Total	3,587,971·13	3,065,208·06	Inc.	522,763·07	40,448,336·11	35,855,174·19	Inc.	4,593,161·12

The stock of coal on hand at tide-water shipping points, December 31, 1891, was 754,432 tons; on November 30, 1891, 637,846 tons; increase, 116,586 tons.

Of the total product in 1891, 52·72 per cent. was from the Wyoming Region; 15·78 per cent. from the Lehigh Region, and 31·50 per cent. from the Schuylkill Region.

Eastern competitive tonnage, including all coal which for final consumption or in transit, reaches any point on the Hudson River or the Bay of New York, or which passes out of the capes of the Delaware.

1890 .... 11,799,317 tons.
1891 .... 12,313,719 tons.

AN ELEMENTARY TREATISE ON THE PRINCIPLES OF COAL MINING.

For the Use of Candidates for Mine-Foremen's Certificates, Mining Students, Mine-Foremen, Mine-Superintendents, Mining-Engineers, etc.

BY A. A. ATKINSON, DURHAM, ENG.

Methods of Working.

Passing on from the subject of ventilation we will now consider some of the different methods of working coal, and the bord and pillar system will be noticed first. The following description of this mode is in practice at a colliery in the North of England with which the writer is acquainted, and it will be treated under two heads:

First. The method of working, including proportionate costs of the different methods and classes of labor connected with them.

Second. Ventilation, describing how the air is coursed round the mine in the whole and broken workings.

GENERAL REMARKS.

The system of pillar and bord working was introduced at this colliery some years ago, and since that time a large number of pillars have been formed and removed by the different methods without any accident of a serious nature, and with a mere trifling loss of coal; therefore it may be justly considered that a system has been hit upon to suit the working of each district. The Hutton Seam is the one under consideration and here lies at 54 fathoms from the surface at the shaft, and the dip which is to the North and West does not affect the working; but the greatest irregularities are caused by "swellies," or sudden depressions of the seam, it again rising ultimately to its former level at some distance. These depressions cause considerable annoyance in consequence of water lodging in them. Faults are not large or numerous and have a bearing North-West and South-East.

The roof varies in each district and is intersected by "backs" or "slips" which give much trouble; their general bearing is about parallel to the line of faults, and should a lift of coal come to stand any length of time in some districts the roof is apt to break off at the face, more especially if near one of these backs or slips.

The following is a general section of the roof:

Ironstone girdles	0′ 1½″
Blue metal shale	0′ 9″
Post girdle sandstone	0′ 3½″
Blue Metal	1′ 9″
Ironstone girdles	0′ 2″
Blue metal	0′ 9″
	3′ 1″

The average thickness of the seam is 3′ 6″ and it is a household coal. The nature of the coal varies somewhat, being generally found harder to the West and North or dip side. It may be remarked that the present output is from the two East districts where it is tender and the system of taking the pillars out to the best advantage cannot be employed.

METHOD OF WORKING.

It has been considered judicious that panel barriers of solid coal 22 yards thick should be left about 330 yards apart, or 165 yards on each side of the wagon-way bord; these are for the purpose of dividing the pit into districts, and possess the following advantages:

First. Should an explosion occur in the district, it may not communicate with any of the other districts by having them so isolated.

Second. Naked lights may be used in the "whole mine," by splitting the air at the face of the main intake and carrying it along the face before allowing it to ventilate the broken and waste or goaf.

The panels at this colliery were laid out with a view to exceed the "putting rank" as little as possible (which for hand-putting the first rank is 80 yards), but at the same time to leave sufficient coal for the "broken working." The method of following up the whole with the broken is adopted, and requires three sheaths of bords on either side of the wagon-way to keep it good.

The size of the pillars depends on the following circumstances:

First. Thickness of cover or depth from the surface.

Second. Nature of the roof and bottom.

Third. Quality of the coal—hard or soft.

Should the size of the pillars determined on be too small the effect upon the "whole" or "broken mine" will be very different: in the "whole," little or no effect will be experienced; but in the "broken" the coal will be crushed, yielding but a small percentage of round coal and a heavy cost in timber as well as in clearing away falls of roof-stone.

The advantage of a large pillar is evidently giving a better support to the roof, the cost of timber is reduced, and when the pillars are being worked off fewer last lifts occur which reduces the risk of loss. Care was taken when fixing the size for the pillars at this colliery to meet the known circumstances. The rectangular form of figure was preferred so that most of the coal might be taken off bordway course.

The pillars are 31 yards bordway course by 18 yards headway course and contain 0·115 of an acre, thus yielding:

Tons of coal at 3′ 0″ thick	540
Tons of bottom coal at 6″ thick	90
	630

OPENING OUT THE COAL.

Three headways are driven abreast in the direction of the cleat (N. 13° W.) for the purpose of winning the coal. The middle headway serves as a main intake for the air and wagon-way, along which from the different off-takes, the coal is brought to the shaft. The back headways act as the return and traveling road for the workings on each side of the wagon-way. Holings are made at every 44 yards; this distance requires fewer stoppings and less narrow work (stenton price) over the whole length of way. The thickness of pillars between the headways is 18 yards.

The main wagon-way bord is turned out of the headway course by driving a gentle curve till it cuts the course of the bords, which are driven N. 77° E. in the middle of the panel.

This has the advantage of bringing the coal worked from each side out by one way, thus reducing the cost of making another horse road and separates the putting.

The panel is further opened out by driving a set or sheath of bords, viz., seven on either side of the wagon-way bord, the seventh being the panel or barrier bord. When the bords have reached a distance of thirty-three yards walls are turned out of them from either side.

After the working face of the sheath of bords has reached seven pillars from the wagon-way head-ways, the broken working may be commenced: the working face should always be not less than three pillars in advance of the broken.

The wagon-way bord is supported by whole pillars on either side of it, so that it may not be crushed by the extra weight thrown on to it; they also keep the return air-ways in a better condition.

After the broken has been worked up to the boundary, the remaining pillars are worked off outbye over.

The largest output worked from a district by this system is 250 tons per day of 10 hours, and requires the following labor:

Class of Labor.	Number of Hands.	Rate of wages in U. S. Money per day.	Amount.	Cost per Ton.
Hewers: Whole Mine	36	$1.944	$69·98	$.436
Broken Mine	20	1.944	38.88	
Hand Putters	10	1.73	17.30	.068
Deputies	3	2.03	6.09	.024
Drivers	1	.54	.54	.015
Flatters	1	.54	.54	
Switch Keeper	1	.46	.46	
Landing Boy	1	.59	.59	
Wagonway-man	1	1.46	1.46	
	74		135.84	.543

the bottom of the old whole pillar. The last of the pillar is generally taken off by holing into the headway in the middle of the lift and working back to the bords with a wedge-shaped piece of coal. The chocks are drawn out and the roof is allowed to break off at the chocks in the headway course.

The proportion of round coal obtained by this method is much larger than by any other method of taking out pillars at this colliery. At a neighboring colliery it is stated that upwards of 60% of round coal is obtained by the same method.

The chocks used are of oak wood 24″ and 22″ long by 5″ square, the number of nobs in each chock in this seam being fifteen, each nob costing about ten cents, so that the cost of each chock is about $1.50.

In setting it is necessary to so fix them that in drawing them they may not fall towards the goaf, thus running the risk of being lost. They are set in the following manner: The first tier of nobs are set on the bottom at one end, the opposite ends being on the nobs in the second tier, one nob being set forward five inches from the goaf side. In drawing one of the bottom chocks is kirved out and the remainder knocked out with a mall or hammer, a few smart blows will generally throw the remaining part of the chock forward.

NO. 2 METHOD.—DOWN THE OLD BORD.

This method is generally adopted when the old bord has not fallen. It stands most favorably at this colliery as compared with the cost of working. The tram-road is laid out of the going headway down one side of the pillar. Then a wall twenty-two yards from the headway is driven across the pillar, and a lift is turned away five yards wide and worked up to the goaf nine yards from the wall. As soon as the lift is done the timber is drawn out by the deputies who are paid days' wages, and nothing extra is paid for overtime; it is to their benefit to try and get the lift finished during working hours. The roof generally subsides immediately, and is supposed to fall about five fathoms up to some post-stone. By this method one and sometimes two men can work in a lift, and it generally takes about seven weeks to work out a pillar. The narrow-work in one of these pillars is 2 split-walls twenty-three yards long and nine feet wide at $ ·243 per yard = $5.59.

The average quantity of timber required to work off one pillar by the old bord method is:

	Old Bord.	Split Walls.	Lifts.
Props	80	38	60
Crowns	30	13	30
Chocks	3		

SCHEDULE OF HEWING PRICES.

Description of Work.	Price.	Remarks.
Hewing—Whole Mine	$3·29	Per XX.
Hewing—Broken Mine	2.89	"
ALLOWANCE.		
Hewing—Double	·24	"

Per X X means a score of 21 tubs.
In Hand-Putting the first rank is 80 yards.

NO. 3 METHOD.—REMOVING PILLAR BY HALF-PILLAR WALLS AND JENKINS.

This method has been proved to be safest and best for removing the pillar where the stone is bad, although it requires more narrow work than the former method and the cost of taking the pillar off will compare favorably with it: this may be accounted for by the removal being effected in much shorter time, in this case about three weeks sooner.

The pillar is split by a Jenkin 3 yards wide driven 22 yards down the pillar, so as to leave 9 yards of coal for the bottom end lifts, and right and left half-pillar walls are either driven over singly or simultaneously as pit room may be required. The pillar is then removed taking the lifts off as numbered in the accompanying sketch:

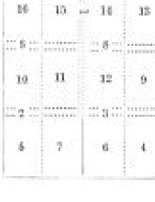

TABLE SHOWING COST PER TON ON WORKING THE BROKEN AS DESCRIBED.

No. of Pay.	Hewing.				Off-hand Labor.					Total Hewing and Off-hand Labor.	Cost of Shift Work.	Total Cost.	Tons of Coal Worked in the Broken.
	Hewing.	Yard Work.	Consideration.	Total.	Putting and Driving.	Overmen and Deputies	Pumping Water.	Sundries.	Total Off-hand Labor.				
7	$·32	·022	·017	·359	·034	·06	·009	·068	·191	·55	·037	·587	800

9	·27	·01	·03	·31	·052	·059	·01	·074	·195	·505	·04	·545	1027
Average	·29	·017	·025	·329	·055	·059	·0097	·078	·20	·53	·041	·572	935

NO. 1 METHOD.—REMOVING PILLARS BY LONGWALL.

This method, under suitable circumstances, is the best and cheapest; it requires little narrow-work, and the pillar can be worked off sooner, as four men can be placed in each.

The first broken was worked by this method in the First South-East District, but it was not a great success owing to the roof breaking off short and the bottom being soft and wet, which has the following section:

Fire-Clay	1′ 3″	
Bottom Coal	5″	
Fire-Clay	3′ 6″	5′ 2″

The pillars are taken off bordways course in two lifts face on nine yards wide. The tramway to each lift is turned out of the going headway down the old bord and along the face, there being a separate tramway with a row of chocks between to each lift. Two rows or tiers of chocks, each consisting of fifteen nobs, or pieces of wood, are set off and on about two feet from the face. Props are used next to the face if required. As the face advances the back chocks are drawn out and re-set in front of the first row, allowing the roof to fall. When the last lift is being taken off, the flat is moved a pillar higher up and the old headway course double-chocked, leaving room for the tramway next to

Nos. 1, 2, 3, 8, and 8 being narrow work, and the other numbers represent the lifts in the order in which they are removed, after 1, 2, and 3 are driven lift 4 is then taken off, and after drawing the timber out lift 5 is taken off; Nos. 6 and 7 are then removed, the latter being a loose lift. Walls 8 are then driven and lifts 9, 10, and 11 are taken off down to the old walls 2 and 3, which is now goafed. When lift 12 is being removed a stook is left at the corner, and the old bord-room chocked. Lifts 13, 14, 15, and 16 are removed from the going headways. A stook is also left at the outbye corner of lifts 14 and 16 to keep the outcome good. In this method lifts are divided into

Fast Lifts	4, 5, 6, 9, 10, 13, and 15
Loose Lifts	7, 11, 12, 14, and 16.

Narrow work in removing one pillar:

Jenkins 22 yards @ $·11	$ 2.42
Split-Work 32 yards @ $·243	7.80
	$10.22

TIMBER REQUIRED FOR ONE PILLAR.

	Walls.	Jenkins.	Lifts.	Total.
Props	60	80	60	200
Crowns	20	30	30	80
Chocks (for bordrooms)			3	3

The cost of narrow-work is sometimes further reduced by driving the two top walls 8 8 only over the width of one lift either way. The lifts are then taken off in the following order: First lift 4 is taken off and the timber drawn out. Lift 9 is then turned out of the opposite side of the wall. Lifts 5 and 10 are then taken off in similar manner. Lifts 6 and 7 are next removed. In order to remove lifts 12 and 11 (12 first) the short wall 8 is only driven over the width of each lift. Lifts 13, 14, 15, and 16 are removed from the headways same as in the previous method.

The narrow-work in this case is

Jenkins, 22 yards at $.11	$2.42
Split Walls, 24 yards at $.243	5.83
	$8.25

This is equivalent to a saving of 19 per cent. on the previous narrow-work, or about $·0026 per ton on the whole pillar of coal.

NO. 4 METHOD.—REMOVING PILLAR BY HEADWAY LIFTS.

The middle of the pillar in this case is removed by taking it off headways course, and although there is a considerable saving in yard work, yet the quantity of round coal is greatly reduced so that it cannot be recommended on this point.

COST OF NARROW WORK.

	Walls.	Jenkins.	Total.	Cost per ton.
No. 1 Method				
No. 2 Method	5·59		5·59	.01
No. 3 Method	7·77	2·37	10·15	.019
No. 4 Method	5·83	2·37	8.20	.015

In No. 4 method a jenkin is first driven down the middle of the pillar distance of 22 yards and a wall set away right and left at this point, each going to the old bord on either side of the pillar; then the 4 bottom lifts are taken off in the same order as previously described by the sketch. The middle portion of the pillar is next taken off by driving four lifts headways course, two lifts on either side of the first jenkin. These headways lifts require extra timber on the goaf side, as the roof stone is more open. Then the last four lifts are taken off in the same manner and order as given in the sketch.

VENTILATION.

The ventilation at this colliery is produced by a Schiele fan, centrifugal in action and 5 feet diameter. Depth of upcast shaft is 70 yards. The guarantee of the maker of the fan was:

Cubic feet of air per minute	50,000
Revolutions of fan	400
Water-gauge	1"

The results were satisfactory as the full quantity was obtained with $\frac{7}{8}$ of an inch of water-gauge.

The fan is driven by a double cylindered horizontal engine which was purchased at a cost of about $1,000 and is of the following dimensions:

Diameter of cylinders	12"
Length of stroke	18"
Revolutions per minute	40

The H. P. developed as shown at the test experiments was 32.

The intake air after leaving the downcast pit is taken in one main current of 24,000 cu. ft. per minute along the North wagonway till it reaches the first split at the first East and West Way Ends; it proceeds from this point in a current of 15,600 cu. ft. to the face of the North Headways. After airing the whole workings in the Far North, it is again split, part returning along the West side, and the remaining portion which is the greater, along the East side. Wood doors are placed in the second East and West Ways to bear up the air coming back from the Far North round the workings in those districts. Following the course of the East side current after it enters the second East panel, it is sheathed up to the face, there being no "broken" on this side; it then crosses to the right-hand side "whole" workings and after being coursed along three headways is carried around the broken workings and thence into the return. The quantities of air are proportioned according to the number of men, acreage of goaf, etc., which they have to pass, being so regulated by "regulators" placed in the returns.

GLOSSARY.

"WHOLE MINE."—Any section of the mine which has been divided up into pillars but in which the pillars have not been taken out.

"BROKEN MINE."—Any section of the mine where the pillars are in course of being taken out.

"PUTTING BANK."—The distance over which the "putters" or "trolley-boys" have to run the cars from the working place to the point where they are taken up by the general haulage.

DIRECTION OF CLEAT.—The line of cleavage of the coal.

STENTON PRICE.—The price paid for stentons or narrow cross-cuts connecting parallel headings.

OUTBYE OVER.—Commencing at the innermost end of the mine and extracting the coal backwards towards the shaft.

DEPUTIES.—Assistant mine foremen or fire-bosses.

KIRVED OUT.—Hacked out.

JENKIN.—A broad heading cut down the center of a pillar to give more room for working while extracting it.

STOOK.—A small pillar of coal left in at the outbye corner when a large pillar is being taken out to maintain a way of egress.

TUBS.—Small coal cars carrying about $\frac{3}{4}$ of a ton.

CROWNS.—Roof timber.

SWELLEY.—A thickening out of a seam of coal over a limited area.

BACKS.—Cracks or fissures in the solid coal running from roof to floor by which the coal readily parts.

FLATTERS.—Boys who work on the main road, greasing cars, etc.

WALLS.—Coal faces.

HEADWAYS.—Headings.

REPORTS OF INSPECTORS OF MINES.

Kentucky.

The eighth annual report, dated October 10, 1891, has just been issued by Mr. C. J. Norwood, the Inspector. Throughout the State of Kentucky there are innumerable small pits or banks scattered through both the Bituminous and Cannel coal fields, and with the facilities at the disposal of the inspector it is impossible to determine the tonnage raised at these or to obtain particulars of the accidents which occur at them. The figures which are given in the report are therefore confined to the operations of the larger companies and private operators.

The total quantity of coal raised during the six months ending June 30, 1891, was:

Bituminous	1,373,665 tons.
Cannel	20,244 tons.
	1,393,909 tons.

The average number of employes for this output was 6,208, and the number of mines at work was 88.

There are 259 bee-hive ovens in the state for making coke. The total quantity produced during the six months ending June 30, 1891, was 9,766 tons.

There are 57 mining machines in the state, 6 of which are worked by electricity and the others by compressed air.

Mr. Norwood devotes a chapter to notes on ventilation, etc., and in it he embodies many hints of a practical and useful character. Speaking of air-ways he speaks strongly of the necessity for maintaining them free of obstruction so that the air may not be impeded. "As the strength of a chain is determined by its weakest link, so is the capacity of an air passage limited by its smallest area."

Attention is also drawn to the expression so common amongst mining men when the flame of a candle or lamp is sharply deflected by the current. It is then said that there is "good air."

But Mr. Norwood points out that while there may be the regulation total quantity of air passing down the downcast to equal 100 cubic feet per minute per person employed there is not always *a proper distribution* of the air to ensure every man receiving his quantity.

An electric mine haulage has been installed at Hecla Mine to haul the coal over a distance of 5,000 feet.

Mr. Norwood devotes considerable space to the question of coal washing. There are two coal washing plants in the State—at Lily and Earlington.

The Lily plant is erected for the purpose of separating the slack and dust from the small coals.

The smaller coals produced in process of screening lump is passed into a receptacle from which they are raised (nut, pea, and slack all mixed) by elevator buckets, and dropped into a chute by which they pass to the washer. Then the heavier impurities, such as iron pyrites, are separated, dropping to the bottom, while the lighter coal, dust, and slate pass over the rim to a revolving cylinder of network of an ever increasing size of mesh. The dust and fine coal drop through the first length of this revolving screen, the pea passes through the next length of mesh, and so on according to the various sizes of coal required. A description of a coal washer in somewhat similar principles is given in THE COLLIERY ENGINEER for July, 1890, page 268.

The coal washing plant of The St. Bernard Coal Co., at Earlington, is described in the report of Mr. Frank Cawley, mechanical engineer. The machine used here is a patent of Prof. A. C. Campbell, of Nashville, and the following is a short description of its action:

The machine or table as it is called, is 8 to 10 feet long by 30 inches wide. The bottom is made of No. 20 galvanized iron and the sides of ash or oak. Above the bottom is another sheet of iron of same size and gauge which is called the "false bottom." This is perforated with peculiarly shaped slots, and is held about a quarter of an inch from the first or true bottom by strips. These bottoms have a peculiar curvature, which, by experiment, has been found necessary to give the best efficiency.

This table is suspended or supported, as the case may be, on hangers from above or rockers from below, which allow it to move endways through from three to six inches, at the end of which stroke it strikes a percussion post, firmly braced to receive the blow, and so arranged that the strains are all transmitted vertically to the building. Water is supplied to the table between bottoms and by two spray-pipes, one at head or percussion end, and the other just in front of the coal feed or two and a half feet from that end. An inch pipe under from ten to twenty feet of head will supply water for one table. Motion is given these tables by a combination of cams, rockers, and levers of a peculiar nature. The required motion being to move the table back from the percussion post with a slow and gentle movement, and return to it with a movement, slow at first, but increasing rapidly in velocity until the moment of percussion.

The principle on which the table operates is that during the slow backward movement the slack coal is slightly moved and jarred, and the impurities, which are heavier than the coal, are thus caused to form a layer next the perforated sheet. Water flowing through the perforations of the sheet aids this separation, and the return or percussion movement still further carries it on. On this portion of the stroke all the work of entirely separating the impurities from the coal is done, for it is the rapid forward movement that carries away the impurities sticking to the bottom of the table while the coal is forced to remain stationary, or nearly so, until at the end of the stroke it will be found a distance equal to the stroke of the table, nearer the coal-discharge or tail end. The impurities, by adhering to the table, gather considerable momentum, and when the percussion occurs this momentum carries them some distance ahead of their former position on the table and finally they are discharged at the head or percussion end. Each stroke of the table, therefore, discharges a quantity of pure coal at one end and a quantity of refuse at the other.

The slack coal is conveyed to these tables by traveling belts. About one-half horse power is required for each table exclusive of that used to elevate and convey the coal to the tables. One man can operate and keep in repair ten machines.

A paper by P. N. Moore, on coal washing, extracted from the Kentucky Geological Survey Reports, is reprinted in the report.

Ohio.

Mr. Robert M. Haseltine has just issued his annual report for 1890.

The total output of coal in the state was 11,788,859 tons, an increase of 881,474 tons over the previous year.

There is also an output of 833,150 tons of clay for the manufacture of the wares and material used in building.

The output of iron ore in the state is gradually diminishing. In 1890 the quantity mined was 169,088 tons. As in all other states so is it in Ohio regarding the causes of accidents. Falls of roof and sides were the cause of 62·4 per cent. of the entire number of casualties, and it is wearisome to read the ever repeated warnings which all mine inspectors issue to miners to be careful *for their own sake* in timbering and supporting roof and sides.

During the year 57 new furnaces for ventilation have been built, 20 new ventilating fans erected, 66 air shafts sunk, and 46 second openings made. Copious reports are given by the sub-inspectors, showing that the mines have been very thoroughly inspected and that great effort is being made to increase the volume and improve the systems of ventilation. Coal is mined in seven different counties by machinery. The power is either compressed air or electricity. Mr. Haseltine submits a report of experiments made on the efficiency of the electrical installations, and he also gives a description of some trials of gas and safety-lamps by the Shaw Instrument for Testing Mine Gases.

Iowa.

The issue of the Fifth Biennial Report of the State Mine Inspectors of Iowa, dated June 30, 1891, is another gentle hint to Pennsylvania.

No. 1 District.—Mr. Binks, the inspector, advises that all mine managers employing over twenty miners should have a certificate of competency.

Mr. Binks describes an explosion which occurred by a blown-out shot igniting coal-dust. The dust was ignited by the flame and traveled back through the workings until a damp part of the mine was reached, which was free from dust, and here the course of the explosion ended.

A short description is given of the Stanley Heading machine at work in Forebush Mines, Iowa. It is cutting fifteen feet per day in solid coal with slate roof and fire-clay floor.

There are very few fans in this district, the chief mode of ventilation is by means of furnaces and many of the smaller mines depend entirely on natural ventilation.

No. 2 District.—In this, as in all the other districts, over sixty per cent. of the accidents occurred from falls of roof and sides, and these were mainly due to want of knowledge and care on the part of the miners.

We would like to reproduce in full the chapter of "Complaints," which Mr. James Gildroy, the inspector of this district, has written, but space will not permit. He complains of want of education on the part of mine bosses, and he has much cause. He tells of finding the ventilating furnace of a colliery extinguished when all the ventilation of the mine depended on it. One mine boss said that there was no air outside and how could any be expected in the mine? We presume he meant that it was a calm day. Another suggested to paint the fan house to get more air in the mine. Mr. Gildroy devotes a chapter to the "Principles of Ventilation," and it is apparently much needed.

No. 3 District.—In this district, which is under the charge of Mr. Morgan G. Thomas, the furnace is the chief means of ventilation. Mr. Thomas devotes a chapter to "Suggestions to Miners," which is of value, and he strongly urges the establishment of a School of Mines by the state, and presents excellent reasons why it should be done.

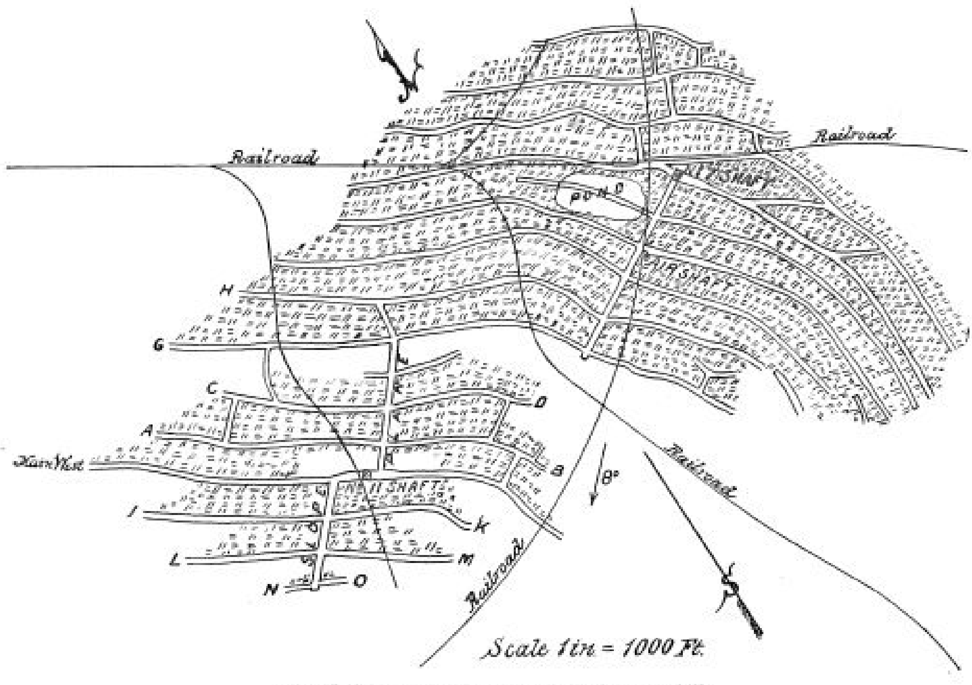
THE McALESTER EXPLOSION.

A Description of the Plant and Account of the Circumstances Attending the Disaster.

BY WHITFIELD FARNHAM, M. E.

[Written for the Colliery Engineer.]

On the afternoon of January 7th, occurred one of the most disastrous colliery explosions that has ever happened in the Southwest. Mine Eleven, of the Osage Coal & Mining Company, near McAlester, Indian Territory, was the scene of this accident. Of the four mines operated by this company in the McAlester Valley, Mine Eleven had the largest capacity, and was the deepest hoisting shaft, being 475 feet deep. The equipment is, in part, as follows:



PLAN OF MINES 7 AND 11 McALESTER, INDIAN TERRITORY.

Entries indicated by letters. All entries are driven double and are shown by a single line.

On the surface near the hoisting shaft, a battery of five boilers of about 300 horse power, aggregate capacity; a pair of 18 in. by 32 in. Litchfield hoisting engines, coupled direct to a nine foot drum; a 35 horse power Thomson-Houston dynamo used for lighting and pumping; all the above in substantial stone buildings.

In the mine near the foot of the shaft one 20 horse power and one 10-horse power electric motor, with corresponding power pumps; two engines and drums for handling empty and loaded trips of pit cars (about one ton capacity each) on the "plane" and "slope" (by which names the inclined roads are known, the former going directly to the rise, and the latter to the dip); one Blake steam pump, 18 inch steam cylinder, 7 inch water cylinder, 18 inch stroke, held as reserve.

An air shaft 238 feet deep in abandoned Mine Seven is used as the upcast, and is one-half mile from the hoisting shaft of Mine Eleven, which latter is used as the downcast. A Crawford & McCrimmon fan, 15 feet in diameter, and a Murphy double fan, 8 feet in diameter are set at this shaft, but only one is used at a time, the other being for reserve, either one being sufficient for ventilating the mine. At the foot of this air shaft is another pump. Steam for these fans and pump is furnished by the boilers at the hoisting shaft of abandoned Mine Seven, which is five-eighths of a mile from Number Eleven shaft.

Three grades or sizes of coal are made, all over straight bar screens, viz: lump, nut, and slack, the daily capacity being 1,000 tons.

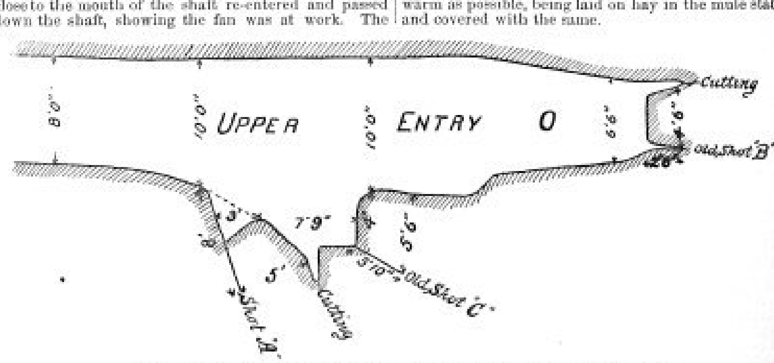
The coal vein is four feet thick, with a nearly uniform pitch of eight degrees or five inches to the yard. It is worked on the room and pillar plan, the mule roads or entries being driven nearly level, and the rooms worked up the pitch.

The plan of ventilation is simple. The air current passes down the main shaft, thence west about 200 feet, to the head of the slope, thence down the slope to its foot, where it is split, about one-half passing into the air course of entry O on the East, and half into air course of entry N on the West. From the faces of these entries, the air currents pass through the working places up from entry to entry until the two are reunited in the entries of abandoned Mine Seven, and pass to air shaft.

The mine has always given off a moderate amount of gas, but no sudden outbursts. The miners work with naked lights, and the mine is carefully inspected for gas every morning before the miners go to work. Shot-firers are employed, going into the mine after all the miners are out, the firing being done between 6 P. M. and midnight. The entry men are the only miners allowed to fire their own shots, and the rule is for them not to commence firing until 5.30 P. M., when it is expected all the other miners will be out of the mine. Coal is hoisted from 7 A. M. until 5 P. M., a half hour being allowed for dinner. No men are hoisted between these hours, except in case of sickness or emergency, or when there is no coal to hoist. Miners begin gathering at the bottom of the shaft before five o'clock, and each one in turn is given a check, so all can be hoisted in proper order. Only six men are allowed on the cage at once. Safety-catches are used, and dusty roads are sprinkled. The number of men employed in the mine was about as follows: 275 coal diggers, 24 drivers, 14 roadmen and timbermen, 7 trappers and 12 miscellaneous. Twenty-six mules were kept in the mine, the stables being between 240 and 300 feet East of the hoisting shaft.

By the above general description it will be seen that the mine is well equipped, and that every reasonable precaution was taken to prevent accident, notwithstanding, there has been no mining law until last summer, and there is no inspector.

On Thursday, January 7th, the mine was running as usual up to 5 o'clock, 850 tons of coal being hoisted. At exactly that hour, the hoisting of the men began. Five cages had been raised, and thirty men safely landed at the surface. As the upper cage had almost reached the upper landing, and the lower cage was yet three feet above the bottom, a cloud of smoke and dust burst forth from the shaft, accompanied by a report and severe jarring. Before the noise died away, the smoke close to the mouth of the shaft re-entered and passed down the shaft, showing the fan was at work. The



SKETCH SHOWING FACE OF UPPER ENTRY O, WHERE EXPLOSION STARTED.

A break through to lower entry O was started where shot A was fired.

man in charge of the fans and their boilers rushed to the air shaft, expecting to find the covering blown off, but everything was undisturbed. He gave the engine more steam, considerably increasing the speed of the fan, which did not stop for an instant.

The superintendent, Mr. William Cameron, was at his office, less than half a mile from the shaft, receiving by telephone the report of the day's work, when notice of the accident came, and he immediately repaired to the mine, first seeing, as he could from his office door, that the fan was running.

The news spread rapidly, and in a few minutes the scene always enacted at such an accident was repeated here, women and children crying for their loved ones, and suffering the terrible anxiety and suspense which only such a calamity can bring.

It was found that the lower cage was fast, and the slides were broken. The upper cage was hardly moved. One of the ropes was taken off the drum, and the other attached to an iron bucket (used in sinking shafts), and volunteers called for, to go to the rescue of those below, which call was bravely and promptly responded to. Three men entered the bucket, and in fifty minutes after the explosion were at the bottom of this deep shaft, helping the injured. Other rescuers were speedily lowered, and the work of hoisting the wounded and burnt men began. Meanwhile, parties were replacing the broken down doors and blown-out stoppings with canvas, and in a short time the air was traveling in its accustomed channels, and every part of the mine was accessible.

The newspaper reports of "200 Men Entombed Alive Beyond Hope of Rescue," and that men were shut in behind falls of slate and could be heard calling and rapping on the rails, was a pure fabrication, without the least shadow of foundation. The fact of the air shaft being so far from the main shaft saved the fan from any harm or even from stopping, and insured a fair current of air over all or nearly all the mine lying to the rise from the main shaft, even before the stoppings were replaced. Large falls of roof slate occurred on the west side adjoining the shaft and at the head of the slope, retarding the work of rescue. Meanwhile, many men who were uninjured or only slightly burned by the flame passing over them, walked through the return airways and made their escape by the stairway in No. 7 shaft, men having already been sent to help them along. One hundred and three made their escape in this way. But some brave men who were in the mine when the accident occurred, and were unhurt, refused to go out, but remained to assist in the work of rescue. One determined miner climbed the whole 475 feet from the bottom to the top of the shaft, hand over hand, on the buntons, between the two hoisting compartments, before the bucket was first lowered. Another had started, and with heroic self-denial said to the men in the bucket, as they passed him, "Go ahead and help those below. I can hold on awhile." He was taken off on the third trip.

After a time the slides were repaired temporarily, and one of the cages substituted for the bucket, making it easier and safer to bring out the injured. At 2 A. M., nine hours after the accident, every live man was believed to be out of the mine, which was true with a single exception. A young man had been overcome and left by his father for dead. At noon Friday he was found alive and uninjured, having been conscious for some hours. He had been pounding on an empty powder can in hopes of attracting notice. His feelings during these hours can be imagined.

The bitter cold prevailing made it impossible to keep the injured men comfortable at the foot of the shaft while waiting to be hoisted, but they were made as warm as possible, being laid on hay in the mule stable, and covered with the same.

None of the mules were injured, but the mule tender was killed. He was washing a mule at the time, and was evidently killed by the mule in his terror.

Fourteen or fifteen miners were killed near the foot of the shaft, where they were waiting their turn to be hoisted, being hurled against timbers or other obstacles, or were struck by flying objects, and many others were injured. A young man stood on the east side of the shaft, exactly in line with the timbers forming the center partition, giving the signals to the engineer above as each six men stepped on the cage. He escaped without a scratch, the force of the explosion coming from the opposite side of the shaft, dealing death and destruction on both sides of him. The middle partition, one foot thick, saved him. Some of the men were probably killed by falling slate, but the larger number succumbed to the deadly after-damp; most of them were prostrated in the vicinity of the slope. Nine were found in entry K, on the west side of the slope, one lift below the shaft. Everyone who followed the return airways escaped.

Let us now consider the cause and course of the explosion. In the first place, it was not a gas explosion. The mine was inspected in the morning, and no gas found. Miners had been working all day with naked lights. All agree that it started near the face of these parallel entries upper entry O (the two parallel entries thirty feet apart, both being called O) were in the "first of the air," the very first working faces to receive the current, where it must have been perfectly pure. This same air current passes through scores of working faces after leaving entry O, but at any point it is safe to work in it with naked lights. Furthermore, no signs of gas could be found in entry O, after the accident, when only the loose canvas curtains had been substituted for the tight doors and stoppings which were blown to pieces by the force of the explosion. I myself saw the face of both entries, and of each of the five rooms on this entry carefully inspected for gas three days after. Enough gas could not be found to burn with a naked light, even close to the roof, and at the extreme face of the rooms, which are all driven to the rise. The course followed by the destructive force was out entry O to the slope and up the slope to the main west entry. Near this point, and between it and the shaft, only 200 feet away, most of the damage to the mine was done. All doors and stopping along its course were destroyed, and its force was evident for considerable distance on the entries to the right and left, especially on the main west and up the plane, but the greatest force was shown in the course first described, and it seemed to increase as it advanced, till the climax was reached near the shaft. Now this travel was in and against the strong current of fresh air which passed down the shaft, swept along the main west and down the slope undivided and unobstructed. This seems to do away with any idea of gas playing any appreciable part in this accident. There had been a fire in the face of entry M, one lift above O, some time since, which proved too difficult to handle and it was walled off and flooded, and the entry allowed to stand. To avoid any suspicion of danger, a pipe was walled in the stopping near the roof, and provided with a valve and a pressure gauge, which was regularly inspected. No pressure was ever noticeable or gas discovered when this valve was opened. After the accident, it was rumored that the explosion was connected in some way with this walled-off entry face, but all the walls or stoppings were found intact, even to the pipe with its valve and gauge.

In the second place, it was not a powder explosion. In saying this, I refer of course to kegs of powder, not to the shots prepared for blasting down the coal. Entries N and O were the lowest in the mine, and were new entries, extending less than 300 feet from the slope. No powder was allowed to be stored in these entries, but was kept on entries L and M, several hundred feet from any working face, the rule requiring the iron powder kegs to be locked in wooden boxes. Cartridges for blasting were made here, and carried to the working faces and immediately inserted in the drill holes prepared for them. Similar precaution was taken everywhere to keep the powder out of reach of shots. No powder or exploded kegs were found in the lower entries, and no exploded kegs or other signs of powder explosion in any part of the mine. The powder used by the men working in entries N and O, was found in its proper place in entries L and M, except that two kegs were found in the center of the entry (not in any box), where they had evidently been thrown by the force of the explosion, with paper plugs in the holes, and unexploded. Other powder was found in boxes over which the fire had passed, but no signs of any having been exploded.

What then was the cause? It has been the custom for the miners to appoint a committee to investigate any serious accident, as there is no mine inspector in the Indian Territory. That was done in this case, and the committee included two or three miners from other coal fields, men who had flocked to McAlester, generously offering their assistance in this sad hour. This committee spent two days in examining the mine, and were unanimously of the opinion that it was not a gas or powder explosion. As to the real cause, or at least the cause of its extending so far they did not so well agree. As ready as they always are, each one with his particular theory, one at least called it a mystery. As to the primary cause and starting point, however, they and all who have carefully examined the mine agree. It came from one or two shots fired by the entrymen working in upper entry O, shots which were badly located, showing very bad judgment, or perhaps disregard of judgment, shots which if found in a room, the regular shot firers would have refused to fire. But the entrymen fire their own shots, and so the shots cannot be condemned before firing, as in the rooms. In another respect these shot firers violated the rule agreed to by themselves, viz.: not to fire before 5.30 P.M. If this rule had been adhered to, while the damage to the mine might have been the same, very few lives would have been lost, as all the regular miners would have been hoisted. These shots were fired at 5.03 or 5.04 P.M., twenty-six minutes before the time, just when the men were all congregated at the most dangerous place (as it proved in this case), the bottom of the shaft. If the two men who fired the fatal shots were to blame, they have at least paid the penalty with their lives. Both they and the two entrymen working in the parallel air course or lower entry O, who lit their shots at the same time, were killed on the slope on their way out. The three entrymen working in entry N, and its air course, just across the slope, felt the force of the explosion, and leaving their shots unfired, rushed out and up the slope, and escaped unhurt. Entrymen in some distant parts of the mine, not knowing that there had been any explosion, fired their shots later, and only learned of it when they met the wreck and the after-damp, as they leisurely made their way out. Hastily retracing their steps, they followed the return airways and escaped unhurt by Number Seven Shaft.

There is a difference of opinion as to how many shots were fired in upper entry O, whether one or two. The miners' committee thinks two were fired, one being in an old hole marked on the sketch B, which had been fired the night before and failed to do its work, and which was recharged and fired again, again failing to do the work expected of it, but succeeding, in connection with the other bad shot, marked A (known to be fired), in wrecking the mine and turning a whole community into mourning. The shot first referred to, marked B on plan, is at the extreme face of the entry, is 2 feet 8 inches deep, and at the point has 4 feet 6 inches solid coal between it and the cutting, too much coal to break out with a shot of that depth. It would naturally belch forth like a cannon, making what is called a "windy shot." C is another old shot previously fired, which had undoubtedly acted in a similar way, although it had broken out or loosened a block of coal at its "heel" or mouth. This hole is now 3 feet 10 inches deep, was probably 5 feet 6 inches or 6 feet when drilled, and the point or inner end of the hole is 5 feet 6 inches from the face of the coal. In other words, it is 5 feet 6 inches "on the solid." No undercutting was done in this entry. A is a shot certainly fired on the fatal night. The hole was 8 feet deep, with the point 5 feet "on the solid," diminishing to nothing at the "heel" or mouth of the hole-weal, where it should be strong, and strong where is should be weak. As might have been expected, it only broke out a triangular block of coal at the mouth of the hole, a ton or less in weight, which was hurled against the opposite rib with such force as to crush it almost to powder, filling the air of the entry with fine coal-dust, which either exploded with the flame of the same shot, or by the flame of the other shot, just at the right instant blazing forth the length of the dust-laden chamber. The entry was well sprinkled, as testified to by the man who did it under orders from the pit-boss; by the man who was ordered to see that he did it (all these men were saved), and as shown by the dampness of the floor three or four days after the explosion. The explosion in entry O may be thus explained, but it is more difficult to see why it should travel with such force the length of the slope 1,000 feet. Water constantly gathers in the sump at the foot of the slope, where it is baled into water boxes or cars, and if not needed for sprinkling, hauled up the slope and emptied into the sump there. This of itself keeps the floor wet, and on the level track from the "knuckle" to the shaft it is decidedly muddy. Water trickling down the shaft keeps everything in that immediate vicinity wet. And yet over this muddy road the greatest damage was done. This level part is double tracked, and is about 300 feet long. It may be this broke down quicker because it was so wide. Near the shaft the entry was ten feet high, while at other places the entries are from five to five and one-half feet high.

Saltpetre powder made by the Laflin & Rand Powder Co., has been exclusively used in the McAlester mines for a long time, as it was considered safer and better than the soda powder in use in the other districts. The tendency of the men here, as elsewhere, is to do less mining, *i. e.*, less shearing or undercutting, and depend on the powder to do the work. In driving entries, about nine pounds of powder per day were used by the two men working together, generally in two unequal shots, one containing about 3½ pounds and the other 5½ pounds. About eleven tons of coal were produced to one keg of powder in this narrow work.

Miners are paid high wages at McAlester, a good miner readily earning $4.00 per day. The price per bushel of coal passing over a one-inch screen is 4¼ cents in summer, and 4¾ cents in winter. Entrymen are paid from $2.00 to $2.50 per yard in addition to the coal. In December, the wages of the two entrymen working in lower entry O for 22 days work, after paying for their powder, was $92.22 each, or $4.19 per day.

37 dead were taken out of the mine and up to the time of this writing 19 more have died. About 120 more were injured, mostly by being burned, and will nearly all recover.

OBITUARY.

Neil Beattie.

Mr. Neil Beattie, inside foreman of the Adelaide Mine, of the H. C. Frick Coke Co., died on the 5th ult., aged 44 years. Mr. Beattie was born at Cumbernauld, a mining village in Scotland. When 17 years of age he enlisted in the 78th Highlanders at Glasgow, and served eight years in this famous regiment at Gibraltar and also in Canada. He came to the United States in 1871 and worked in the Arnot Mine, in Tioga County, Pennsylvania. In 1880 he went to the Connellsville region and secured employment in the Mines of the Cambria Iron Co. He was promoted to the inside foremanship of the Morrell Mine shortly after, and was subsequently transferred to the Wheeler Mine, where he remained as inside foreman for ten years, when he resigned on account of ill heath. At the time of his death, he had again secured employment at the Adelaide Mine.

Mr. Beattie was a man of more than average intelligence and was a constant student of the best mining literature. He had the faculty of handling his men so that the interests of his employers were protected, and, at the same time, he always had the friendship and respect of his subordinates. In his twenty years of mining life in America, he made hosts of friends, many of whom will regretfully learn of his early death through this notice. In his death the Frick Coke Co. has lost a faithful official and THE COLLIERY ENGINEER a valued friend.

NEW MINING INSULATOR AND CLAMPING EAR

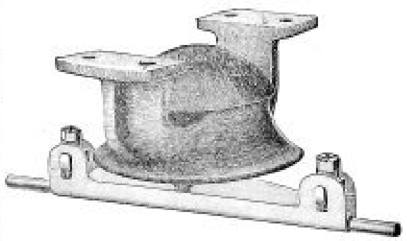
The requirements of electrical appliances, for use in mines, has necessitated the production of a type varying considerably from those employed above ground. The condition in the former case being much more severe than in the latter.

The insulator and ear shown in the accompanying cut was designed for the use of the Thomson-Van Depoele Electric Mining Company, and is particularly suited to the purpose for which it was made.

The insulator body is of iron, thoroughly painted with Graphite paint, to withstand the action of the sulphuric acid in the mines, the insulator itself being made of pieces of porcelain, rubber, or other suitable material, strong and large to withstand severe strains. Its construction is such that the insulation is entirely protected from the blows of the trolley, should it leave the trolley wire, and at the same time little opportunity occurs for grounding, as the head of the hanger-bolt is embedded in the porcelain or rubber, and the only joint in the insulation filled by a soft rubber washer firmly forced into position when the trolley wire ear is screwed into place.

The only opportunity for surface leakage is on the under side of the insulator along the surface of the cone, and as this has been corrugated the liability of leakage is reduced to a minimum.

The clamping trolley ear which was designed by Mr. J. P. B. Fiske of the Thomson-Houston Electric Company is very easy to install, as no soldering is necessary.



Its security is greater than any soldered ear, as the wire cannot come down until the phosphor bronze clamp is worn through. Its life is almost indefinite, as the clamp is ·032 in. thick and 8 in. long.

As the clamp can be loosened in a moment's time, the slack in the wire can be taken up at a little expense of time and trouble, a feature not possessed by the soldered ear.

The excessive sparking which occurs with the other types of clamping ear is entirely obviated by making the bronze very thin, so that it can be easily reduced to a knife edge, at the end, where the trolley runs on. The clamping devices being located at the end just over the point where the trolley runs on the phosphor bronze, the latter is sure to be pulled tight against the wire at this point, thereby securing a good fit and preventing sparking.

The clamping devices are positively locked by means of a stout German silver lock-wire. It is not possible for the screw to back out even the fraction of a turn, without shearing off this wire, which is quite improbable, as the shearing force is practically nothing. There can be no corrosion or rusting of the clamping ear as in its construction, iron and steel have been entirely eliminated. Should the bronze clamping strip wear out, a new one can be substituted at a moment's notice

Announcement.

We desire to call the attention of our readers to the advertisement of Messrs. G. L. Stuebner & Co., of Long Island City, N. Y., in another column. Messrs. Stuebner & Co. are extensive manufacturers of self-dumping steel iron hoisting tubs, side and bottom dumping cars, and iron wheelbarrows, hoisting blocks, etc. Their works are very complete, and they have facilities for manufacturing of such a nature that they can furnish high grade goods at prices that will compete with inferior manufacturers. Their location is such that freight rates do not enter into the question of cost. By the peculiar arrangement of tariff sheets, freights from Long Island City are lower than from most places several hundred miles nearer the place of delivery. They issue a handsome illustrated catalogue of their various products, which will be sent free on application.

An Enterprising and Successful Firm.

It is with pleasure we note the success of Messrs. H Ward Leonard & Co., Electrical Engineers, Electrical Exchange Building, New York. A recent letter from Mr. A. S. Vance, General Superintendent, informs us that among the prominent plants they are at present installing, as contractors, are the following:

Mail and Express Building, New York City.
Catherine Bradley Building, New York City.
Geraldine Building, New York City.
Germania Fire Insurance Building, New York City.
Du Vivier & Co. Building, New York City.
F. O. Du Lous Building, New York City.
Franklin Trust Building, Brooklyn.
Fifth Avenue Theater, New York City.
Columbia Theater, Brooklyn.
Graham Hotel, New York City.
Mr. John H. Inman's residence, New York City.
Curtis residence, Greenwich Conn.

Among the leading concerns for whom they are acting as Consulting Engineers, are the following:

Otis Elevator Co., New York City.
Wm. Sellers & Co., Philadelphia.
Ingersoll-Sergeant Drill Co., New York City.
Eastern Electric Co., Limited, St. Johns, N. B.
Providence Journal Co., Providence, R. I.
Rock Hill Electric Light Co., Rock Hill, S. C.
Middletown Music Hall, Middletown, Conn.

Easy Lessons for Beginners in the Study of the Art of Mining and the Sciences Related to It.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the sciences related to mining and to learn how to answer the questions in ventilation, surveying, and mechanics which are asked at the examinations for mine foremen's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine foremen and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and many calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

Practice is indispensable in bringing to perfection any art, science, or profession, and this is especially true in the study of penmanship. It will not do for the student to merely read over these articles, but considerable time must be spent in faithful practice, if he would write a good business hand.

The capital letter M is generated by the same elements as the letters already given. Letter 1, Fig. 34 beginning at the left is drawn on correct principles

Fig. 34.

It consists of the capital stem united at the top with a downward left curve which is joined in a short turn at base to an ascending left curve which is drawn to the same height as the stem of the letter; it is completed by a downward curve, the upper portion of which is on the same slant as the stem, together with another ascending left curve one-third of the full height of the letter. In letter 2, the first and fourth laws of penmanship are violated; and further, the second left curve retraces the first half way. In letter 3 the strokes are not parallel and the left curve is imperfectly developed.

Fig. 35.

The scroll of the capital stem of the fourth letter is left out entirely and it is otherwise imperfect.

In Fig. 35, we have the letter N as it should be made in letter 1. The capital stem and descending left curve are united as in M, the left curve is joined by a turn at the base to another curve rising two-thirds of the full height of the stem. The probable faults in making the capital N are shown in letters 2, 3, and 4 of the figure, counting from the left. In letter 2, the descending left curve is carried too far to the right of the stem, and the ascending curve should have been made just as long again. In letter 3, the ascending left curve is carried too far to the right of the capital

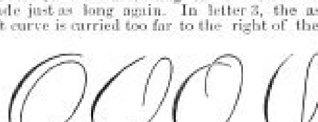


Fig. 36.

stem and the strokes are not parallel. The scroll to letter 4 is imperfectly made and all its parts are disproportionate.

The capital letter O as it should be made, is shown in letter 1, Fig. 36. It is drawn on a slant and is composed entirely of curved lines. Its width is one-half its slanting height. Letter 2 is faulty in that the lower section of the first curve is drawn to the left instead of to the right thus spoiling the ellipse. Letter 3 is a violation of the fourth law of penmanship, namely, all curves should be elliptical. Letter 4 is made without enough slant and is displeasing to the eye. It is also terminated with a straight line instead of a curve.

UNITS OF WORK.

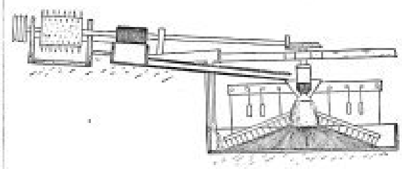
Education is simply a process for training the mind to understand and apply unit values. Without these units, no definite ideas can exist in the mind, nor could we estimate the values of the great forces which are used by man to soften his toil and increase his comforts. We have units of time, units of length, units of area, units of volume, units of weight, units of money value, units of heat, units of pressure, and many others; and in addition, units of work. It is with the latter that we propose now to deal. A unit of work then, is the work done when a pound of force is exerted in any direction, through the space of one foot, we have work lost and work usefully applied. Work lost should properly consist of that which cannot be prevented, such as the friction due to the moving parts of machinery. Work usefully applied, so far as machinery is applied, is that which adds to the wealth and comfort of man; in some men's lives, nearly all the work is lost work or work wasted. Wise men seek to minimize lost work, and expend their energies on such useful work as will upraise them, and make them honorable members of human society. We intend, in succeeding numbers, to treat under the head of Stepping Stones, on all the great and mechanical principles that are of value to mining students. Let us then proceed with a few examples, and first notice, that the distances in feet through which a force is exerted, multiplied by the value of the force in pounds, in the equivalent of the units of work done; observe then, that we have three units before us: first, the foot unit; second, the pound unit; and the foot and the pound unit when involved, generate another unit, called, a foot pound, or unit of work.

Example 1. A stone 2 pounds weight is thrown upwards into the air to an elevation of 30 feet. How many units of work were exerted by the throwing of a stone in projecting it upwards? Here then $2 \times 30 = 60$ foot pounds or units of work.

SOME TERMS USED IN METAL MINING EXPLAINED AND ILLUSTRATED.

THE BUDDLE.

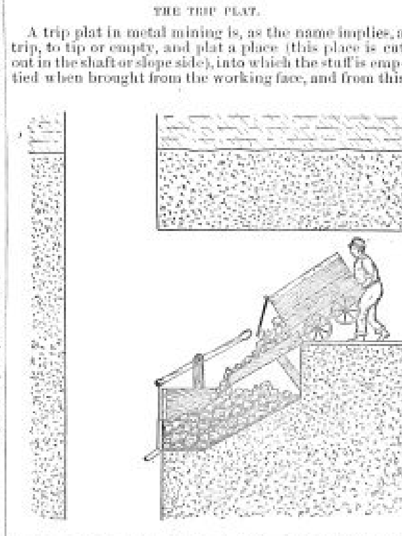
Buddles are for the purpose of separating the very finely powdered material which cannot otherwise be separated, into useful and useless. They depend for their action upon the principle that if a uniform stream of water carries down along a suitable slope a mixture of fine particles, some of which are very heavy, and others much lighter, the friction of the heavier particles will be greatest, and they will be carried a less distance down the slope, the very lightest going farthest.



The sketch represents a machine buddle, which is a conical structure, eighteen to twenty feet in diameter, and circular in plan, the surfaces are set at a suitable angle, and smooth beams receiving motion from shafts, to which are attached other beams, having brooms which just touch the surface of the buddle as they revolve. The fine material comes in along with water in the form of mud by spout into the funnel, the spout leading from a cistern, in which the fine material is kept agitated in the water as in the hand buddle. The heavier the material the nearer to the top of the cone it will be found, the light material being nearer to the bottom. At intervals the different classes of material are washed off to suitable channels, by which they are led into settling tanks.

THE TRIP PLAT.

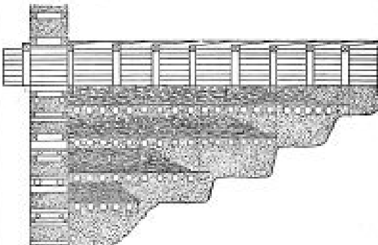
A trip plat in metal mining is, as the name implies, a trip, to tip or empty, and plat a place (this place is cut out in the shaft or slope side), into which the stuff is emptied when brought from the working face, and from this



"trip plat" the skip in the shaft is easily filled (as the plat slopes toward the shaft), by means of a slide which is worked with a lever being raised to allow the stuff to run into the skip, which is stopped just immediately below the trip plat side.

DRAWING A STULL.

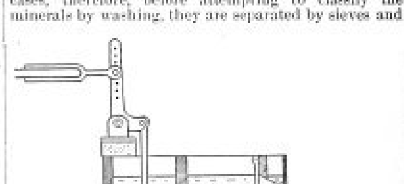
In metal mining the term stull has the same meaning as the scaffold in coal mining. In the operation of metal mining, when the shafts have been sunk in the lode, levels are driven about ten fathoms apart one above another, cut-throughs are also made from one to another for ventilation. The metal is worked either by overhand stoping, or underhand stoping from the levels. In the overhand stoping the roof is plucked to as great a height as it is convenient. The face of the metal being now out of reach, stout pieces of timber 8″ or 9″ square are placed across the place in order to make a scaffold to work upon, whilst they are proceeding with their work. Holes are made in the side for the lower end of the timber, and a groove is made in the opposite side for the upper end, then it is driven down into a level position. These timbers are placed about two to three feet apart, and planks 2″ thick are placed across these. The whole, when finished, makes a cover to keep all the rubbish from falling down and



filling the level up. As the stoping is proceeded with, pieces of wood cut the required lengths and shapes are sent down and built up, and these when finished form a wooden trough two feet square, which is used for sending down the metal as it is worked. At the lower end there is a door, and when the drawer comes along with his wagon he runs it under the trough's end and opens the door, filling the wagon immediately with the metal sent down by the workmen. The wagon, when full, is taken to the shaft bottom and thence to the surface. The stulls are very rarely drawn except when the rubbish plucked onto them is mixed with the metal, and it has to be sorted out. They commence by chipping one of the timbers in the center, and opening the boards above with a bar, so that as the rubbish slides down gradually it is filled into the wagons and sent away. Where the stull has to be drawn and the rubbish not to be assorted, they commence by chipping away one side of the level at one end of the stull, and proceed backwards until the whole have been drawn.

THE JIG.

The dressing of the metallic ores by jigging is that process in which advantage is taken of the difference in the specific gravities of the useful ore and the gangue. It is of the greatest importance that the grains or particles of ore to be classified by washing should be of uniform size, otherwise the less surface of one fragment in proportion to its weight may make up for the greater density of another fragment. In all cases, therefore, before attempting to classify the minerals by washing, they are separated by sieves and



trommels into distinct parcels, the fragments of each parcel being as nearly as possible of the same size. The character of machinery for jigging purposes, shown in the figure, ought to be influenced by the character of the ores it has to wash. Each fragment of material when ready for washing or jigging must be in one of the following three classes: First, Useful mineral with practically no admixture of earthy material. Second, A mixture of useful mineral and earthy matter in different proportions. Third, Earthy matter or gangue itself without any useful mineral attached. The most difficult ores to wash are those where the mineral is distributed sparingly, but pretty evenly through a very heavy gangue, *i. e.*, where the specific gravity of gangue and mineral are somewhat alike. In this case there will be very much loss during the washing. If the ore is fairly distinct from the gangue, and the specific gravity of the mineral and gangue differ considerably, the separation by washing will be simple and cheap, and with comparatively little loss in the operation. These are the considerations which influence the character of the machinery to be erected for washing purposes.

PROBLEMS ANSWERED.

Q. 1.—The anemometer reads 564 in. 47 seconds, what is the velocity in feet per minute and per second?

A.—To find the velocity in feet per minute and per second, proceed as follows:

$$\text{Velocity} = \frac{564 \times 60}{47} = \frac{33840}{47} = 720 \text{ feet per minute.}$$

$$\text{Velocity} = \frac{564}{47} = 12 \text{ feet per second.}$$

Q. 2.—The form of an air-way is that of an arch with a semi-circular top, it is 8 feet high and 8 feet wide, what is the area of the section?

A.—Assuming the arch to be 4 feet from the bottom of the arch to where it begins to circle, then the bottom part will be equal to $8 \times 4 = 32$ feet, take the top part as a circular arch, whose diameter is equal to 8 feet, then we have $8 \times 8 \times \cdot 7854 = 50 \cdot 2656$ area of circular arch, therefore, $50 \cdot 2656 \div 2 = 25 \cdot 1328$ area of the circular part of the arch, then $32 + 25 \cdot 1328 = 57 \cdot 1328$ feet area of section.

Q. 3.—The velocity is equal to 10 feet per second, and the area of section is equal to 80 square feet; what is the quantity of air passing through the arch per minute?

A.—10 ft. $\times$ 60 secs. $\times$ 80 = 48,000 cubic feet per minute passing through the arch.

Q. 4.—Which portion of an air-current moves quickest, and which slowest?

A.—The air-current moves the quickest in the center of the air-way, and slowest at the sides of the air-way; but it depends on the smoothness of the sides of the air-way; when the sides are smooth the air-current moves quicker than it does when the sides are rough and uneven, that is, the current moves faster against the sides when they are smooth than it does when they are rough, but under all conditions the center of the air-current moves the quickest.

Q. 5.—Show how you would handle the instrument in measuring air.

A.—I would first find a measured area, then I would examine the instrument, to see what it really indicated at the time, and note it down in my book. I would then have the instrument fastened on to a rod, and hold it in my right hand and my watch in my left. After setting the instrument away, I would move it from the middle up to the top, back to the middle, then to the bottom, and back to the middle, then over to the left side and back to the middle. By so doing, I would get the most correct velocity; after letting the instrument run for one minute, I would stop it by the little catch at the side. By subtracting the former reading from what it now indicates, I get the velocity of the current in feet per minute.

Q. 6.—How would you test for gas with an ordinary safety-lamp?

A.—Before entering a place for the purpose of testing for gas with an ordinary safety-lamp, I should first subdue the light, with the aid of the pricker, by drawing down the wick, and then, screening the eyes from the light with one hand, cautiously raise the lamp towards the roof with the other. And if there be any gas present, which will be detected by a blue halo or cap appearing on the top of the flame, slowly and carefully retire with the lamp to a safe place.

Q. 7.—If a puff of powder smoke traveled 123 yards along an air-way measuring 8 feet by 7 feet in 1 minute and 18 seconds, what would be the total quantity of air passing per minute?

A.—1 minute 18 seconds = 78 seconds, therefore, if the smoke traveled 123 yards in 78 seconds it would only travel

$$\frac{60}{78} \times 123 = 94 \cdot 61538 \text{ yds.} = 283 \cdot 846 \text{ ft.}$$

per minute. The area of the road being $8' \times 7' = 56$ square feet of section, then

$$56 \times 283 \cdot 846 = 15{,}895 \cdot 376$$

cu. ft. of air passing per minute.

Q. 8.—What is the area of a road which is passing 15,000 cubic feet of air per minute at a velocity of 5 feet per second?

A.—

$$\frac{15{,}000}{5 \times 60} = 50 \text{ feet of area.}$$

Q. 9.—How many tons of coal are contained in a pillar of coal 60 yards long and 30 yards broad, the seam being 5 feet 6 inches thick, and the coal weighing 80 lbs. per cubic foot?

A.—Reduce all the dimensions to feet and multiply the length, breadth, and thickness of the pillar together then multiply by 80 and divide by the number of pounds in a ton, thus

$$\frac{180 \times 90 \times 5\frac{1}{2} \times 80}{2240} = 3{,}182\tfrac{4}{28} \text{ tons.}$$

Q. 10.—How much work would be required to pump 7,400 cubic feet of water from a mine 280 feet deep?

A.—One cubic foot of water weighs $62\frac{1}{2}$ lbs., therefore, $7{,}400 \times 62\frac{1}{2} = 462{,}500$ lbs., and as this weight has to be raised 280 feet, $462{,}500 \times 280 = 129{,}500{,}000$ pounds to be raised 1 foot high, or one pound to be raised 129,500,000 feet high. The work required to do this would, therefore, be stated as 129,500,000 foot pounds or units of work.

Q. 11.—What is a horse power?

A.—A horse power is the power required to perform 33,000 units of work, or in other words to raise 33,000 lbs. one foot high or one pound 33,000 feet high in one minute. In the previous question the power required to raise the water was 129,500,000 units of work, therefore,

$$\frac{129{,}500{,}000}{33{,}000} = 3{,}924 \cdot 24 \text{ H. P.}$$

Q. 12.—What is the theoretical horse power of a steam engine of the following dimensions: Diameter of cylinder 15 inches, length of stroke 2 ft. 6 ins., number of strokes per minute 50, pressure of steam 40 lbs. per square inch?

A.—The units of work of an engine are found by multiplying the steam pressure, length of stroke in feet, area of cylinder in square inches, and number of strokes per minute by each other, and if this result is divided by 33,000 the quotient will be the horse power. An excellent way of remembering this is as follows:

Call the steam pressure P.
Call the length of stroke L.
Call the area of piston A.
Call the number of strokes N.
and multiply all together.

Now, divide the word P L A N by 33,000 to obtain the H. P. In this case P = 40, L = 2·5, A = $15 \times 15 \times \cdot 7854 = 176 \cdot 715$, N = 50, therefore,

$$\frac{\text{P L A N}}{33{,}000} = \frac{40 \times 2 \cdot 5 \times 176 \cdot 715 \times 50}{33{,}000} = \frac{883{,}575}{33{,}000}$$

= 26·77 + horse power.

Q. 13.—What is the difference between the theoretical horse power and the calculated horse power of an engine?

A.—The theoretical horse power is obtained as shown in answer to the previous question, and is the amount of work which would be performed by a *perfect* engine, supposing the pressure of steam was the same at the piston as it was when it left the boiler, and supposing there were no friction of its parts, nor leakages, but as these are impossible conditions it is found in practice that an engine loses a certain amount of its efficiency in working owing to these causes, and the efficiency of an engine is found by dividing the actual work performed by the theoretical horse power. For instance, if the theoretical horse power of an engine is 50, and the work performed in horse powers is only 40, then

$$\frac{40}{50} = \cdot 8$$

which is the modulus or percentage of the efficiency of the engine.

Q. 14.—What is the calculated horse power of a winding engine to raise 1,000 tons from a depth of 268 fathoms in 11 hours?

The modulus of a winding engine is very low because the engine only runs intermittently, and to obtain a high speed in the shaft the horse power is greater than is required at the lift, so much so that full steam is only given for the first few strokes, and all these things require that the engine be constructed of greater power than the actual load to be lifted would seem to demand. In this case, therefore, we will call the modulus of the machine ·4. To find the horse power we first find the units of work, thus, 1,000 tons $\times$ 2,240 = 2,240,000 lbs., and 268 fathoms = 1,608 feet, therefore, $2{,}240{,}000 \times 1{,}608 = 3{,}601{,}920{,}000$ units of work. Now, divide this by 33,000 multiplied by the modulus and the time in minutes in which the load has to be lifted, thus

$$\frac{3{,}601{,}920{,}000}{33{,}000 \times \cdot 4 \times 11 \times 60} = 413 \cdot 44$$

actual horse power.

WHY THE E. AND W. POINTS ON THE MINER'S COMPASS ARE REVERSED.

QUESTION.—Why, as in Fig. No. 1, is the E. marked to left of the North and W. to the right of North in the miner's compass?

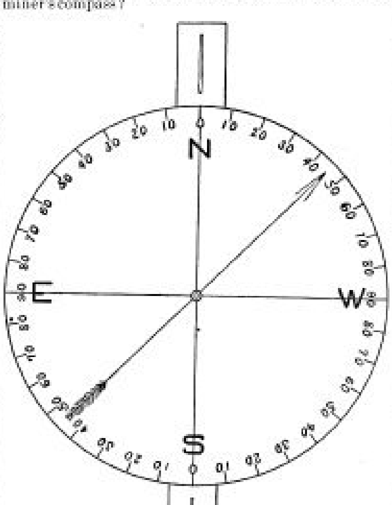


FIG. 1.

ANSWER.—To thoroughly comprehend the reason for this seeming anomaly it must first be thoroughly understood that the magnetic needle is the fixed point and it is the plate of the dial that moves, not the needle. Suppose, in the first place, the compass is set up in a gangway going due North, as in Fig. 2. The needle is exactly over the letter N. on the dial plate.

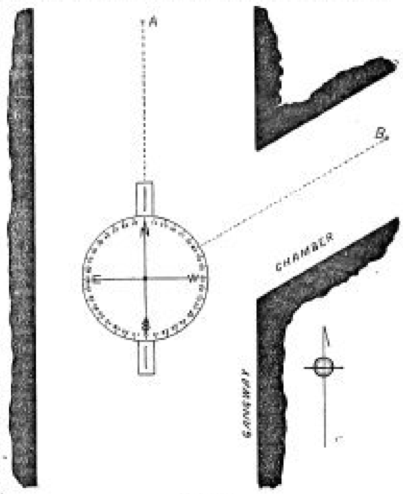

FIG. 2.

This would make the course or direction from the compass to A, North, Now, turn the compass gradually round so that the end of the dial plate with the letter N. on it will point to B, as in Fig. 3, up-chamber.

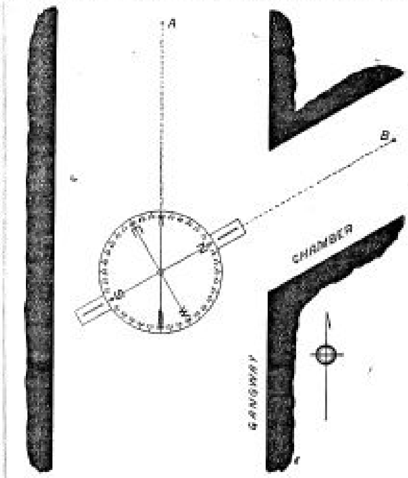

FIG. 3.

It will now be observed that although the direction of the sights of the compass is changed, the magnetic needle remains pointing to the North at A. By the figures on the face of the dial it will be observed a turn has been made to the *right* of 60 degrees. It is well known that *East* is to the *right* of *North* and, therefore, the chamber will be going *North 60° East*, and by looking on the dial plate of the compass (Fig. 3) it will be seen that the magnetic needle is pointing *60°* from the letter N. in the direction of the letter E. Now if the E. and W. were in their *true* positions, the course of the chamber would read N. 60 W., which would be wrong.

FAULTS.—WHIN DYKES AND WASHES OUT.

The rocks forming the earth's crust may be grouped under two great heads—stratified and unstratified; and may be again divided into three classes—aqueous, igneous, and metamorphic, which names indicate the agency which brought them to their present state.

Aqueous rocks, forming the greater portion of the earth's crust, are formed by the agency of water, and deposited in layers or beds.

Igneous rocks do not lie in layers or beds, but are intermixed with aqueous rocks, and appear to have been once in a molten state, and forced outwards from the center of the earth through the cracks or fissures produced in the aqueous rocks by internal heat or latent pressure, and afterwards cooled by contact with the adjoining rocks.

Metamorphic rocks were formerly aqueous rocks, but have been changed when at a great depth by a chemical action called metamorphism, by which their particles are slowly crystalized.

Stratified rocks are divided into three groups according to age, beginning with the older group, the primary; with the secondary group next, and the tertiary, or most recent group, nearest the surface.

Each group is again subdivided into formations. One of these, the carboniferous formation, a member of the primary group, is of especial interest to coal miners, as being the great coal-containing formation.

The substance from which coal is derived is organic matter, apparently bog deposits, which when isolated from air but exposed to moisture (which are the conditions of vegetable matter overlaid by a water deposit) chemical changes set in, and it is gradually converted into peat, from peat it passes to lignite, and from lignite to Bituminous coal and Anthracite.

So that each stratum or bed of coal is a separate surface growth, and each stratum of sandstone, shale, seggar, or ironstone, however small, which separate beds or seams of coal, are water deposits; so that in the formation of the coal measures the portions of the earth where coal is found would be alternately covered with vegetable matter and water.

Coal may, therefore, be defined as a mineralized vegetable substance, consisting principally of carbon, and derived from organic matter, which has undergone considerable chemical and physical changes.

Seams of coal are frequently interrupted in their continuity by faults, such as dis-jointing of the seams, brought about by the action of earthquakes, or by side pressure produced by shrinkage of the rocks, and generally causing the upheaval of the strata on one side of the fault.

The coal is generally found on the side of the greater angle, which means, that when you get the fault at first near the thill, and it inclines towards the roof, you may expect a rise fault, but if you find the fault near the roof first, and it inclines towards the thill, you may expect a dip fault.

Whin-dykes interrupt the continuity of coal seams, by forming a nearly vertical partition through the strata, and destroy considerable quantities of coal on each side of it, by the great heat of the once molten or liquid matter.

Washes-out also destroy the continuity of coal seams. They appear to have been rivers or streams of water which have become silted up, and filled in with sand, pebbles, clay, or soil.

We have also minor washes, which only cut through a portion of the seam, and these, when found near the roof, are known as rolls or balks; and when found near the thill are named horse-backs.

EXAMINATION QUESTIONS ANSWERED.

QUESTION 20. Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1889.

In the section of the mine mentioned in Question 14 (see January COLLIERY ENGINEER, page 140), which we will designate as Section "A," the air travels 6,000 ft. of entry, including the return. In Section "B" of the same mine there is required 14,400 cu. ft. of air per minute, but it must travel 12,000 ft. of entry, including the return, how would you arrange the regulator, or in what proportion would you split the air for these two sections to equalize the ventilating currents in them? Size of entries in both sections is the same.

ANSWER.—This question was ably and clearly answered on page 140 of last month's COLLIERY ENGINEER, by Mr. J. L. Beard, and we refer our readers to that answer.

QUESTION 21.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1889.

How would the friction of the air current in section A compare with the friction in section B?

ANSWER.—By referring to the answer of question 20 it will be seen that the conditions are as follows:

Section A is 6,000 ft. long, and the volume of air in circulation in it is 28,800 cu. ft.

Section B is 12,000 ft. long, and the volume of air in circulation in it is 14,400 cu. ft. In other words, section A is only one-half as long as section B and therefore presents only one-half as much rubbing surface as section B; and as the volume in section A is double that in section B the velocity is twice as great. Now as friction varies directly as the rubbing surface and increases as the squares of the velocities we have the following compound proportion, if we assume the friction in section B to be 1:

$\frac{2}{1^2} : \frac{1}{2^2} :: 1 : ()$, or $\frac{2}{1} : \frac{1}{4} :: 1 : 2$ therefore the friction in section A is twice as great as in section B.

QUESTION 22.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1889.

Describe the style or form of regulator you would advocate?

ANSWER.—In practice it is seldom possible to so arrange the splits in a mine that the resistance from rubbing surface shall be equal in each; and it is also generally necessary to have more air in the longer splits than in the shorter ones; so that some means must be used to increase the resistance in the shorter roads and so prevent their getting more than a proper share of the air circulating in the mine. This artificial resistance is obtained by placing a regulator in the return airway.

The best form for a regulator is a sliding shutter, the frame of which is fixed either in a stopping or a door. By moving the shutter, the aperture through which the air passes can be made larger or smaller according as the quantity of air in the split is required to be more or less.

The power necessary to overcome the resistance offered by a regulator to a current of air is, of course, a waste of energy, and every regulator placed in a mine means an expenditure of work that would otherwise be available for increasing the total quantity of air in the mine.

QUESTION 23.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1889.

Two airways having each an area of sixty-four square feet, and their lengths are each three thousand ft., one of the airways is circular and the other square, is there any difference in their rubbing surface?

ANSWER.—Yes. The circular airway has 85,076 sq. ft. rubbing surface, and the square airway has 96,000 sq. ft. For the square airway has a perimeter of 8 + 8 + 8 + 8 = 32 ft., and 3,000 × 32 = 96,000 sq. ft.

Then the circular airway has a perimeter of

$$\sqrt{\frac{64}{\cdot 07958}} \text{ or } 28{\cdot}36 \text{ ft.},$$

and 3,000 × 28·36 = 85,076 sq. ft.

QUESTION 24.—Asked at the Examination of Candidates for Mine Inspector, held at Des Moines, Iowa, April 9, 1889.

What is meant by magnetic variation?

ANSWER.—The magnetic variation is the distance East or West of a true North and South line that the needle of a compass points. It is not constant but increases or decreases to a limited extent, (from six to ten minutes) during the course of a day, and finally returns to its former position. This is called diurnal variation. If the observations be continued throughout an entire year, it will be found that the diurnal changes vary with the seasons, being greater in summer than in winter. The period of this variation being a year it is called the *Annular Variation*. The needle is also subject to local attraction and the variation thus produced might be called local variation, because it ceases when the instrument is removed some distance from the cause.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since our Last Issue.

Security Land and Exploration Co.,	Duluth, Minn.
The Beaver Creek Mining and Milling Co.,	Colorado Springs, Colo.
Kansas City Clay and Coal Co.,	Kansas City, Mo.
The Capitalists and Investors Company of the Pacific Coast,	Spokane, Wash.
Lithemur Milling Co.,	Alexandria, Va.
Greene Bodine Coal Co.,	Tacoma, Va.
The New Crescent Mining Co.,	Roseville, Ohio.
Old Provincial Gold Mining Co.,	Portland, Me.
Royal Phosphate Co.,	Kansas City, Mo.
Pioneer Tin Plate Co.,	Joliet, Ill.
Lick Creek Coal Co.,	Chatham, Ill.
The Spooner Refractory Ore Smelter Co.,	East St. Louis, Ill.
The American Onyx Co.,	Louisville, Ky.
Superior Smelting and Refining Co.,	Superior, Wis.
Loretta Gold and Silver Mining Co.,	Milwaukee, Wis.
The Scranton New Tripoli Slate Co.,	Scranton, Pa.
Sonman Coal Mining Co.,	Philadelphia, Pa.
The Tavern Rock Sand Co.,	Becker's Station, Mo.
The Sophie I. Mining Co.,	Rolla, Mo.
Morning Star Mining Co.,	Joplin, Mo.
The Confidence Mining Co.,	Jersey City, N. J.
The Hall Chemical and Gas Co.,	Chicago, Ill.
Mesabe Central Land and Exploration Co.,	Duluth, Minn.
Great Northern Mining Co.,	Duluth, Minn.
Philadelphia and Boston Petroleum Co.,	Philadelphia, Pa.
The Birdseye Mining Co.,	Leadville, Colo.
The Fortunatus Mining and Milling Co.,	Denver, Colo.
The Colorado Prospecting Co. Limited,	136-137 Paternoster Building, London, Eng.
The Mount Elbert Mining and Milling Co.,	Denver, Colo.
The Shoe Basin Mining Co.,	Peoria, Ill.
Atlantic Mining and Milling Co.,	Great Falls, Mont.
The Tacoma Prospect Mining and Milling Co.,	Tacoma, Washington.
Bainbridge Placer and Quartz Mining Co.,	San Francisco, Cal.
Ophir Gold and Silver Mining Co.,	San Francisco, Cal.
Riverside Silver Development Co.,	Riverside, Cal.
Junior Coal Co.,	Elkins, W. Va.
The Citizens Gas Co.,	Delphi, Ind.
The Lucky Boy Mining Co.,	Prineville, Oregon.
Pawtucket Mining Co.,	Pawtucket, R. I.
Hanover Improvement Co.,	Hanover, N. M.
The Incorporators and Underwriters Co., of New York,	Jersey City, N. J.
The Buckeye Coal and Iron Co.,	Jackson, Ohio.
The Enterprise Mining Co.,	Rico, Colo.
The Tower Smelting Co.,	Colorado Springs, Colo.
The Silver Ledge Syndicate, Limited,	London, Eng.
Warsaw Blue Stone Co.,	Warsaw, N. Y.
The Kickapoo Valley Mining Co.,	Springfield, Mo.
The Elk Creek Mining Co.,	Seattle, Wash.
The Cascade Mining Developing and Milling Co.,	Tacoma, Wash.
The Montana Mining, Loan and Investment Co.,	Butte, Mont.
American Mining and Improvement Co.,	St. Paul, Minn.
The Central Mining Co.,	New Lisbon, Ohio.
The Bay State Lead and Zinc Co.,	Mansfield, Ohio.
The Savage Mining Co.,	Great Falls, Mont.
Whitney Water Supply Co.,	St. Louis, Mo.
The Quaker Valley Mining Co.,	Youngstown, Ohio.
The Taylor and Rathven Investment Co.,	Denver, Colo.
Master-Lode Nickel Mining Co.,	Chicago, Ill.
Black Boy Mine and Quarry Co.,	Chicago, Ill.
The Wilson Oil Co.,	Washington, Pa.
The French Creek Mining and Milling Co.,	Chicago, Ill.
Loomis Coal Co.,	Bevier, Mo.
The Union Leasing and Mining Co.,	Denver, Colo.
The Yule Creek Slate and Mining Co.,	Colorado Springs, Colo.
The Yule Creek Marble and Mining Co.,	Colorado Springs, Colo.
The Mt. Rosa Mining, Milling and Land Co.,	Colorado Springs, Colo.
Metropolitan Land and Investment Co.,	Joplin, Mo.
Buena Vista Mining Co.,	Stevensville, Mont.
Victor and Burnt Fork Mining Co.,	Victor, Mont.
The Boston Structural Steel Co.,	New York, N. Y.
Lake Hancock Pebble Phosphate Co.,	Bartow, Fla.
Eagle Mining and Milling Co.,	Seattle, Wash.
Keystone Mining and Milling Co.,	Spokane, Wash.
The Washington Improvement and Investment Co.,	Port Angeles, Wash.
Utah Reduction and Refining Co.,	Washington, D. C.
Witte Water Power Co.,	New York City, N. Y.
Central City Brick Co.,	Central City, W. Va.
Old Dominion Mining Co.,	Richmond, Va.
Columbia Smelting and Refining Co.,	Cerrillos, N. M.
Lehigh Coal Co.,	Alma, Kans.
The Union Pacific Coal Co.,	Rock Springs, Wyo.
The Green Mountain Mining Co.,	Chicago, Ill.
The Union Mining and Smelting Co.,	Denver, Colo.
The Spur Daisy Mining Co.,	Denver, Colo.
Rocklin Granite Co.,	Oakland, Cal.

Acknowledgement.

The Canton Steel Roofing Co., of Canton, Ohio, with a desire to excel in everything issued from its works or office, has just issued a handsome office calendar, good for two years, framed most conveniently in Russia leather. It is the finest calendar that we have seen this season and is typical of the corrugated metal manufactured by the company—the best. Accompanying the calendar was a beautiful and convenient leather bound memoranda book, for both of which we extend thanks

Dissolution.

Messrs. Pepper & Register, manufacturing and contracting electrical engineers whose office is in the Provident Building, Fourth and Chestnut Streets, Philadelphia, sends us the following announcement under date of January 15th:

"The firm of Clay, Pepper & Register has this day been dissolved by mutual consent. The business will be carried on as heretofore by the remaining partners under the firm name of Pepper & Register."

ENGINEERING

Progress of the Inter-Continental Railway.

The following is an abstract of the report of Mr. L. J. Blanco, member of the Inter-Continental Railway Commission for Venezuela, concerning that work:

United States and Mexico—The railways in these two countries, being in perfect communication, the Commission has only been occupied with their continuation and the choice of the most suitable point of departure. It has decided for Ayutla, on the Guatemala frontier.

Guatemala—From Ayutla, the Inter-Continental Line will descend by the Pacific coast, passing in the neighborhood of Rotalhuleu and Mazatenango as far as Santa Lucia. Thence will be used the branch, in course of construction, of the Central Railway from Guatemala to Escuintla, and will pass from Cujinjilapa to Santa Anna, in the Republic of Salvador.

Salvador—In this Republic the route of the proposed Central line will be utilized, passing by Santa Anna, Nuevo, San Salvador, Cujutepeque, San Vincent, and San Miguel, entering Honduras by Guascoran.

Honduras—From Guascoran the line will continue by the shore of Gulf Fonseca, crossing the State of Cholutcen via the town of that name, going thence to the south towards Nicaragua.

Nicaragua—In this Republic the line will arrive at the town of Chinandega, where it will join the railway from Corinto to Lake Managua, utilizing this line up to a suitable point, for example, Pueblo Viejo, skirting the lake and coming to the town of Managua, where it will take the line already constructed from Managua to Masaya. From Masaya the line will pass to Rivas, will cross the proposed Nicaragua Canal, and will enter into the Republic of Costa Rica.

Costa Rica—Following the shores of the Lake of Nicaragua and penetrating the country by the plains of Guatuso and San Carlos, the line will continue as far as the town of Alajeula, where there is a branch to the capital. From Alajeula a continuation will be made by the railway from San Jose to Puerto Limon, thence, by points which are not yet determined, the length of the Isthmus of Panama, as far as the entry of the Atrato Valley in Colombia, will be traversed.

Colombia—Colombia being reached, the Inter-Continental will traverse the western cordillera of the Andes, entering into the Cauca Valley, and, reaching the environs of the town of Antioquia, it will ascend by this valley, connecting the principal localities met with, and arriving at Popayan. The central cordillera will be crossed in order to survey the branch intended to connect Bogota with the main line. From Popayan the line will pass into the Patia Valley, making toward Pasto or Ipiales, with continuation towards Ecuador. The passage of the cordillera on the route from Popayan to Pasto will be one of the greatest difficulties met with in Colombia; it is at this point that the great ramifications of the Colombian Andes commence.

Venezuela—In order to place this Republic in communication with the trunk line, a branch will start from a point (still undetermined) of the route in the Cauca Valley, going to Medellin, where it will rejoin the line, running from that town to Puerto Berrio, on the Magdalena; thence it will go to Bucaramanga, and thence to San Jose de Cuitica and San Cristobal, La Grita, Merida, Trugillo, Barquisimeto, terminating at Valencia.

From Valencia to Caracas via La Victoria a railway is in course of construction and will be completed in a few years. Other lines, having been conceded, are being surveyed in the regions just indicated, and the route of the Inter-Continental will undoubtedly adapt itself to circumstances at the time of the execution of the project, whenever that may be.

Ecuador—The line will touch at the town of Tulcan, then, descending by the central valley of Quito, will serve the towns of Ibarra, Quito, Latacunga, Ambato, Cuenca, and Loja, there entering Peru.

Peru—The line will traverse the Department of Cajamarca, or the Amazonas, till it meets the river Maranon, and will ascend by that valley as far as Cerro de Pasco. From the latter point it will follow the course of the Perene up to a suitable point for a deviation to Santa Anna, then to Cuzco, Santa Rosa, and Puno, skirting Lake Titicaca in order to penetrate Bolivia.

Bolivi—The Inter-Continental will connect the towns of La Paz, Oruro, and Huanchaca, where it will divide into several branches, going to Chili, the Argentine Republic, Brazil, Paraguay, and Uruguay.

Chili—The Chilian branch goes from Huanchaca to Antofagasta, a port on the Pacific.

Argentine Republic—This branch, which has already been surveyed, goes from Huanchaca to Jujuy, the extreme point of the railway system of this Republic.

Paraguay and Uruguay—The line which is to connect these two countries to the proposed system will start from Huanchaca, will follow the left bank of the Pilcomayo, in order to rejoin the Osborn concession, which from Asuncion goes to the north of Paraguay. From Asuncion use will be made of the lines already constructed, or in way of construction, as far as Montevideo.

Brazil—The Brazilian branch starts from Huanchaca, going eastward, clearing the Paraguay River at Corumba, where, penetrating on Brazilian territory, it follows the river Taguary as far as Coxim, a railway the concession for which is granted from this point to Uberaba; from this latter city are existing lines to Rio de Janeiro.

The scientific commissions are authorized to search out and survey the best directions and routes. The above plan must only be considered as a general idea, which, according to the plans drawn up at the Washington Central Bureau, would appear to have met most effectually the interests of the American Republics.

Some Historic Canals.

The canal is an ancient institution. It co-exists with the remotest periods of human history, since primitive man discovered the value of an artificial water-way across a peninsula, or from one remote stream to the navigable waters of another. Historians allude to these artificial channels as existing in Egypt and elsewhere in the far away centuries preceding the Christian area.

In the year 1282 the Chinese completed an imperial canal that traversed a distance of 1000 miles, a forty days' sail for the Mongolian junk.

In 1681 the famous Languedoc Canal was completed. This gave France an artificial water-way 148 miles in length with, a summit level of 600 feet above the the sea, and including upwards of 100 locks and fifty aqueducts.

In Great Britain Roman spades dug the first canal one or more of which are holding water to-day. The canals of the United Kingdom now exceed 47,000 miles in length and are amongst the best of their kind in the world. The Manchester canal now in course of construction will, when completed, be a masterpiece of enterprise and engineering skill, and will place the Manchester manufacturer in direct and unbroken communication with the ocean.

The North Holland canal was completed in 1822 and is fifty miles in length. The Amsterdam and other artificial water-ways are among the most vital auxiliaries of Dutch commerce and prosperity.

The Suez Canal, which up to the date of its completion was the most stupendous undertaking of its kind in modern history, extends from Port Said on the Mediterranean to Suez on the Red Sea, the whole length of navigation being eighty-eight geographical miles. This trans-Egyptian water-way is navigable by steamers 400 feet in length and 50 feet beam, the cost of this gigantic enterprise, including its harbors, being about $100,000,000.

In the western hemisphere, both in the United States and the Canadas, the inland canal has long been an economic necessity, and in the Erie and the Welland, etc., we have examples of their service.

In a strictly national sense we have the magnificent mistake of Panama, with its big holes and insolvent stockholders. At Nicaragua American enterprise is already at work. The importance of this canal to the United States and to other commercial nations, as a route between the Atlantic and Pacific, is probably beyond any present calculation, and is of so undeniable value, that be the engineering difficulties what they may, the consummation of the idea is among the historic certainties of the future.

A Prospective Railroad.

The survey of the canyon of the Colorado has been completed, and Mr. R. B. Stanton has given a full account of it in the *Engineering News*. In spite of the great depths of the canyon and the cliffs of sandstone, marble, and granite composing it, a railway can in his opinion be built through it without much tunneling, thus opening up some of the grandest scenery of the world. In many places the canyon expands into wide valleys, and even where it narrows there are terraces along the sides like the "parallel roads" of Glen Roy in Scotland, which seem designed by nature for track and rail. The tributaries which enter the canyon laterally are, as a rule, small, and can be easily bridged. The distance of 1,049 miles through the canyon district will comprise only 20 miles of tunneling and 90 miles of granite cutting.

USEFUL INFORMATION

Choosing a Business.

The all-important question to every young man when he arrives at that age where he begins to look about him for the purpose of settling upon something as his life's work, is one that is not always easily determined or judiciously considered.

Advice upon this subject is frequently but slightly appreciated, as most young men consider themselves capable of choosing for themselves. However, it is fair to suppose that the experiences of others are worth something, and when these experiences have proved successful they are all the more worthy of consideration.

We judge of a man's success by the fortune he has accumulated in the business he has chosen to follow, and upon this theory the following advice, from one of the most successful men of the present time, Mr. Russell Sage, is worth a careful study. He says: "The question of choosing a business is a serious one. As a rule, a young man should adopt the calling for which he has a preference. If he has no particular choice, it would be well for him to try different occupations, until he finds one that suits him. I do not counsel changing about to gratify a spirit of uneasiness, for once a young man is installed in the business that he is suited to, he ought to stick to it. I have known young men who entered employments reluctantly, and after a trial became fond of them. A young man must be determined to succeed. After all, there is one great lever, and that is will power. Without it very few men succeed.

"It depends on the circumstances whether failures betray incapacity in a man. If a failure is due to a cause not general, then it may be attributed to a lack of foresight and understanding. A shrewd merchant will not stock up with unsalable things; a shrewd farmer will not plant his ground to raise unsalable crops. Both the merchant and the farmer must find out what is salable, and act accordingly. There are exigencies, to be sure, like contagions, disasters, combinations, strikes, and boycotts, that cannot be foreseen. The prudent man of business has prepared himself to stand losses from such causes, and when the troubles have passed the fact of his having weathered them makes his financial position in the community stronger than ever. The present condition of the coal trade well illustrates the uncertainity of things. The mild, open winter could not be foreseen, and has caused great dullness and loss in the trade. Then there is the march of improvement. This is an age of competition, and it requires energy and perception to meet it. It used to take ninety days to find out the conditions of the tea crop in Japan or the coffee crop in Brazil. Now the inquiry can be sent and an answer secured in a single day.

"The young man should start out in the world by the time he is twenty-one. If he is qualified to begin life at an earlier age he should do it. I begun as a clerk when I was twelve. At eighteen I was in business for myself, and I have kept my sign up ever since. I should say that the average boy could take a clerkship at the age of 16 or 18. A wrong start may not mean a permanent failure. Many of the most successful men have started wrong and afterward righted themselves. There are many instances where men educated for the pulpit have gone to the bar and been conspicuous successes. Then, again, men educated for the bar have gone to the pulpit and achieved success."—*The Manufacturers' Gazette, Boston.*

How to Make Gas.

To make coal gas is very easy. Most schoolboys know how to do it at a few minute's notice. Here is the process which I tried a hundred times or more before I was ten years old:

Get a little bit of Bituminous coal—as much as the size a walnut will answer. Pound it small, almost into dust, with a hammer or cobblestone. Take an ordinary tobacco pipe (one with a long stem is preferable) and fill it with the pounded coal, pressing it pretty closely with your thumb—I should have said nearly fill it. On the top press down some tough clay, reduced to the consistency of putty by being tempered with a little water. Then insert the pipe, filled with coal and closely covered with the tenacious clay, carefully between the bars of the grate, so that the clay on the top of the bowl may not be disturbed. In a minute or two the heat of the fire evolves carbureted hydrogen gas from the coal in the pipe.

If the covering be compact and complete the gas flows out of the long stem of the pipe, which projects out of the fire, and you can immediately see and smell it.

The smell is that of escaped gas—which is so unpleasant and unwholesome when perceived in a room—and the appearance is that of a thick smoke. Then apply a lighted match to this vapor which, being inflammable, instantly is all aflame—burning brightly until all the coal in the bowl of the pipe has parted with its gas. When this is done there is an end of the flame.

Take the pipe out of the fire, remove the clay cover of the bowl, and the residuum remaining therein is coke.

Now, this is the distillation of gas from coal, which lights our houses and streets—only at the gas works the vapor is submitted to processes which purify it, thereby producing a clearer and brighter light when burning. What is left after making the gas has a commercial value.—*New York Recorder.*

The Poison of the Toad.

Lovers of Shakespeare will be glad to see the credit of their favorite poet rehabilitated even in a small matter. The lines:

> "Toad that under the cold stone
> Days and nights hath thirty-one,
> Sweated venom,"

have of late years been looked upon as simply the expression of a popular prejudice current in Shakespeare's time, but now completely exploded. A correspondent of the *Field* remarks that "Fleming, in his well-known 'History of British Animals,' maintains that the toad is destitute of any venomous quality, and is only despised, hated and persecuted by the ignorant; and he remarks that it is surprising that prejudices so unjustifiable still continue to prevail." In two letters which appeared in the *Lancet* of August 29, a large amount of evidence is brought forward to show that Shakespeare's word's, instead of being merely an expression of a mistaken popular idea, are really a most truthful description of fact.

The toad does secrete a venom of a tolerably powerful character; and instead of this secretion taking place, as in the case of snakes, entirely through the salivary glands, it is actually secreted by the skin, so that the word "sweated" is most accurately descriptive. In his interesting letter, Doctor Leonard Guthrie mentions that the secretion also occurs in the toad through the parotid glands, and that the venom is a thick milky fluid like the juice of dandelion stalks in taste and appearance. When inoculated subcutaneously, it kills small birds in six minutes, and dogs and guinea-pigs in half an hour to an hour and a half; the symptoms in birds being loss of co-ordination, followed by death; in guinea pigs convulsions, and in the dog depression, vomiting, and intoxication.

Dr. Guthrie describes two very interesting observations of his own on the effect of toad's venom. He kept a small toad in a cage with some common lizards, and, one day, a lizard, having bitten the toad, immediately afterward rushed wildly round the cage, burrowing its head in the sand, became convulsed, and died in less than two minutes. His dog, having seized a toad, was attacked by instantaneous and profuse salivation, violent vomiting and collapse. He also noticed that the venom has a most powerful local action on the skin, so that, after carrying a toad in his hand, he got numbness and tingling in it, with a slight swelling and dryness of the skin lasting for several hours.—*Lancet.*

Razors, Safety-Pins, and other Inventions of 3000, B. C.

The *Washington Star* has been through the patent office in Washington in pursuit of inventions of antiquity and finds that not only were telephones used by the ancients of some thousands of years back, but several other alleged inventions of modern times, are duplicated in the collection of remote antiquities at the Smithsonian Institute.

The relics exhibited in this collection are mostly of the bronze age, from 2000 B. C. to 400 B. C. Among them are razors of bronze, some of which nearly resemble in form the razors of the nineteenth century, while others are crescent-shaped, with modern handles. They are not in condition now to shave with, though hardly less so than the tools employed by the astute barber upon the customer who never pays a fee. Even more wonderful is the safety-pin with which the Roman women in the time before Christ was born, fastened their garments. It was precisely like the safety pin of the year A. D. 1892, with the little coiled spring at one end and the catch at the other. Fish hooks in the bronze age were in shape precisely what they are now, with the same barbs and the same bends, of which the famous Limerick and Shaughnessy types are merely copies. The ends of their shanks, to hold the lines, were either flattened or looped, just as at present. In short, they were the same articles exactly, barring the nature of the metal.

In the Smithsonian collection referred to are shown hat-pins with big round heads more than twenty centuries old, in all respects resembling those of to-day, though they may have been employed merely to bind the hair together. Also there are ordinary hair-pins, equally ancient, like those sold at dry goods shops now, and likewise thimbles of bronze with the customary indentations, though such implements are generally supposed to have been invented in the Middle ages under the name of "thumb bells." Tweezers and strainers, after the modern fashion, are included in the same assemblage of curiosities.

Others of the same epoch are woven goods from the Swiss lake dwellings that were built on piles, bronze beads from Rome actually plated with gold, bronze buttons made just like those of to-day, bronze chains with the same mesh precisely as is employed now by jewelers for watch guards, bronze mirrors, bronze awls, bronze bodkins, bronze needles, and bronze sickles for cutting grass or grain, with wooden handles—the originals of the McCormick reaper.

One of the funniest things in the collection is a small vase with a hinge at the top for a cover—just like the modern beer mug. It dates from before Christ. There are also stone molds of the same epoch for casting bronze knives, spear heads, hatchets, sickles, and other implements precisely in the manner followed now. An ancient Etruscan vase shows mending with rivets after the same method as is employed in this day.

MECHANICAL NOTES

Antiquity of the Carpenter's Plane.

A very interesting discovery has been made at the Roman city of Silchester. The excavators came across a dry well, which, on being explored, proved quite a museum of antiquities. Some fifteen feet down, a correspondent says, the diggers found an urn-shaped pottery vase, about a foot in length, quite intact, and curiously enough, protected by lumps of chalk built around it. The vase, which probably originally contained some precious substance, was, however, quite empty. Above it were deposited a great number of iron implements, most of which were in a wonderful state of preservation. They seem to have been the tools of a carpenter and a coppersmith, with some miscellaneous objects of blacksmith's work thrown in. The principal specimen is a carpenter's plane of quite modern type, although unquestionably more than fifteen hundred years old, three or four axes retaining their fine cutting edges and quite serviceable, a number of chisels and gauges of all shapes and sizes, hammers, adzes, saws, files, etc.

In the smith department may be specified a brazier for burning charcoal, quite complete; two or three anvils of different sizes and shapes, a fine pair of tongs adapted for lifting crucibles, a curious tripod candelabrum lamp, or candlestick, and several other curious objects, the precise uses of which have not yet been determined.

Fire-Arms of Early Settlers.

The precise population of New England, either Indian or white, at the time of Philip's war cannot be stated, but for the purpose of war it may be said that the forces on one side and the other were equal. At that time the Indians were as well used to fire-arms as the whites, but the firelock of those days was but an inefficient weapon compared with the musket of later times or with the rifle of to-day.

It seems certain that in Europe flintlocks had been introduced before this time; but, on the whole, the concurrence of evidence shows that such locks were not used in the civil war in England, and that both the king's party and the Puritans still relied on the matchlock. The form of this can be readily explained to any person who has seen the old flintlock of the present century. A hammer—a good deal larger than the hammer which afterward held the flint, but quite like it—had a screw which tightened or loosened the hold which two pieces of iron had upon a match.

Each soldier was obliged to carry some yards of this match with him, and when the battle began he lighted the piece of this match which was fixed to the hammer of the gun. A pan which held powder, exactly as the pan of a flintlock afterward did, was in front of the hammer, with a cover projecting, from which a sort of a horn ran up nearly vertical, to be opened by the hammer when the soldier pulled the trigger. The fire of the match communicated with the powder, and the gun went off.

This was a sufficiently complicated way in which men should go to battle, perhaps, in a wilderness, where even the procuring of fire at that time was attended with some difficulty. The accounts of skirmishes of those times are full of occasions when a shower put a stop to the whole battle. This is because the fire of the matches was extinguished by the rain.

To change this rather clumsy lock into a flintlock simply required that a flint of sufficient size should be screwed into the hammer in the place made for the match. The flint, then striking upon the cover of the pan, made a spark which fell at the moment the pan opened into the powder. Eventually these locks were made with great precision, so that the gun missed fire very seldom.

I have no doubt that one and another soldier in Philip's war found for himself that a flint Indian arrow-head screwed in the place of his match could be made to answer the purpose of firing the powder much more readily than the match itself could do. A similar invention, however, as I have said, had already been made in Europe, so that it is thought that flintlock guns had been found in France as early as 1640. In 1672, however, just before the war with Philip began, the law of Massachusetts and the provision made for her soldiers still required the use of matchlock.—*The Chautauquan.*

Some Successful Mechanics.

In this country there is practically no end to the number of men who found a trade the most valuable of all helps on the road to fame and fortune, writes Foster Coates in his boys' department in the January *Ladies' Home Journal.* There is Thomas A. Edison, the greatest genius of our day. Learning telegraphy was the first thing that led him into that intimacy with electricity which has ended with him being its master; Andrew Carnegie was a telegrapher; Charles Pratt, who did more to help young men to acquire trades than any man whom I can mention, started in life as a machinist; Judge Daniels, of the Supreme Court of the State of New York, was a shoemaker; William R. Grace, who was Mayor of New York, and who is worth some $20,000,000, was a butcher; the late George Jones, who, as editor of the New Lork *Times*, was one of the most powerful men of his day, was a printer's "devil," in the same office with Horace Greeley when both were boys; Jay Gould, the great financier, was first a tanner and then a surveyor; Dr. John R. Paxton, D. D., who preaches to the wealthiest congregation in the world, began life as a carpenter; Philip Armour, the Chicago millionaire, was a moulder; the late John Kelly, the famous politician, was a grate setter; John D. Rockefeller, now worth $125,000,000, was a mechanic in iron; Rev. Robert Collyer, D. D., was a blacksmith; John A. Mackay was a stone-mason before he became the owner of the Comstock Lode, and one of the richest men in the world; Jesse Seligman, the eminent banker and philanthropist, laid the foundation of his fortune by studying in the very poor night trade schools that existed when he was young; United States Senator Hill, of New York, was a printer; the late Henry W. Grady, the greatest orator the South has given us since the days of Calhoun, was also a printer. And so it goes. I could give scores of other names of men who were mechanics, or were skilled in trades and became great after serving faithfully at their various tasks.

To Remove Iron Rust.

The engineer who is so unfortunate as to have a portion of his engine become rusted, or the more unfortunate man who takes charge of an engine which has been neglected and is covered with rust, finds before him a tedious job in cleaning and getting the metal to again present a polished surface. Rust, chemically considered, is an oxide of iron when it appears on iron or steel; but the combination of oxygen and any other metal will form a rust, although in such cases it is usually given another name. The combination of oxygen with iron can only take place to an appreciable extent in the presence of moisture or hydrogen and, if extensive, leaves little depressions in the metal when the rust is removed. This occurs from the fact that when the oxygen combines with the iron, that portion of the iron forming the combination is loosened or separated from the mass. There are two ways in which rust may be removed from iron or steel. The first and most common practice is by the use of some abrasive material, and the process is usually termed scouring. Another method is by chemical action, by the application of some chemical applied in solution, which has a high affinity for oxygen, and which withdraws the oxygen, leaving the iron particles free.

One of the best compounds for such purposes is given by the *Chronique Industrielle*, as follows: Potassium cyanide, 15 grammes; soft soap, 15 grammes; whiting, 30 grammes, and sufficient water to form the ingredients into a paste. This is to be applied as a scouring material and well rubbed over the rusted surface, after which it is to be thoroughly wiped off, and a coating of oil applied to stop further action. The active material in this composition is the potassium cyanide, which has the strongest deoxidizing property of any substance with which we are acquainted; and, further, it is one of the most poisonous substances known, the base being potassium, which is combined with cyanic acid, and cyanic acid is so poisonous that it is extremely dangerous to use in any manner unless partially neutralized by combination with some other substance, as in the present case.

Cyanic acid is of itself a gas, and in this condition it is extremely destructive to life, the inhalation of even a small quantity being sufficient to cause instantaneous death. When in solution in water, the liquid is called hydrocyanic acid, a single drop of which, if taken internally or entering the system in any manner, being sufficient to cause death within the short space of two seconds of time.

No particular danger is to be apprehended from the use of the composition given for removing rust, as the addition of soft soap, which is of equal weight with the cyanide of potassium, goes far to counteract the acridity of the cyanide. Then the further addition of whiting in double the amount of cyanide reduces the strength of the compound so much that it is relieved of the greater part of its dangerous properties.

If any one attempts to make use of this compound for scouring purposes, we would suggest that he do so only when the hands are free from abrasions of any kind, as, if it should come in contact with any portion of the flesh where the skin is removed, a very bad sore would probably be the result.—*Progressive Age.*

Combustion by the Steam Jet.

The steam jet is no aid to combustion. The only way in which steam in the fire box proves a help to combustion, is by carrying with it considerable air which would not otherwise be forced into the furnace. Steam or water in any form is not a benefit to fuel, or on fuel. Every pound of water thrown upon coal "to help it burn," only absorbs a certain quantity of heat from the fire. It is claimed that a like amount of heat is returned by combustion of hydrogen yielded up by the steam when disassociated.

Even if this is true, there is a loss instead of gain by the operation. It is too much like a piece of iron in the furnace, with the exception that after the iron becomes heated by the burning coal, it will give out, on cooling, as much or more heat than was put into it.

Keep steam or water out of the fire-box; put in a certain amount of hot air, the hotter the better, but do not force in too much. Too much air extinguishes a flame about as quickly as so much water. This is proved by the blowing out an ordinary kerosene light. A great volume of air forced against the blazing wick by the breath, cools off the hot gases so suddenly that they can unite with oxygen of the air and the flame is extinguished, and the gas, which would burn if it had the chance, may continue to rise during several seconds from the hot wick.—*The Tradesman.*

HOW TO LIVE

To Prevent and Restrict Diphtheria.

The Board of Health of Philadelphia, has issued a circular giving the following regulations for the prevention and restriction of diphtheria:

Recent investigations having proved that the poison of diphtheria is portable, communicable by infection, and capable of reproducing itself outside of the human body, diphtheria must now be ranked as both a contagious and infectious disease. The following rules are therefore more imperative than ever before:

First. When a child or young person has a sore throat, a bad odor to its breath, and especially if it has fever, it should immediately be separated and kept secluded from all other persons except necessary attendants, until it be ascertained whether or not it has diphtheria, or some other communicable disease.

Second. Every person known to be sick with diphtheria should be promptly and effectually isolated from the public. Only those persons who are actually necessary should have charge of or visit the patient, and these visitors should be restricted in their intercourse with other individuals. Children residing in a house where there is a case of diphtheria should not be permitted to attend school.

Third. When a case of diphtheria is fully developed the same precautions in regard to free ventilation, disposal and disinfection of discharges, bed or body linen, etc., isolation during convalescence (or management of the corpse should death unfortunately occur), etc., etc., ought to be enforced which have already been recommended in regard to small-pox.

Fourth. It is particularly important that persons whose throats are tender or sore from any cause should avoid possible exposure to the contagion of diphtheria. Children under 10 years of age are in much greater danger of taking the disease, and, after they do take it, of dying from it, than are grown persons. But adults are not exempt, and mild cases in them may cause whole series of fatal attacks among children.

Fifth. Numerous instances are recorded where the contagion of diphtheria has retained its virulence for weeks or months, in cesspools, heaps of decaying vegetable matter, damp walls, etc., and been carried for long distances in clothing, in sewers, in waste-pipes from stationary washstands, and in other conduits. Hence all sewer connections and other carriers of filth should be well ventilated and disinfected, and children particularly should not be allowed to breathe the air of any water-closet, cesspool, or sewer into which discharges from patients sick with diphtheria have entered, nor to drink water or milk which has been exposed to such air or the atmosphere of the sick room.

Sixth. Beware of any person who has a sore throat; do not kiss such a person or take his or her breath; do not drink from the same cup, blow the same whistle, nor put his pencil or pen into your mouth.

Seventh. Do not wear nor handle clothing which has been worn by a person during sickness or convalescence from diphtheria.

Danger in Wearing Rubbers.

A chiropodist says: Since the streets became so muddy I have had a number of sufferers apply to me for relief. If a man has a corn I can take it out and relieve him, but if he is suffering from what I call "rubber fever" I can't help him and can only prescribe liberal foot bathing and a removal of the cause of the trouble. Rubbers should only be worn to keep the wet out, and they should be removed the moment the wearer gets indoors. Failure to note this gives a man wet feet in a far worse sense than if he had waded through mud ankle deep. It was the trouble resulting from forcing the perspiration to soak the stockings and keep the feet perpetually damp that drove rubber-soled boots out of the market. Even loose rubbers are a source of danger and the cause of many more serious colds than they avert.—*St. Louis Globe-Democrat.*

Prevention and Treatment of Influenza.

The article "What the Doctors Say," which we reprinted recently from the European edition of the *Herald*, was devoted to a timely discussion of the influenza, its symptoms and three leading forms, the history of previous epidemics, the mode of treatment, and the precautions which are demanded during convalescence.

The first question for the great mass of people is, How shall we prevent ourselves from catching the grip? Our foreign medical correspondent answers, "Avoid fatigue, live well, dress warmly, and keep dry, avoid all fogs." If this advice is lived up to the present epidemic is not likely to become pandemic, as it was in last year and in 1890. But we venture to suggest that to these precautions one or two others may be judiciously added.

The most fatal complications of influenza are those of tubercular and heart disease, and unquestionably dust is the most prolific source of infection with tuberculosis. Crowded apartments and all assemblages in which we are liable to breathe air containing the germs of the disease are especially to be shunned. Wherever headache and malaise are suffered in theatres, the air is foul, but, as an authority says, "the most subtle dangers lurk in the dust, which, equally with the bad air, is forced upon us." On the streets, where in windy weather one is compelled to inhale much infected dust, the danger may be considerably lessened by taking the leeward side of the street. While the grip is not very contagious it is infectious, and prudence dictates an avoidance of all unnecessary contact with influenza patients.

But, after taking all due precautions, if the epidemic continues many may be stricken down with the grip and all should be instructed in the diagnosis and treatment of the disease. Its attack is sometimes slow and very insidious, sometimes very sudden and overwhelming, though in cases of the latter type a careful study of the patient's previous history will probably show that he has been run down by overwork or dissipation. When the attack is decided the temperature of the body rises to 102 degrees Fahrenheit, or thereabouts, and sometimes even higher, with loss of appetite, thirst and febrile conditions, and in many, but by no means all cases intense pain in the side and more or less coughing. The immediate sequel of the attack is great weakness. If this were all, the malady might not be so dreaded. But the tendency to grave complications and relapses is so marked that often the grip retiring, like an army on the retreat, strikes more deadly blows than when advancing.

Our medical correspondent discusses the treatment demanded for this fierce malady. Of course, as he shows, the medication must be varied according to the many phases of the attack. There is no specific remedy for influenza, and, once it is contracted, no time should be lost in summoning a competent physician, no matter how mild the first symptoms appear.

But perhaps the most urgent injunction our correspondent gives is to convalescents: "When convalescence sets in," he says, "it is of the utmost importance to prevent the patients from going out too soon and from being in too much of a hurry about resuming their ordinary occupations." The medical profession and also the public will do wisely to consider the points brought out by our correspondent.—*New York Herald.*

Three Perils to Avoid in Winter.

1. Perils from heedless exposure. Winter is the gay season, the season of balls and dancing parties, and, in general, of prolonged amusements and excitements. We need not say how common it is for young ladies to attend such gatherings imperfectly clad.

The excitement, physical and mental, extending to a late hour of the night, renders the surface of the body peculiarly susceptible to the outside chill; the susceptibility is enhanced by the exhaustion, which at the same time lessens the power of resistance.

The danger is especially great in rural districts, where so many must ride long distances to their homes through the icy air. Tens of thousands have in this way laid the foundation of fatal disease.

2. Perils from infectious diseases. In summer our dwellings ventilate themselves, with little care on our part; but in winter we economize heat at the expense of ventilation. Few houses are provided with artificial ventilators, while the drainage is generally far from perfect. Even houses supposed to be above suspicion in this respect are often found to be dangerously defective.

Unnoticed leaks are common and a bad leak in a neighbor's house may long have been discharging itself freely beneath the wooden floor of our own cellar. The main sewer is seldom or never free from the microbes of disease, and these may find entrance into our rooms through untrapped or imperfectly trapped connecting pipes. It was from this cause that the noble and good Prince Albert came to his untimely end.

3. Perils from school rooms. Comparatively few schoolrooms are furnished with adequate adjustments for ventilation. Hence the pupils at an age of great susceptibility, breathe much bad air, often from diseased lungs, and always charged with deleterious bodily exhalations.

At the very least, the vital resistance of the system is dangerously lowered. On the other hand, when the air becomes insufferable the teacher may order the windows opened, thus endangering those who sit within the draught, at a time when they are least able to bear exposure.—*Youth's Companion.*

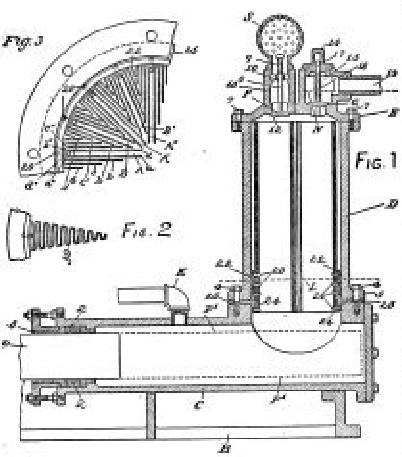
NEW INVENTIONS

AIR COMPRESSOR.

No. 462,776. Francis H. Richards, Hartford, Conn. *Patented Nov. 10, 1891.* The compression cylinder C is partly filled with water, which stands at about the line L when the plunger P is at the outer end of its stroke as shown, and which rises to the line N in the delivery valve chamber at the other end of the stroke. The chamber D is partly filled with metal plates shown in end view in Fig. 3, and a different style in Fig. 2. When air is compressed heat is also generated, which increases the pressure of the air and so increases the resistance to the plunger. This heat is soon radiated and the power it represents is thereby lost.

These plates are designed to abstract the heat during the act of compression and so prevent the undue increase of resistance and waste of power. A small pump, not shown, slowly changes the water in the cylinder and prevents it from getting too warm.

At each stroke the heat-abstracting plates are entirely immersed in the fluid, and thereby thoroughly cooled, ready

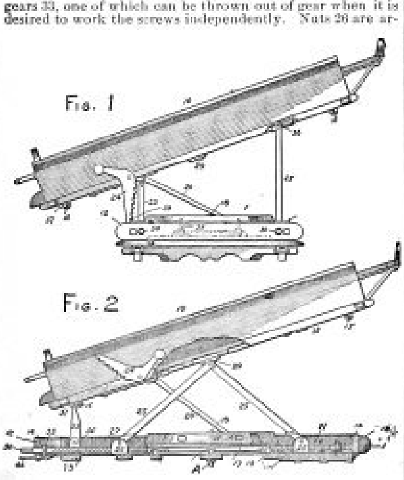


for effective operation at the next stroke of the compressor The plates, being continuous solid metal to a point below the water-line, act during the compression to receive the heat and rapidly conduct the same downward and discharge it into the fluid, thereby materially reducing the heating of the upper portions of the plates, and maintaining those portions in the most effective condition. During the compression the plates are submerged from the lower end upwardly.

The plates or other forms of heat-abstractors, divide the chamber into a multitude of narrow spaces, and being immersed at each stroke of the plunger in the fluid are on the descent of the fluid covered with a thin coating or layer of water, which promotes the action of the plates for cooling, the air being compressed.

COAL WAGON.

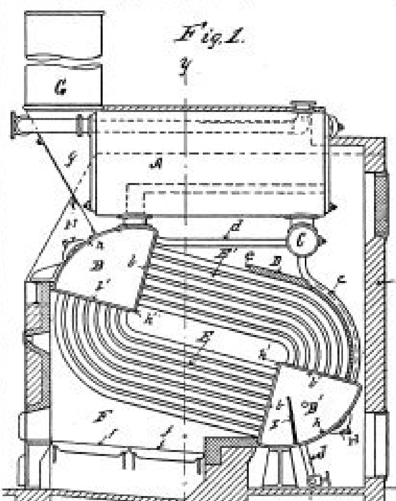
No. 463,251. Edward L. Layton, Trenton, N. J. *Patented November 17, 1891.* The main frame is composed of two side-bars 11, united by end-bars 12 and several cross-bars 13. A ring or turn-table 17 is secured by a center pin A to the middle cross-bar, and it runs on castors attached to the cross-bars, as shown. The wagon body is attached to the ring 17 by links 20, so that it cannot slide out of place. On each side of the frame there is a long right and left screw which can be turned by a crank slipped on the rear end. The screws are geared together by a cross-shaft and bevel gears 33, one of which can be thrown out of gear when it is desired to work the screws independently. Nuts 26 are ar-



ranged to travel along these screws, and toggle-rods 25 are hinged to them. The middle joint and block 29 is not attached to the box but merely bears under it. To dump to the rear, both screws are turned simultaneously, thus elevating the front end of the box, which tilts on the posts 35. To dump to either side, the box is first swung around on the turn-table and locked against further turning by a hook not shown. Both screws are turned until the box is high enough to deliver properly, and the notched legs 24 are then turned down until they hook over the edge of the frame. The screws are disconnected, and the toggle under the front end is operated until the load slides out.

WATER-TUBE BOILER.

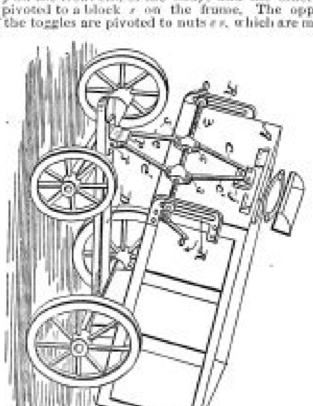
No. 464,109. Harry W. Seller, Brooklyn, N. Y. *Patented Dec. 1, 1891.* The drawing shows a boiler constructed with two tubular steam-drums A, the front ends of both of which are connected to the upper sector-shaped box B and at their rear ends to a large cross pipe C, from which pipe a row of small tubes *e* extend down to and enter the rear portion of the lower sector-shaped box B' at the rear of the bridge-wall D, the pipe C being also connected to the upper box B by means of a row of horizontal pipes *d*. The boxes B and B' are connected by means of water-tubes E and E', the ends of which enter the plane surfaces *b* and *b'* of the boxes B and B' and are secured therein, preferably, by expanding the ends in the manner ordinarily employed in securing tubes in boiler-heads. The tubes E and E' are preferably located at an inclination of about thirty degrees from a horizontal, so as to admit of room under the front ends for a furnace F. At the rear of and above the upper tier of tubes E', is a bridge or fire wall, which extends from the upper face *b'*, of the box B', forming the rear of the furnace F, up, say, about three-fifths of the distance from the face *b'* of the box B' (following the curve of the bank of tubes E') to the face *b* of the box B, so that the heat from



the fire-box F passes up between the tubes E and E' and out between the end *e* of the bridge-wall D and the face *b* of the box B and up between the horizontal pipes *d* against the lower sides of the steam-drums A, and along to the front ends thereof, and out through a chimney G, secured to the front ends of said steam-drums A by breeching *g* of ordinary construction. The boxes B and B' are provided with man-holes H on the curved sides *k*, so as to admit of access to the inside, and in the lower and rear box B' is a partition I, extending from the lower and curved side *k* upward, about two-thirds of the distance to the angle *k'*, the object of this partition being to form a chamber in the rear portion of the box B' for the reception of sediment, which can readily be blown out therefrom through the blow-off pipe J in the usual way.

COAL WAGON.

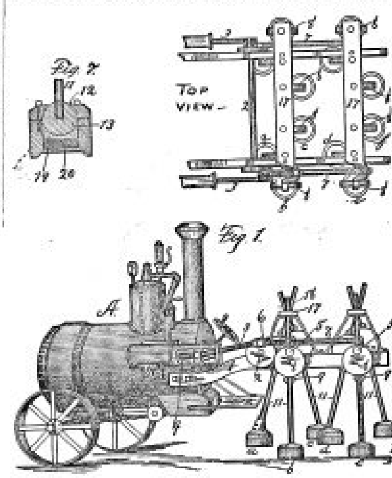
No. 463,254. Charles Fay, Providence, R. I. *Patented November 17, 1891.* The wagon-body tilts on the back axle in the usual manner. The front end is lifted by four toggles arranged as shown. Two toggles *c* c^1 are pivoted to a block *j* on the front end of the body, and the other two *e* c^1 are pivoted to a block *s* on the frame. The opposite ends of the toggles are pivoted to nuts *e e*, which are moved



to or from each other by a right and left screw 5. This screw has a square shank on each end, for a crank by which the driver operates the device. Slotted guards R guide the ends of the screw and prevent the toggles from buckling or springing forward out of line with each other. The effort required to lift the load is small, and the box will remain suspended at any point without danger of the screw running down.

WALKING TRACTION ENGINE.

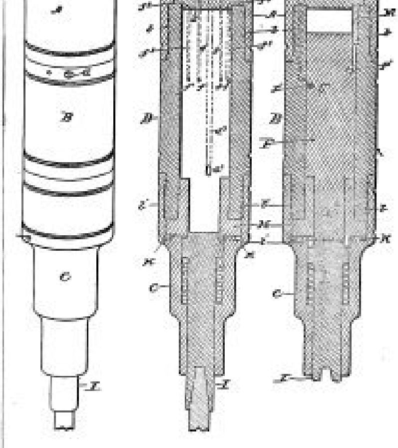
No. 461,441. Edward M. Knollin, Lacona, N. Y. *Patented October 20, 1891.* The front end of the boiler is carried on a pair of wheels which are controlled by steering chains in the usual manner. At the rear end of the machine twelve "legs" are arranged in two sets of six each. Each rod 11 plays through a hole in the top bars 17, and carries on its lower end a pedal or hoof, constructed as shown in Fig. 7. The rod 11 ends in a ball which bears in a block 19, and a block of rubber 20 is placed under 19 to ease off shocks. The rods or legs are operated by eccentrics on the shafts 5, and the shafts are driven by cranks and coupling



rods attached to the main driving shaft 2. The eccentrics are all set at angles of 90° with each other. It will be seen that *b* and *e* are on the ground and are pushing the machine forward, *a* and *d* are ready to descend, and *c* and *f* have risen and are about to pass forward to make new steps. By reversing the driving engine the machine will "back" as powerfully as it will go ahead. The feet take hold of the ground like a horse's hoofs, and consequently they will not slip as the wheels of ordinary traction engines do when on muddy ground. The firm bearing of the feet enables the machine to climb very steep grades.

PNEUMATIC STONE DRILL.

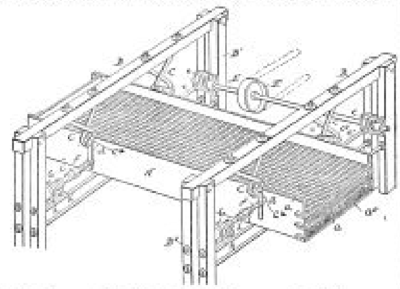
No. 464,820. Daniel Drawbaugh, Eberly's Mill, Pa. *Patented December 8, 1891.* This tool is designed for drilling and dressing stone and similar operations. It is held in the hands by means of handles attached to the collar A^1. Air under pressure is supplied by a hose attached to the plug-cock on the top end. Fig. 1 is a perspective view, Fig. 2 is a lengthways section, and Fig. 3 is a similar section at right angles to Fig. 2. The shank I holds the tool, and is held up to its stops, as in Fig. 2, by a coiled spring, as shown. The piston or hammer F is shown in Fig. 3 at the end of its stroke. The valve-chest D is clamped between the collar A and the body B, and it consists of a solid block



bored to receive a small piston-valve E which moves crossways of the cylinder. Small holes are drilled in the top side to serve as inlet ports, and other holes in the under side lead to the opposite ends of the working cylinder. Other passages *f* are made in the metal of the cylinder which register with grooves 5 in the piston, and serve as exhaust ports. A small pin-valve G, Fig. 1, serves to choke the exhaust and reduce the number of strokes per minute without reducing the force of the blows. To reduce both at the same time the air is throttled by the plug-cock *g* at the top. The inventor declares that this tool will strike thirty thousand blows per minute under favorable circumstances, and will penetrate stone very rapidly.

SCREEN.

No. 464,776. JAMES POLLOCK, WILKES-BARRE, PA. *Patented December 8, 1891.* A number of ordinary flat screens are combined in a single frame, as shown, the coarsest one on top, and all are inclined in the usual manner. The set of screens are suspended from the cross-beams B by links C, which are hinged by jaw bolts and pins to the beams above, and are connected at



their lower ends by links C^2. The hangers *d* of the screen frame take hold of a pin in the middle of the links C^2, thus forming a practicable straight line motion. The screens are shaken sideways by the eccentrics shown on the driving shaft E, and on the opposite side they are connected to air cylinders or cushions G, which are designed to absorb the momentum of the screens and thus soften and diminish the shocks incident to the shaking movement. Turnbuckles *i* are provided by which the air cushions may be regulated.

ORE CRUSHER.

No. 464,083. GEORGE AND ALBERT RAYMOND, CHICAGO, ILL. *Patented Dec. 1, 1891.* The crushing head K is globular in form, and is carried on the top end of a stiff spindle J. The lower end of this spindle is moved in a circle by the crosshead I, which is moved by two eccentrics *d* on the driving shafts D. They are driven at equal speeds in the same direction by the bevel gearing shown. The crushing head with its shaft, and the crosshead I are adjusted vertically by two hanger rods H, which support their weight.

Fig. 1.

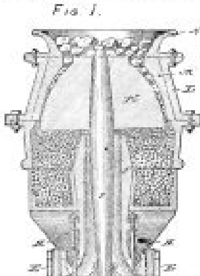


Fig. 2.

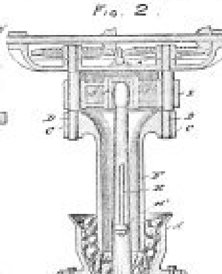
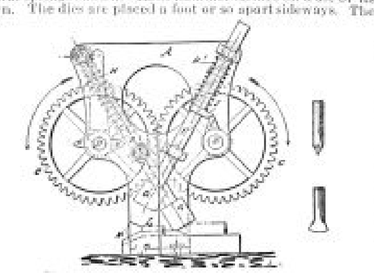


The crushing head has no fixed center to vibrate upon, but is centered by the material passing between it and the sides of the hopper M. The head has the greatest motion near its lower edge, where the finest crushing is done, consequently all packing or clogging with fine stuff is easily avoided.

Fig. 2 shows another form of the machine in which the driving gear is placed at the top, and the hopper and crushing head at the bottom. With this form of machine the material is shoveled in from the floor, and is preferable for many uses.

MACHINE FOR SHARPENING DRILLS.

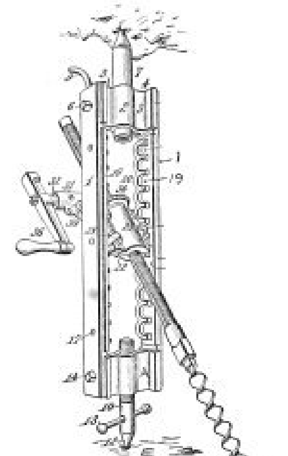
No. 459,931. JOHANNES GUTHERLET, JERSEY CITY, N. J. *Patented Sept. 22, 1891.* This machine is intended to aid the blacksmith in sharpening rock drills. The hammers are attached to rods which slide in guides as shown. They are lifted by cams on the shafts B B^1, and are thrown by the spiral springs shown. Each hammer strikes on a die of its own. The dies are placed a foot or so apart sideways. The



hammer G^1 serves to swage the shoulders of the drill, and the hammer G draws down the cutting edge. As this part of the work requires more blows than the other, the shaft B is provided with a double cam, so that the hammer G makes two strokes to one of G^1. The machine can be operated by a crank, or it can be driven by a belt.

DRILLING POST.

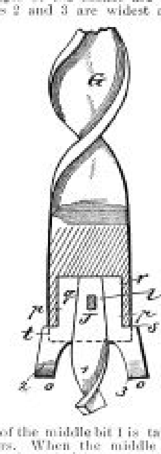
No. 463,469. ALEXANDER WALKER, WHAT CHEER, IOWA. *Patented November 17, 1891.* This post is composed of two end castings A and 3, which are united by wrought iron side plates 1. The top casting is provided with an adjustable center 7, and the lower one is threaded to suit the jack screw 10. Long cast plates 19 are made with a



flange on the front edge to lap over the edge of the bars 1, and are fastened to them by suitable rivets. Each plate is provided with ribs 20 which form a series of pockets to receive the trunnions of the drill nut 22. This nut is made in halves hinged together in the usual manner. The drill is supported in any direction without tendency to run sideways or twist.

COAL-DRILL BITS.

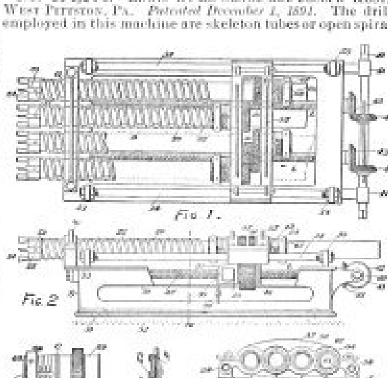
No. 464,497. JAMES EAGEN, WYOMING, PA. *Patented Dec. 8, 1891.* The auger is provided with a flat socket at the front end, which holds the shanks of three bits as shown. The edges of the socket are parallel, and the shanks of the bits 2 and 3 are widest at the inner end,



while the shank of the middle bit 1 is tapered to suit the taper of the others. When the middle bit is put in its place and the cross key *t* is driven up tight, the side bits are securely held in place. The cutting edges of 2 and 3 are lipped in the usual manner.

MINING MACHINE.

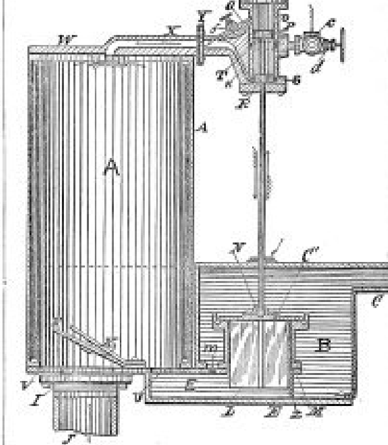
No. 464,374. LEWIS W. LE GRAND AND JOSEPH KLOTZ, WEST PITTSTON, PA. *Patented December 1, 1891.* The drills employed in this machine are skeleton tubes or open spirals



52, armed with removable bits 54, which are held in dovetail slots in the heads 53. The spiral is made by winding a bar into a spiral and making occasional connections between the coils as shown by 51 in Fig. 4. The bar 52 is grooved on the outside, as shown. Power is applied to the end shaft 40, which drives the feed-screws L by bevel gears. These screws are slotted to engage feathers in the gears 46 on the cross-head 35. Behind each gear 46 is a divided nut, the halves of which are operated by the slotted levers 29, Fig. 3. The pinions 40 drive several gears 61, each of which turns a chuck C, shown in detail in Fig. 5. This consists of a shell through which the drill-tube passes, and the end of the shell is tapered and threaded for the collar nut 64. Slots 62 make the shell compressible, and by screwing up the nut the drill-tube may be gripped at any part of its length. The drill-tubes may be of any length desired. Each drill leaves a solid core, and the borings pass out along the groove in the outside of the spiral bars 52. When the cross-head is fed forward as far as it can go, the nuts 36 are thrown out of gear by the handle 39, the nut on each chuck is slacked off, and it is run back as far as desired, the chucks are again tightened, and the drills are ready to bore still deeper. Any depth of undercut can thus be made.

STEAM VACUUM PUMP.

No. 464,037. GEORGE H. NYE, CHICAGO, ILL. *Patented Dec. 1, 1891.* This pump employs but one cylinder or working chamber A. K is the suction valve and C^1 is the discharge valve. Steam is admitted by the globe valve *d* to the steam chest O. Two grooves T and S are made in the bore of the steam chest, which are covered and uncovered by the valve rings P and R. When they are in the position shown, with the steam groove T uncovered and the lower groove S closed, the pump is ready to start. The chamber B is primed with water enough to cover the discharge valve C^1, and this water makes its way through a small hole *w* into E and into the working chamber A. Steam is turned into the chest O and it passes through the valve ring P, and the port *a*, small throttle valve *f*, and pipe X to



the chamber A. The jet is very small, only enough to displace the air, and it quickly condenses. Water enters by the valve K and fills the chamber. When the chamber is about full and the vacuum is gone, the head of water in A above that in B is sufficient to lift the discharge valve which was held down by air pressure as long as there was vacuum in A, and also shift the steam valve which is attached to C^1 by a rod as shown. The groove S is thus uncovered and steam in larger quantities is admitted by port *s* to the cylinder A, which drives the water out into B and off by the pipe C. The valve C^1 now falls by gravity and diminishes the supply of steam, condensation again begins and the order of operations is repeated. The machine is intended for low lifts, for irrigation and washing purposes, and for small steam consumption.

"Rose Must Wait."

Our readers will remember that a short time ago we called their attention to two valuable little books published by the Mason Regulator Co., of Boston, Mass. These books have met with a very warm reception from steam users in all parts of the country, and the following letter from Mr. James H. Hocking, of Paterson, N. J., shows how they are appreciated by practical men:

MASON REGULATOR CO.,
Boston, Mass.

SIRS:

Enclosed find 35 cents, for one copy each of "Common Sense in Making and Using Steam," and "Key to Engineering." Our machine shop has just been burned to the ground, and the two above copies added to the flames, together with "Rose's Machine Shop Practice." "Rose" will have to wait, but I must have the above works at once.

PERSONALS

MR. ROBT. SPENCE, formerly mine boss under Messrs. Sommerville and Buchanan, at Winburne, Pa. has accepted a similar position under Supt. R. A. Shillingford, of the Clearfield Bituminous Coal Corporation, at Pleasant Hill Colliery, near Peale, Pa.

MR. C. B. ROSS has resigned his position as Assistant Mine Boss at Brownfield, Pa., and accepted a similar position at the Oliver Coke and Furnace Company's new works, near Uniontown, Pa. The exchange took effect Jan. 1st last.

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 8. SCRANTON, PA., MARCH, 1892. WITH WHICH IS COMBINED THE MINING HERALD.

MACHINE MINING.

Its Advantages—Under What Conditions the Various Types of Machines are Most Successful—The Method of Keeping Accounts of Cost of Mining.

BY LEWIS STOCKETT, ST. LOUIS, MO.

Ten years ago, in this country, machine mining was looked upon almost entirely as an experiment in which few had any faith, or were willing to hazard capital in. To-day the experiment has become an assured success, and machine mining is fast becoming the rule and not the exception. In the State of Illinois, for the year ending July 1st, 1890, out of a total of 12,638,364 tons mined by all methods, 2,881,983 tons were mined by machinery, being 23% of the total. In the Fourth Inspection District of this State for the same period, of a total of 3,716,464 tons mined, 1,615,453 tons, or 43.5% of the total, were mined by machinery; and in the Fifth Inspection District, covering the same period, of a total of 3,240,004 tons mined, 1,101,262 tons, or 34% of the total, were mined by machinery; and succeeding reports will show increased percentages.

Pennsylvania, Ohio, Indiana, Michigan, Iowa, Missouri, Kentucky, Alabama, and several western states, will show percentages that compared with previous years, will show that machine mining is steadily increasing, and there are scarcely any of the coal producing states or territories of the Union where machines are not being or have been used with more or less degree of success, in other respects as well as financially, when under proper conditions, and earnest effort has been made to make them succeed.

Ten years ago the miner that worked with or after machines was a "blackleg" to be shunned by his fellow workmen, and often followed his occupation at the risk of the "boycott," personal injury, and even loss of life from those opposed to the innovation. This has all changed, and to day the machine miner and laborer form a large portion of the mining class, and are often the commanding influence. Where machine mining has been successfully organized and carried out the result has been greater regularity of work and better wages for the employes.

So far machinery for mining is confined to machines for "undercutting," "shearing," and "drilling," and which by cutting the vein horizontally or vertically, and drilling the holes for blasting, prepare it for the work of the miner in charging, blasting, assorting, loading, and timbering. Machinery for these latter purposes has not been introduced, though experiments are continually being made with machines for loading, and the writer has seen two patterns that in a large vein with good roof would do the work very well; it is to be hoped that a successful machine will finally be devised to relieve this the most laborious portion of securing coal. The cleaning of the coal from its impurities, where the same exist, and throwing of them back into the gob is a task that can hardly be accomplished by machinery, which can only be expected to lift the mass from the floor and deposit it in the cars. Where these impurities do not exist in too great an amount the cleaning can be done more thoroughly and more economically by proper coal cleaning machinery placed in the tipple outside.

Electric batteries for firing the blasts after the charges are tamped, and the use of lime cartridges and power wedges for breaking down the coal may be mentioned as attempts to do the breaking down by machinery, but have not come into general use.

For timbering, machinery has nothing to offer and it is only indirectly that a saving can be effected in this department of the work; by deep undercuttings, the roof if tender is shattered less by the blasts, and as machine mining gets over the ground much quicker than the older method, rooms are driven their length and finished before timbers need replacing. To offset this places for machinery are generally driven as wide as possible in order to give the machine the advantage of working steadily and preventing the loss of time in moving frequently from one face to another; this will take more timber, and it becomes a nice point to determine on the score of economy just where to draw the line between the two.

The power used to operate mining machinery has been almost entirely compressed air, of late electricity has become a recognized factor as such, and there is no doubt but that in time, with improvements in application, it will become more and more so. At present the most successful machinery being driven by compressed air necessitates its use, and for this reason is preferred by the writer.

DRILLING MACHINES

are of two classes, revolving and reciprocating, the first of which classes can be again divided into those that leave cores, and those that take out the full space. For blasting purposes the first are seldom used, and of the latter we have those operated by hand and those operated by power; both consist of a worm or auger, one end of which is dressed to an edge to cut the coal and the other end fitting into the socket, or *vice versa*, of a threaded feed-bar, and which revolving forces the cutting edge against the coal, cutting off a portion the diameter of the hole and equal in thickness to the advance of the screw per revolution. The box through which the feed-bar revolves is held in place either by a post held to place by pressure of a screw-jack against the top and bottom or by a wedge fastened in the face of the coal; in a strong coal where the roof is high this latter is preferable, and in a soft, slippery coal, with low roof, the post is preferable. In some soft, pure coals an auger turned by a brace and held to its work by the pressure of the breast is all that is necessary, and where the same can be accomplished it is undoubtedly the most economical mode of drilling, both for cost of equipment and cost of operating.

Where power is used for this class of drills, its application is generally a high speed engine of the rotary, trunk, or oscillating types, geared down to give the required speed to the drill and for power, and the power itself is compressed air or electricity. The rotary, when used for compressed air, is the most wasteful form of application, its simplicity and few wearing parts, however, have brought it into general use, the later patterns fitted with double rotaries at right angles to prevent dead centering, are an improvement.

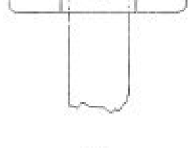
The augers for both machine and hand drills are generally in sets of three, the first two feet long, the second four feet long, and the third one six feet long; when the first one has gone in its full depth it is removed, the hole carefully but rapidly scraped or cleaned, the second one entered and so on until the required depth is reached. These augers requiring frequent sharpening, it is done by means of a file in the hands of the driller who keeps up the edges as long as possible by this means, until they become too thick or broken off, when it becomes necessary to send them to the shop for sharpening at the forge by the smith. Care must be taken to keep these augers of standard width so that the succeeding length will easily follow and not bind in the hole; where it is necessary to concentrate the powder in the back of the hole, the shortest length can be made $2\frac{1}{2}$ inches wide, the next or middle length $2\frac{1}{4}$ inches wide, and the last or longest length 2 inches, and where it requires that the powder be spread out more in the length of the hole, these widths can be made $2''$, $1\frac{3}{4}''$ and $1\frac{1}{2}''$ for the respective lengths. A little experimenting will soon show the best form of bit to meet the requirements of the particular coal in question, a little change in this respect sometimes being the difference between failure and success of the machine. These augers are now, in some cases, being made with removable points, which allow of them being taken out and ground on an emery wheel when requiring sharpening; this is a very convenient arrangement and saves the carrying out and in of the long augers, a driller going in at the beginning of a shift carries in as many bits as will suffice for the shift's work, strung on a piece of wire through a small hole drilled in the bits for that purpose, taking them out at the close of the shift to be ground and made ready for the next shift, or where a duplicate set can await the opposite shift. The necessity for carrying in and out the augers being thus done away with, it allows of their being made much heavier and stiffer, preventing their bending and binding in the sides of the holes. The feed-bars have screws of different pitch varying from 6 to 20 threads per inch, and with such give positive feeds. Drills are now being made with variable feeds, by means of ball bearings and friction clutches, and where the same are made strong enough to stand the work intended are a decided advantage giving an almost instantaneous change of feed from 4 to 1,000 threads per inch, adjusting itself to the changes of material in the hole. Other drills are fed by the air pressure, the feed-bar being the piston rod of a long cylinder, and others are fastened against the top by the same means, a piston and rod taking the place of the screw-jack.

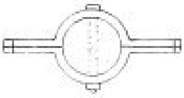
In order to facilitate the rapid handling of these machines, all screws and jacks that require turning should be fitted with large-sized hand wheels, by means of which they can be tightened or loosened much more rapidly than if turned by a wrench on a nut or a bar through an eye. A set of blocks, say a foot long and three, six, nine, and twelve inches thick, shod with iron on the side next the drill and bolted through horizontally to keep them from splitting, will help the rapid setting up of the column or frame, as well as give a better bearing against the top and bottom. All frames should be made sufficiently stiff to stand the thrust of the feed-bar without the assistance of any back-jacks, which not only take time to place them, but are apt to throw the machine out of line and cause binding in the hole.

In fairly clear coal or where the impurities are mostly slates, the auger drill is the most convenient and rapid, but in some coals that are liberally and irregularly interspersed with pyrites in the shape of round or flattened nodules, the revolving drill will not do the work satisfactorily, and recourse is then had to drills with reciprocating motion. The writer has seen nodules of pyrites that could not be drilled in a drill press of a machine shop with twist drills, easily shattered by the light blow of a hammer. So it is with reciprocating drills, a nodule that would completely stall a revolving drill, is shattered into small particles by the continuous blows of one of these drills, and is passed out with the other drillings.

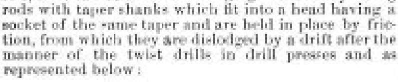
Of this class of drills we have the hand or churn drills, and the power percussion drills, both of the same principle and working exactly alike, in the first the blow is given and the drill turned by hand power and in the latter by power applied through machinery. Both of these drills are familiar enough to the mining public not to need any description; the hand drill should be double-bitted, that is, with a bit on either end, except one which will need a head on one end for the purpose of knocking off sulphurs, four drills constituting an outfit for a day,s work.

Any standard rock drill, such as the Ingersoll, Burleigh, Rand, or Edison Electric, with a few modifications, will do the work. it is essential that they be as light as possible in order that two men may easily and quickly move them, a column of four-inch gas pipe is sufficiently heavy and stiff for any height not exceeding eight feet, the top of the column should be as represented below in order to prevent the possibility of any turning of the same, and all clamps,





saddles, etc., should be sufficiently large to hold the shell rigidly in place. The drill is the same as that used for rock, requiring only the smallest size, time can be saved in changing the bits by using rods with taper shanks which fit into a head having a socket of the same taper and are held in place by friction, from which they are dislodged by a drift after the manner of the twist drills in drill presses and as represented below:



The drill rods should be of cross steel about 1¼″ × ¾″, and made up in sets according to the travel of the drill in the shell, if this is 18″, a convenient set would be four of the following lengths in addition to shank, 24″, 42″, 60″, and 78″, care being taken to preserve the difference of lengths in the rods, for if they are less than the travel of the drill, time is lost in drilling, and if they exceed it the rod cannot be entered without first increasing the length of the hole by churning in the rod by hand. The bits should be of the following widths:

24″ long, 2⅜″ wide, or 2¼″ wide,
42″ long, 2¼″ wide, or 2″ wide,
60″ long, 2⅛″ wide, or 1¾″ wide,
78″ long, 2″ wide, or 1½″ wide,

and are made by forging out the cross steel by special swedges and dies to the required width; gauges should be provided the smith and every bit sharpened accurately to its gauge, the cutting edge is filed hot and of the same angle as a hand drill. The channel of the cross steel cleans out the hole as the bits turn round, but time will be saved by cleaning out the hole at every change of bits, by a few rapid strokes of the ordinary scraper. These drills should also be fitted with the same complement of blocks as the power auger drills to ensure rapid setting of the same, and if the variation in the height of the rooms, entries, and so on, is too great, a saving of time will be found in using two columns, each one a different length, as required, and having its own clamp and saddle.

The number of holes that will be bored by each class of machine per shift is as follows:

Hand Churn Drill	6 to 10,
Hand Auger Drill	8 to 15,
Power Auger Drill	20 to 50,
Power Percussion Drill	20 to 40,

the first two requiring one skilled man to operate, the latter two requiring one skilled man and one laborer each, so that if due allowance is made for the amount of labor required and to this be added the cost of repairs and interest on the investment, it will not always follow that machine drilling is the cheaper, besides which the following should be considered, the greater rapidity with which a man carrying a drill on his shoulder can move from place to place as compared with a machine drill and its accessories loaded on a truck, and which must be pushed from place to place on the truck dodging trips, cars, mules, etc.; and, as is often the case, from failure of the shots to do their work, a single "pop" shot is wanted, a man with a hand drill can have the same drilled while the machine is getting around to the work. This with delays from break downs, which will at times happen and which must be provided against, as far as possible by duplicate parts conveniently kept, make the question of how the drilling is to be done, one for careful consideration. There are some veins so full of impurities and pyrites that the only way to drill them is with power drills, and no choice presents itself in the matter; in some localities scarcity of skilled labor makes it a necessity to drill with power, but when the vein is ordinarily pure and skilled labor abounds, the hand drill will be found the cheaper.

In entry and narrow work hand drills can attack the work quicker, as a rule, and have it prepared for the blasting, loading out, timbering, and cutting again sooner than the power drill can leave the locality it is working at, and it will not pay to load up a drill before it has finished *all* the drilling in a room or face to go and do some other work load up again and come back and finish. Where the narrow work is being pushed this is an item of considerable importance. The rule prevalent at so many mines of requiring all the shots to be fired at a certain hour or hours of the shift is also detrimental to getting entry and narrow work ahead. The true plan for economy is always having the entry and opening work ahead of all requirements and to proceed with it in regular routine, to push anything means to add extra expense, and may often eliminate all profit. Entry and narrow work should be blasted as soon as it is cut and drilled and gotten ready for the cutting machine as soon as possible; the ventilation should be such that the smoke from the blasts is quickly carried off; if not true economy demands a sufficient volume of air for this purpose, and that the air current be carried in "splits" so that the smoke of one section is not carried into and interferes with another section.

It can readily be seen that while the hand miner can work ahead in the "tights" or on the "bench" and keep entry work going during delays and idle time, the machine requires that every portion of the work go ahead regularly without delay, and that any block in any particular department works through and delays the whole.

MINING MACHINES.

Cutting machines can be divided into three classes as follows:

1. Those that plane or scrape the face of the coal or along the face of the same.
2. Those that bore the coal.
3. Those having a reciprocating motion, attacking the coal by a blow.

Examples of the first class are the Kangley Longwall Machine, Legg, Lechner New Arc Machines and others.

Of the second class the Smith, Van Depoele and Stanley Entry Driver.

And of the third class the Ingersoll-Sergeant, Chouteau, Harrison, Sperry, and others.

This last class has the advantage of the same machine being also a "shearing machine."

Like the drilling machines, there are some conditions under which a revolving mining machine cannot do the work, and where a blow is required to shatter and displace impurities. In a clear coal or undermining not too hard, machines of Classes 1 and 2 will not only do the work well but more rapidly than those of Class 3 and have the advantage that more of the work is done by the machine, less depending upon the operator, whose work consists only of setting the machine and stopping and starting the same; with them a cut of a positive depth is made, though with some of them this cut is not of sufficient height to tumble the coal when blasted; and when the cutting is done in the coal a smaller percentage of it is lost in the cuttings than with those of Class 3. Machines of Classes 1 and 2 require a better roof and more room at the face clear of the props, and for this reason cannot be used at all in some localities where these conditions are unfavorable; running at high speeds their wear and tear is heavy and require considerable expenditure for renewals and labor of repairs.

Machines of Class 3 would be better named "power tools" than machines, and differ from Classes 1 and 2 in that a large part of the work requires to be done by the operator and requires more or less training and skill on his part to manipulate them, like the percussion drill they can cut coal containing nodules that would entirely baffle a revolving cutter or drill, accomplishing it by either cutting around and dislodging them or shattering them by a blow or blows. This gives them the advantage of being able to cut coals that other classes fail on as well as those they succeed with, and as they can be handled where there is very little room between props and props and faces, together with the fact they can both "shear" and "cut," and that wear and tear and consequent cost of repairs is light, make this class of machines the best "all around" machine for the purpose for which they were intended.

Having selected one of this latter class as the machine we will use, and compressed air as the power let us proceed to investigate the elements that enter into a successful machine organization, these may be listed as follows:

1. Machinery used.
2. Conditions of mining.
3. Organization of working faces.
4. Regularity of work.

With a properly selected and installed plant, that its success will largely depend upon the mining conditions must be self-evident, these are enumerated below, giving the extremes, variations being found all the way between:

Clear cutting.	Cuttings full of nodules.
Soft cutting.	Hand cutting.
Free cutting.	Woody cutting.
Dry face.	Wet faces.
Strong coal.	Free slippery coal.
Top and bottom partings.	Lack of top and bottom partings.
Freedom from impurities.	Containing impurities.
Partings from impurities.	Lack of partings from impurities.
Good roof.	Poor roof.
Face and end joints.	Knotty curly coal.
Regularity of floor.	Irregularity of floor.
Width of work.	Narrowness of work.
Freedom from faults.	Faults.

With the conditions enumerated in the first column we can expect exceedingly favorable results, and need not despair of results with those in the second, though for machinery with conditions in second column to compete with hand mining under conditions of first column would be almost a foregone conclusion, unless part of it can be made up by a superior organization of the machine forces, as compared with a loose organization of the hand mining, which brings the point that after all it is largely in the organization and control of forces which machinery enables, that the true success of machine mining lays. By it each person located at just the kind of work he is particularly fitted for and by continued practice at the same kind of work soon becomes very skillful and quick at it; and no needles props are set, no useless holes are drilled, powder is not wasted, no false blows of the cutting machine and so on, by the workman; and water drained, ventilation secured, roads, cars, and motive power in best of condition, tools and equipment kept in order, and everything up to the top notch for results, on the part of the management; are the benefits which will result from organization and count in the direct cost per ton. The same may, in part, be true of hand mining forces, but it cannot be as thoroughly carried out where the miner has to do all departments of the work and no arrangement by which each person is put at the particular work he is particularly good at.

By no means least, comes the regularity of work without which a successful machine organization cannot be maintained. The different portions of the work being carried on by separate gangs, it becomes very necessary that an unbroken routine be kept up, and that the several portions join together as the tenons of a dove tail to form a complete whole. The exigencies of trade, car supply, etc., can best practically be met by the mine having a large number of working places sufficient for several days work of the machines, and no more machines than that by working every day can cut the required amount of coal. This will keep the machine forces steadily at work and when trade demands and car supply warrants, a large force of loaders and timbermen can be put on, and the product of several days cutting loaded and hoisted. The usual difference between summer and winter trade is best met by running the machines single shift during the summer and when the fall trade comes, running the same double shift, putting the helpers of the day shift through the summer on as runners for the second shift of winter, their places in turn as well as extra loaders to be filled by the labor that naturally comes to the mines in winter when much out-door employment ceases. Extra timbermen and blasters having been educated during the summer from the ranks of the loaders.

In starting a machine organization, the better plan is to have every one connected with the working forces paid by day's wages or by the hour, with an allowance for use of tools, and for furnishing lamp, oil, and wicking, a premature attempt to force contract prices upon the men before they know what the machines are capable of doing, and what they are capable of doing themselves under the new order, and before even the management are practically posted on these points, nearly always resulting disastrously. Contract or piece-work for the *different portions* of the work after two or three years running when every one has become entirely familiar with the work then becomes an advantage to both parties, and is to be preferred to any *lump* contract.

In organizing machine forces the following portions of the work are entirely distinct from each other and should be kept as entirely separate departments.

Undercutting and shearing.
Drilling.
Blasting and timbering.
Loading.
Mechanical.

Variations of the above are allowable as follows: if hand drills are used it may be advantageous to combine the drilling and blasting, and where the roof is good and little timber is required, the timbering and loading may go together, but generally the best results will come from an organization laid out as above.

The whole to be placed under a general foreman or machine boss, who has entire charge of the machines and all men working with them, but in everything else is subordinate to the pit boss or underground manager who directs the workings, see that they are kept in safe and proper condition, mine properly ventilated and drained, coal hauled away, etc. The line is easily drawn, one directs what work is to be done, the other directs the men and machines to do it; on a proper understanding and carrying out of this, success or failure may often depend, and unless the organization is small, it is impossible for one man to attend to the duties of both places and do either of them anything like justice. If a second or night shift is needed, a night foreman will be necessary and this is all; too common a mistake made is to load down organizations with several foremen for different departments whose jealousies and bickerings entirely destroy any possible chance of success. This foreman may, in the early stages of the installation and at various times need several instructors, who should simply be competent workmen, on workmen's pay and without any authority whatever.

The general foreman should be a person with the following qualifications:

1. Ability to get along with and handle men.
2. General knowledge of mining.
3. General knowledge of machinery.
4. Sufficient schooling to keep time and record.

As said before he should have the entire charge of the men and machines, and be responsible for results, hiring such men as he may need and discharging or changing those that will not carry out his instructions, or who may not in his judgment, after sufficient time has elapsed for them to become competent, give required results.

The undercutting is generally done by two persons, one called the "runner" and the other the "helper," some conditions requiring a third man or second helper called "slackman," as in soft fire-clay mining, in which the machine cuttings are of such large quantity, that to store them away in the gob before the coal is blasted down is the work of another man. The runner operates the machine, directing the cutting, the helper changes the cutters as they become dull, and shovels back the cuttings; the two move the machine from cut to cut and from place to place. Every machine should be supplied with the necessary tools to operate same, and an oil can (the size to contain the proper quantity for one day and no more), these to be charged the runner when taken out, and to be returned by him at the close of his shift when reporting his time and amount cut. The amount cut in lineal feet by feet in depth, the number of entries or narrow places and the number of shearings should be reported at the close of every shift and entered upon a record. If these measurements are reported to the general foreman he will, from his own personal knowledge of the day's work, be able to check the reliability of the same, and should give them frequent checks by actual measurement, especially as to depth, for on this one particular the success or failure of the undertaking will greatly depend. Every inch increased depth of cutting, not only counts directly on the amount of coal produced, but also indirectly in the decreased cost of blasting, the less shattering of roof, and consequent saving of timber, and large percentage of large coal. Other matters of importance to be looked after, are that no more of the coal is cut than is necessary to get back the full depth, and that when there are no partings the cutting is kept to its proper place, and loss avoided by this means.

Runners are taught by first working as a helper to a competent runner, then by cutting turn about with him or another helper, under the instruction of an instructor or the general foreman, until by practice he becomes sufficiently skillful to take a machine, after which much depends upon himself; any ordinarily intelligent workman possessed of either mining or mechanical skill, and capable of doing a day's work at other branches of labor, can in from six weeks to six months, according to conditions, become good runners.

Entry and narrow work often requires shearing or cutting up and down vertically in addition to the undercutting, and under some conditions this shearing of itself is all that is needed, without any previous undercutting.

The drilling, as conditions may decide, will, in some cases, be most economically done by hand and in others by power; if done by hand either with the churn or auger drill, each man called a "driller" is supplied with drills or augers sufficient for a days work, and follows after the cutting machine, drilling such holes as directed by the general foreman, at such places, angles, and depths as experience gained from day to day may prove to be best. Some coal will allow of shooting over the mining from six inches to one foot, and when this is the case advantage should be taken of it, as all coal gained in this way is almost a direct profit; other coals again will shoot short of the mining, and it is better to let this be done, than to

attempt to get it all down at a waste of powder and sacrifice of coal blown into slack.

In Longwall work, work having a good top parting, and weight from the roof, and gaseous coals, drilling and blasting are not always necessary, in these cases wedges under the cutting or sprags against the face are needed to hold the coal while being undercut, the removal of which afterwards allows the coal to drop, with now and then an occasional pop-shot to bring down some portions that may have failed to come.

With power drills, the work is done by two men, a "driller" and "helper," the two together set and connect up the machine, the former runs or feeds the same, the latter taking his station close to the hole to quickly change drills and scrape out the hole, or while one looks after the running of the machine, the other with a file sharpens up such bits as may have become dull and yet not sufficiently so to be sent to the forge. With power drills it is an advantage to drill ahead of the cutting machines avoiding the cuttings which, if of coal, are left laying in a heap, about the place the drill column or frame is set up. Like the machine runner, each driller should be supplied with the necessary tools and oil cans to be charged up to him and returned by him at the end of each shift.

The blasting and timbering together are usually done by the same persons and their duties consist of charging and firing the holes drilled by the driller, breaking up large coal, trimming the face and top and setting the required timbers, and are responsible for the safe conditions of their places. To them the powder and other blasting supplies are given out each shift and they are accountable for the same and their proper use, and by them the timber needed is ordered from the party whose business it is to see that the same is sent into the mine. Each blaster and timberman should have a box or shanty made in a cross-cut, under lock and key to keep his tools in, and which will consist of the following: Light trimming picks, heavy breaking picks, wedges, sledge, needles, tamping bars, scraper, powder can, cartridge stick, axe, saw, hatchet, etc.

The loading is done by men called "loaders," who work singly or in pairs, as circumstances suggest. Their duty consists of loading up the loose coal into the pit cars, cleaning it of impurities and casting the same back into the gob; their tools are the shovel or fork, a heavy breaking pick, and their own hands. Much of the loader's success will depend upon the shape the coal is thrown down to him, the distance from car to loose coal and which should not exceed twenty feet to the extreme end, the regularity with which empty cars are supplied to him and the loaded ones taken away, and the amount of impurities to be picked out. An average day's work will vary according to conditions from eight tons per man to fifteen tons per man, to make which average means that at days it will run below this and others beyond it; under very favorable circumstances a good loader has been known to load twenty tons per day for several days.

No more important division of the work is there than that of the mechanical, for on proper sharpening and tempering of cutting tools, and general overhauling, repairing, and keeping up of machinery the success of the entire plant depends. The mechanical force of a machine plant will consist of one or more smiths and helpers as may be required, pipeman, machinist, the occasional services of a carpenter and the tool boys whose business it is to get in and out the sharp and dull tools from the workman at the face to the shop outside, unless as is seldom the case, the cutting is so exceedingly favorable as to allow each runner and driller with their helpers to carry in sufficient tools to do a shift's work, to be brought out again by them at the close of the shift.

The shop should be fitted up with the required number of forges, the blast for which can be taken direct from the compressed air pipes or receiver, a wet emery wheel, grind-stone, drill press, lathe, and small planer, and if so equipped will put in order many a part that otherwise would be thrown aside, as well as make many of the parts needed for renewals. A small steam hammer will soon pay for itself in drawing out picks and drills and re-steeling the same, and if supplemented by a heating furnace will be still more efficient. If the vein of coal is not or has not any bench sufficiently good for the purpose, it will pay to procure a good blacksmith coal even at a pretty high figure, and boxes of dry sand ashes or slacked lime should be provided in which to put the tools to cool off after the same have been tempered.

All machinery should be regularly inspected and the machinist should not wait to receive word that something has broken down to go into same, but endeavor by anticipating such and keeping everything in first class order to lessen the number of breaks and keep the machinery up to its highest mechanical efficiency. Runners should, under no circumstances, be allowed to attempt any repairs of their machines but should report the same to the general foreman, who will call in the machinist to attend to same; by this the runner will understand that his business is to run the machine and keep it going during working hours, and will avoid the habit of constantly tinkering, to which so many are prone, and which, if allowed, is not only done at the direct cost of the owner but finally ends in a lot of very inefficient machinery.

An extra machine always ready to use, to take the place of a disabled or irregular running machine should be kept where the same can be quickly reached in case of need; and a supply of duplicate parts kept on hand to quickly replace and repair any broken or worn out parts should be in the hands of the machinist and kept by him under lock and key.

Next to the general foreman on no one depends the success of machine mining so much as upon a careful, painstaking, active, and economical machinist. A careless one, not only by allowing the machinery to run down may prevent a profit from being made, but many to keep up their machinery may spend in doing so any profit there is to be made.

The pipeman's duties consist of taking care of and extending the pipe lines, and taking up such as are no longer needed, being careful to so arrange his work and the time of the same as not to stop or interfere in any way with the continuous working of the machines. In small operations these duties may devolve upon the machinist. The pipeman should be furnished with a place under lock and key in which to keep the several tools needed for his work and the necessary valves, fittings, etc.

When a carpenter's services are needed, as will sometimes be the case for such matters as boards, trestles, tool boxes, blocks, sprags, wedges, etc., the carpenter employed about the mine for other purposes can be used and that portion of his time engaged upon the same charged to the machine mining account.

The tool boys keeping the runners and drillers at the face of the work constantly in sharp tools have much to do with the success of the work, for any delay for want of tools is a direct loss, and running with dull tools is very little better. Sufficient tools must be furnished by the management to keep a supply at the face, and for the same number in the shop being sharpened, and a like number on the road either in or out. A hole bored through (if one is not already there) the tools, allowing them to be strung together by a rod or heavy wire will assist to keep them from getting scattered in transit, and they should not be sent out on top of loaded cars, but when a sufficient number are ready, loaded into an empty car, care being taken that one is selected which has a tight bottom and sides. As a general thing there is some one out side with other duties, part of whose time can be given to getting the tools from the top of the shaft mouth of the drift or slope to the shop and back again, and which portion of his time can be charged to the machine mining account. Inside, one or perhaps two boys (remember the old saying) will be required to meet the incoming cars, take them to where they are needed, unload them and reload the car with dull tools. The unloading should be done at central points where the machine helpers can come with their dull tools and take back to the machines a supply of sharp ones.

Records sufficient to enable the general foreman to know just what each individual or set of men have done each day should be kept in a clear concise form; if made up every evening and results furnished the foreman it will enable him to look after weak points and correct them the following day. Such records should show the number of lineal or square feet cut by each machine, whether in rooms or entries, yards of narrow work cut, and the number of tons produced per machine; number of holes drilled by each drilling machine or man; number of blasters and timbermen and tons per man; number of loaders and tons per loader; all mechanical and general expense; powder and blasting supplies and tons per keg; oil and supplies used; cost of power and a general charge for depreciation, based upon the footings of the equipment account, a certain percentage of which should be charged off daily to finally retire the cost of the plant.

A convenient form is given on preceding page.

Sheet A is a basis sheet to get at the proportionate expense per machine of general, mechanical, and power expenses, under each head blank lines are left for other items that may from time to time come up. The amounts of these charges are divided by the number of machines and drills and give the *pro rata* chargeable to each machine. The total cost of running each machine a shift (cutting machines and drills) is then arrived at by adding together the wages of the runner, helper, and *pro rata* of general, of mechanical and of power expenses; to this is added an arbitrary charge based on experience and corrected from time to time of the amount to be charged each machine for the oil and waste used, parts for repairs, steel for cutting tools, etc., and which will vary in different localities and machines from 50 cents to $2.00 per day; on blank lines below may be added any other expense for which provision has not been made before. The total of this column gives the total cost of a mining machine per shift, and will be found to vary from $8.00 to $12.00, according to conditions and location.

Below is given a column for the record of the drilling machines (or drillers if hand drills are used) giving the name of the driller, number of holes drilled, time in hours and cost of running taken from the basis sheet. The addition of these figures gives the total number of holes drilled and total cost of same, the latter divided by the shift's production gives the cost per ton for this item. Also, a column for the record of blasting supplies, in which are entered the supplies when given out; blank lines below providing for dynamite, caps, fuse, barrels, soap, grease, and other supplies that may from time to time be needed; the addition of these figures give the total cost of supplies, and divided by the shift's production in tons, the cost per ton for supplies; which added to the cost of drilling gives total cost per ton for this department of the work.

On the lower left hand portion of the sheet the total cost for the day is entered as taken from the second sheet, this is entitled to a credit for the yardage driven and rooms turned either at prices previously paid for hand work, or the prevailing district prices. This, divided by the day's tonnage, will give the actual cost per ton and show at once whether the same is being conducted at a profit or loss.

On Sheet B is entered the number of the machine, the name of the runner, the check number the coal from the machine is being loaded on, the number of feet cut, yards of entry and room work, tons produced by the machine, time worked in hours and cost as shown by the basis sheet. The cost of drilling and blasting supplies is approximated by multiplying tons produced per machine by the cost per ton as shown by basis sheet, or if a drill does the work for a group of machines, the actual cost of the drilling and blasting supplies that went to this group can be charged directly to them. The number of timbermen and blasters or parts of timbermen and blasters chargeable to each machine is next entered and their cost for wages; likewise the number of loaders and their cost for wages. All of which added together will give the total cost, connected with the tonnage of the machine from cutting the same to placing it on the pit cars at face, beyond which it is not necessary to go, the cost thereafter being the same whether cut by hand or by machinery.

In succeeding columns will be found space for entering the cost per ton for each of the previous items, which are found by dividing the cost by the tonnage of the machine.

Each mining machine having been entered up in this way totals are made, and from these totals averages arrived at, a comparison of which from day to day and with each separate machine will show weak points and what need looking after, and where they are located.

ENGINEERING ASSOCIATION OF THE SOUTH.

The regular February meeting of the Engineering Association of the South was held at the headquarters of the association at Nashville, on Thursday evening, Feb. 11, Vice-President Jas. Geddes presiding.

The Standing Committees for the ensuing year were announced by the Board of Directors as follows; Committee on Finance, W. F. Foster, W. L. Dudley and John MacLeod; Committee on Rooms and Library, E. C. Lewis, Jas. Geddes and F. P. Clute; Committee on Papers and Printing, Olin H. Landreth, W. B. Ross, Chas. B. Percy, Hunter McDonald and John B. Atkinson. Applications for membership were received from E. B. Cushing, Resident Engineer Southern Pacific R. R., Houston, Texas, W. N. McDonald, Asst. Engineer N. C. & St. L. R. R., Nashville, Tenn. and A. H. Wood, Asst. Engineer T. C., I. & R. R. Co. Tracy City, Tenn.

The President of the Association, Mr. A. V. Gude, of Atlanta, who was unavoidably absent, sent a communication inviting the Association to hold the March meeting at Atlanta. The invitation was accepted and a committee was appointed to make provisions for transportation. This committee subsequently reported that Maj. J. W. Thomas, President of the N. C. & St. L. R. R. had very generously offered to furnish transportation to the members of the Association to the meeting at Atlanta, and would place a private car at their disposal. The trip will be made by daylight in order to give the members of the Association an opportunity to inspect the extensive improvements being made on the Western and Atlantic R. R., which has recently been acquired by the N. C. & St. L. R. R. Co.

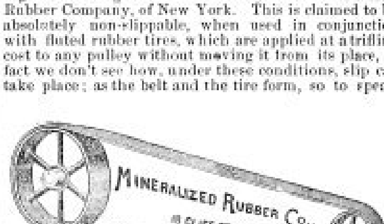
Mr Olin H. Landreth then spoke on the subject of "The Calorific Power of the Southern Coal Fields." One of the results presented was that a series of coal tests covering a large number of southern coals had developed the fact that there were at least three southern coals which were superior in calorific power to the standard second pool Pittsburgh coal and but slightly below Cumberland, Md. semi-bituminous coal. The paper was discussed by Messrs. Hunter McDonald, J. B. Atkinson, W. L. Dudley, J. S. Walker, W. G. Kirkpatrick, and Gordon Hicks.

Fluted Rubber Belting.

We annex a cut of the new patent fluted rubber belting now being manufactured by the Mineralized Rubber Company, of New York. This is claimed to be absolutely non-slippable, when used in conjunction with fluted rubber tires, which are applied at a trifling cost to any pulley without moving it from its place, in fact we don't see how, under these conditions, slip can take place; as the belt and the tire form, so to speak,



an elastic cog-wheel. Even when the fluted belt is run on an ordinary uncovered pulley it is claimed that much of the slip is prevented, as the flutings in the belt prevent all air-cushioning (a great provocator of slip) and the elastic flutings or ridges act as claws and take hold of the pulleys much as a man's finger nails or teeth hold an article that would slip from the fingers. For outdoor or exposed work it would seem as if a new and valuable invention had appeared.

Reduced Rates and Enlarged Privileges for Clergymen on the Pennsylvania Railroad.

The Pennsylvania Railroad Company announces that commencing on February 15th, 1892, tickets will be sold to Ministers of the Gospel, holding proper clerical orders, at half rates. This arrangement will apply to all tickets sold on the Pennsylvania Railroad lines east of Pittsburg and Erie as well as to the Pennsylvania lines west of Pittsburgh, so that a clergyman may not only be able to secure a ticket at half fare between any stations east of Pittsburgh and Erie, but may enjoy the same privilege in the purchase of a ticket to Cleveland, Chicago, Columbus, Cincinnati, Indianapolis, St. Louis, or intermediate points.

This concession in the interest of so deserving a class is fresh evidence of the liberality of the Pennsylvania Railroad, and cannot fail to impress itself upon the appreciation of those whom it is designed to benefit.

THE PROGRESS IN MINING.

Reviews of Important Papers Relating to Mining in the Proceedings of the Mining and Scientific Societies, and in the Mining Journals of Europe, United States, and Canada.

Automatic Dumping Device. The following described dumping arrangement has been in use for some time past at the main hoist of the Schubert's Pent Coal Mines, at Olbersdorf, near Zittau. Being completely self-acting, it offers the advantage of saving the expense of the workman that receives the coal at the top of the hoist. Its construction originated with the proprietor of the above mentioned mines.

THE HOISTING CAGE

can be considered as the skeleton of a horizontal cylinder which is suspended on the bail *a*, made of strong square iron, so that it can rotate around its axis. The circular sides are connected with each other by the bars 1, 2, 3, 4, and receive through them as well as the broad vertical bar *b* and the bottom band *c* the required

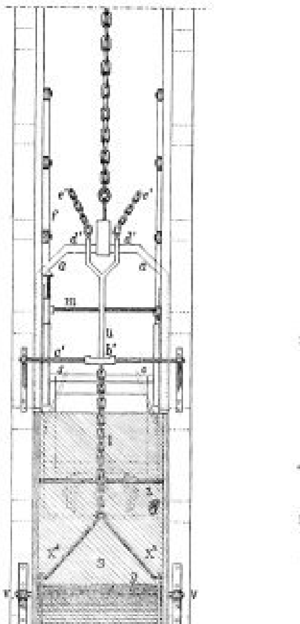


FIG. 1.—FRONT VIEW. Scale 40 to 1.

stiffness. The lower bars 1 and 2 carry the rails for receiving the car. The frame 4 is made of angle iron and placed at a convenient height to serve as a reliable support for the upper edge of the car whenever the cage is tilting. To lock the latter, and to hold the car in its place, there are two flat bars 5 and 6 placed on the sides of the shaft in strong hinges in such a manner that they slide along the cage as it ascends and grip over the top of the car with their hooks which

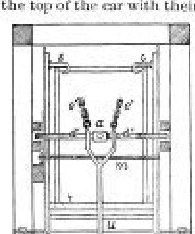

FIG. 2.—TOP PLAN. Scale 40 to 1.

are bent towards the inside and come to lay angling across them. In emptying the car the latter is thus prevented from dropping out.

For the purpose of dumping, the two circular sides are provided with a segment from *d* to *e* which, as the cage ascends, gears into the rack *f* which is bolted to one of the guide posts at the proper height. To hold the cage in its ordinary position, an eye *g*, Fig. 5, is cast on the segment pointing inward and in the direction of the vertical axis of the cage. The bolt *h* which slides up and down, and is pressed down by the spring

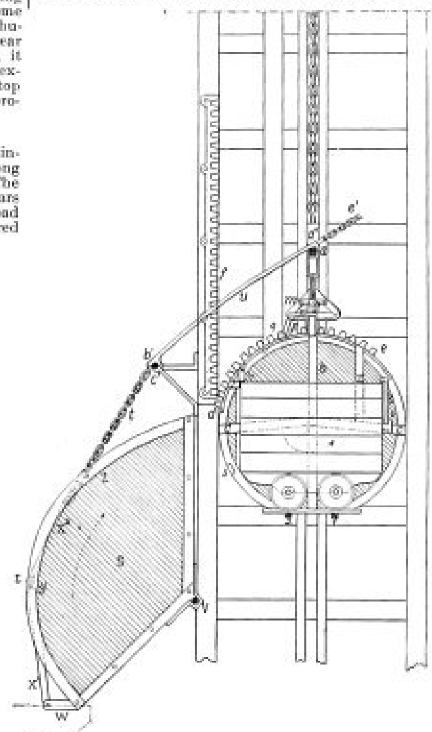

FIG. 3. SIDE VIEW: AT THE BEGINNING OF THE EMPTYING OF THE CAR. Scale 40 to 1.

i, fits into this eye or slot. Whenever the cage is ready to tilt this bolt is raised in the following way:

The shaft *m* is placed parallel to the axis of the cage

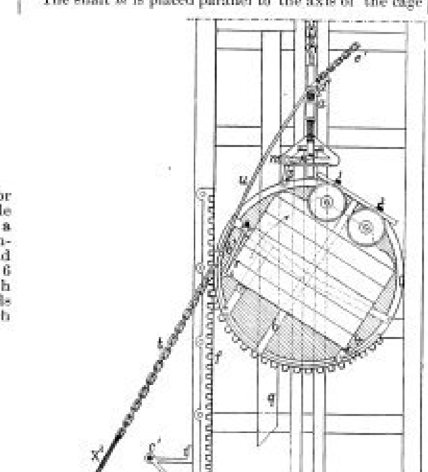

FIG. 4. SIDE VIEW: AFTER THE CAR HAS BEEN EMPTIED. Scale 40 to 1.

in the two strong wrought iron bearings *k*, Fig. 5, which are bolted to the bail *a*. This shaft carries the lever *n* which acts upon the little toe *o* of the bolt *h* and raises the latter when turned upward.

The lever *p*, provided with a small roller, is keyed to the same shaft, pointing half downward and half outward. This lever *p* strikes on the up-trip of the cage the guide bar *q*, which is beveled at its lower end under 45° and fastened to the sides of the shaft at the required height, in such a way that it is first pushed with its little roller to the inside, rolling along the beveled side and then slides upward along the inner face of the guide bar *q*.

Through the first part of the movement, the shaft *m* is turned and consequently the bolt *h* raised out of the slot by the lever *n* pushing against the toe *o*, and thus the cage is free to rotate.

To secure with the descending cage always a reliable and correct setting of the bolt *h* into its place, so that the cage comes again into its normal position and is kept there, the slot has been tapered from above to about ⅓ of the thickness of the metal. The guide bar *q* has a set screw on the side of the shaft for the purpose of bringing it into the right position. This adjusting, which is only done once, must be such that the bolt leaves the square part in the slot in the moment when the segment gears into the rack, and then, as the cage begins to rotate, leaves the slot on the tapered part, to be kept in its highest position until with the down-trips of the cage the levers *n* and *p* return into their original position. The bolt *h* is forced into the slot as soon as the segment leaves the rack.

THE SCOOP.

As a receptacle for the dumped coal for each hoist serves a scoop *s* and for both hoists a common receiver *r*, as indicated in Fig. 3, from which latter the coal is taken to the separators.

The shape of the two scoops is that of a cylinder segment with an angle of 135° with parallel sides. They rotate on the strong axis *v*.

Two stay bolts are placed near the upper edge at *y* and *z* for stiffening the scoop. The two flat bars *w* are fastened to the sides and to these are hinged the two rods x^1 and x^2, which latter join into one at the top. The lower rods x^1 each have a slot *z*, Fig. 4, into which fits the stay-bolt y, Fig. 3. The rods x^1 and x^2 are continued by a chain *t*, the rod *u* and the chains e^1. The latter are fastened with their upper ends to some support and only have the purpose to keep the rod *u* swinging in its ordinary position, Fig. 3, so that it is free to move according to the requirements, as will be shown below.

The rod *u* is provided on both ends with claws that point downward. It generally rests with its lower claw b^1 on the cross-bar c^1, and the scoop then has the position shown in Fig. 3.

The upper claws d^1 are taken hold of by the bail of the ascending cage and carried along. The scoop is thereby placed in a position as shown in Fig. 4 and in which it receives the coal that is dumped from the car,

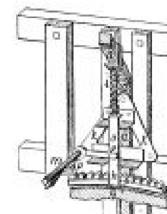

FIG. 5.—UNCOUPLING ARRANGEMENT.

To prevent it tilting from this position toward the shaft and empty into it, it is made heavier on the side of the receiver so that the center of gravity remains on this side. With the return of the cage the scoop goes back to its normal position and at the same time empties its contents into the receiver.

As the cage descends, the lower claw of the rod *u* catches again the cross-bar c^1 the upper claws are left by the bail of the cage and the rod suspends from the chains e^1 across the shaft.

This whole arrangement makes it necessary that the cage shall not be lifted beyond a certain height, since otherwise some of the working parts would have to break. At the Schubert mines this is done without difficulty with a little attention by the engineer.

The Columbia Daily Calendar.

An old friend in a new dress, and an article that has come to be one of the indispensables of an editor's desk, comes to hand in the Columbia Daily Calendar for 1892. The calendar is in the form of a pad containing 367 leaves, each 5½ x 2½ inches; one for each day of the year, to be removed daily, and one for the entire year. Each slip bears a short paragraph pertaining to cycling or some kindred subject. At the bottom of each leaf is a blank for memoranda. The stand is an entirely new departure, being made of sheet metal finished in ivory black, and is very compact. At the close of the year the stand will be available for another pad. This is the seventh issue of this now well known calendar, yet all the matter is fresh and new, and comprises notable events in cycling, opinions of physicians and clergymen, hints about road making, and numerous other topics.

AN ELEMENTARY TREATISE ON THE PRINCIPLES OF COAL MINING.

For the Use of Candidates for Mine-Foremen's Certificates, Mining Students, Mine Foremen, Mine-Superintendents, Mining Engineers, etc.

BY A. A. ATKINSON, DURHAM, ENG.

Methods of Working.

The Longwall Method of Coal Working.

The following system has come under the notice of the writer and as he believes it to possess some special advantages, it will no doubt prove interesting to those for whom it is intended. The method was introduced into a seam lying about 300 yards from the surface and of about 3′ 6″ in thickness. The floor of the seam is a fire clay of not very good quality, of variable thickness from a few inches up to as much as two feet occasionally. The roof is composed of blue shale, with layers of sandstone running intermittently through it—there being always a few inches of shale next the coal. The top of the seam always adheres very strongly to the roof, so that it is necessary to use explosives to bring it down.

The coal was previously worked Longwall but under another system that did not give a very satisfactory result as regards the percentage of round coal it made, so it was decided to try working the seam in a straight face as long as possible under the existing conditions, and to underhole the band of fire clay at the bottom of the seam, and apportioning the labor into the following three divisions:

(a.) The holer, to be paid by the yard.
(b.) The getter, to be paid by the shift.
(c.) The filler, to be paid by the score.

The two first classes of men may be termed skilled, but the third is not, and of course receives a much lower rate of wages than do the others.

It took some little time to get the new system properly under way, as there was opposition displayed towards it from all sides, but which a masterly determination in time overcame.

The work assigned to the different sets of men may be described thus:

The holers cut in under the seam to a depth of 3 ft. 6 in., or such other depth as may be at any time determined on. They have to cast back into the waste gob or goaf all *debris* made in holing, and to keep it behind the front of the timber and pack walls, and to put in their own sprags as may be required. When the holing has been completed to the required depth and length, all stone and *debris* are to be cleared away along the line of coal face, so that there may be no chance of the coal falling upon it when it comes down.

The getters have to take down during the night time the coal that has been undercut during the previous daytime.

The fillers have to fill up into tubs the coal taken down, dressing off all loose coal that may be hanging and has been loosened by either shots or wedging, as the case may be: the hours of the latter are eight a shift, from bank to bank. On the commencement of the system some years ago, a face of about 250 yds. in length was chosen for the experiment, which gradually extended and the roads were made and kept in the goaf, other districts have been opened out until three-quarters of a mile of face are working under this method.

Some modification in the method of keeping the faces is necessary owing to the thickness of the band changing; it will be an advantage to give details of the methods pursued, in the case of where the band is thick and where it is thin. In the former case the gate-ways are about 40 yds. apart, the wagonway gateways being 9 ft. between the pack walls, which are 4 yds. wide on either side of the road. It is an advantage to build these pack walls with the roof stone that is taken down for height in the gate roads, as this stone is harder and in larger pieces than that which comes from the band and consequently bears more weight, and answers the purpose better than a smaller and softer stone would afford. The other roads are packed on either side to 3 yds. in width. Smaller packs are put in along the faces and between the roads to support the roof. These are about 5 or 6 ft. in thickness and are kept up to within about 6 ft. of the face, and are built with the largest pieces of stone from the band. These packs materially lessen the amount of timber required, which is in the shape of props from 4 ft. 6 in. to 5 ft. 6 in. in length and 8 inches in diameter, one being required about every 2 yds. on an average. The small *debris* and refuse made is thrown into the gob and fills it.

On an average there is a holer for each 20 yds. of face, working in alternate shifts. The undercutting is effected in the bottom coal of 4 to 5 ins. in thickness, and as this work progresses the band is liberated from the seam of coal by the weight on the coal face, sprags and stays being used to support the coal. On the holing being finished, fresh timber is set close up to the face, and the standing timber drawn out.

During the night the getters are at work taking down the coal that has been made ready during the previous day. A chargeman is there with these men who carefully examines all the faces to see that all is safe, that all *debris* is out of the way where the coal has to come down and to fire any shots that may be required, and to see that no timber is wasted. The fillers go to work in batches of two shifts early in the morning, the second shift going down two hours after the first men, and all coming to bank at their eight hours end.

The hands employed in working the coal are as follows:

Holers,	56 per cent.
Fillers,	22 " "
Getters,	22 " "

The tram rails are laid down right and left from the face of each gate-way, branching off at a double turn, and the tubs are taken along the faces. The rails are laid down by the fillers as they fill up the coals, and they are laid upon sleepers that have notches in them for their reception—a quicker method than nailing them. As the coal face advances new cross-gateways are formed at distances varying from 80 to 100 yds., as circumstances decide. It is found that the faces advance at the rate of 80 yds. per annum.

In the places where the band of stone is thin it is found there is not sufficient material for building the middle packs with, so that it has been necessary to resort to the use of wooden chocks for the support of the roof. What small dirt is made in undercutting is thrown into the goaf as before stated.

Where the band is thick and the goaf consequently well packed, the roof does not fall, but rather gradually sinks on to the packs and stowed dirt behind the faces. Even where the dirt is thin and the goaf not stowed tight very little roof stone falls: it is more of a gradual subsidence and goes on for some 100 yards back from the face, where it is found to have become settled. The roof stone in all the roadways is exceptionally good, the use of timber for supporting it being exceptional. The faces are very seldom lost from the roof coming in except perhaps when the first weight or crush comes in a new district.

The ventilation is very simple and effective as the air is taken in the first instance to the innermost end of the faces and brought back along them, the quantity varying according to the length of face to be ventilated.

In the same seam of coal where the bord and pillar system is at work it is found that the produce of round coal is 46 per cent. taken upon a district after the coal has been exhausted. Assuming a loss in working of 5% in bord and pillar workings and half that quantity is Longwall, and taking into consideration the larger yield of round coal by the latter method—68 per cent. of round coal in this case—then in an acre of the coal worked we get 1200 tons more round coal, a most important consideration.

The cost of working the coal by this method is somewhat higher than if worked by bord and pillar, something near sixpence per ton more; but this might be reduced were the roadways driven in the coal to the boundary first and the coal worked homeward, leaving the goaf behind, as the roads in the coal would take so much less to make and maintain, than in the goaf as at present.

It has been found that the consumption of timber is extremely low—thanks to the good roof—on an output of 14,000 tons it was found to be under 0·02 of a penny per ton. Taking in consideration the difference in the amount of round coal obtained from this method of working as compared with the bord and pillar system, the effect financially is very considerable. Assuming the difference in value of round and small to be 4s. a ton, then in an acre of coal, say one foot thick for comparison, there is pecuniary advantage of about £30, or about 5d. per ton on the whole output. And as the present extra cost of working is certain to be reduced by at least 4d. per ton, a saving will ultimately be effected.

The effect on the economy of coal producing which the method of working exerts, calls for the most careful consideration in deciding on the system to be adopted. The competition of the present day causes every one to attain to cheapness and efficiency, and only those who attain this object can expect to work to an advantage. Some of the advantages of Longwall working may be stated as follows:

1. Greater produce than by the pillar and stall system—the loss in working being perhaps only one-half as compared with the latter mode: thus effecting a better return for the lessee, as well as the lessor when the royalty rent is at so much per acre.

2. A larger produce of round coal: the immense advantages of this point are so obvious as to require no remarks.

3. There is less straight or narrow work and consequently less hard labor required in cutting, nicking, or shearing.

4. The weight of the overlying strata so acts on the face of the coal as to cause it to be worked more easily, and consequently more cheaply. It also acts in a beneficial manner on the holing dirt, making it work more freely, as well as assisting to bring down the coal itself after the holing is performed.

5. Ventilation is more simple and more effective, as the air has a much less circuitous route to travel.

6. A larger output can be obtained from a given area, as more men can be employed in getting coal.

Some of the disadvantages may be stated as follows:

1. Greater expense in maintaining and forming the roadways in the goaf—and unless the pack-walls are fully efficient the expense may become very heavy; they should be built perfectly solid, with as hard a stone as can be obtained.

2. Unless the faces advance regularly and constantly, the roadways and faces are more difficult to keep.

3. Faults and dykes are more difficult to deal with when met.

The following are some conditions which may be considered as favorable for adopting Longwall:

1. If the seam of coal is hard and strong and thin, and if the top and bottom are not too hard in case extra height is to be made for roads.

2. If there are bands of dirt in the seam which require to be stowed below ground thus affording good opportunities of stowing the gob or goaf well.

3. If the boundary be not a great distance away, so that there will not be long roads to keep in the goaf.

4. If the overlying strata do not contain water, which would get into the workings and thus increase the cost of working.

5. If the surface is free from buildings, railways, water-ways, &c., which might be damaged by subsidence.

In a general way it may be said that depth is immaterial so long as surface buildings will not be injured nor water let into the workings. It is better adapted for moderate areas and outputs than very large ones. That where the coal is tender and will not bear the extra pressure produced by the weight occasioned, it will be more advantageous to go in for bord and pillar. The best position for the undercut is decidedly when the bottom is suitable for it, as for instance, a soft warrant of six inches to a foot in thickness. The cost of getting the coal at the face is generally less than would have to be paid for the same under bord and pillar, and more especially if the work advances regularly and is worked in the direction most suitable to the circumstances of each particular case. There is always a larger yield of round coal and a larger yield per acre as compared with the other system.

Perhaps the most important point to be considered is the cost of the necessary pack-walls and buildings. It will rarely, if ever, pay when the material for this work and for stowing has to be brought any distance—it must either be got from the roof or floor close at hand or out of the seam itself, where bands of dirt or stone exist. The size of the packs varies from say 4 feet to 12 feet in width and according to the thickness of the seam. The cost per ton of the packs depends upon their size, the labor expended in getting the material for them and the width of face between the roadways: the nearer together the roadways are the more packs are to build, and *vice versa*. But the greater the width between the roadways the greater will be the pressure upon the packs, and therefore there must be greater strength in them. The cost of these packs varies considerably as will be readily understood, but if the price ever exceeds 6d. a ton, it may be taken as being abnormally high—3d. or 4d. may perhaps be taken as about a fair average cost for them.

The following particulars apply to some collieries in Derbyshire, and for the purpose of simplification they will be divided into the following heads:

1. As to the method of working.
2. The conditions under which the Longwall system can be adopted.
3. In relation to ventilation.
4. Comparison of the Longwall system with that of bord and pillar.

The method of working coal seams by the Longwall system is exceedingly simple, and may be described in general terms as follows:

Two or more parallel levels are driven from the pit, for main roads, opening winnings, water-levels, and return air-ways, as the case may require. From the main road, at a suitable distance from the pit, and at convenient distances from each other, roads are driven to the rise of the seam, and after a certain distance has been left solid for the support of the main road, Longwall working is started. The faces average a width of from 100 to 500 yards; the length however being much influenced by the nature of the roof and floor, and the quality of the coal to be worked. The working may be thus described: A gang of men called holers proceed usually through the night to cut away or undermine the face of the coal, usually to the extent of from three to four feet, and averaging six to eight inches high in front, and tapering down to nothing at the back of the undercut. Sprags of wood are fixed between the coal and the floor, at distances of about six feet or less if necessary if it appears probable that the coal may fall after being undercut. At the end of the holing or last side of the coal the men make a vertical nicking or cut into the coal at right angles with that under the coal. This work having been finished, another set of men come to work and proceed to take down the coal that has been undercut, by means of picks, wedges or blasting, as the case requires. By this means large blocks of coal are obtained, which in some cases necessitate being broken into smaller pieces before being loaded into tubs for conveyance to the surface. Lastly after the coal has been removed from the face, the packers come in and it is their duty to keep the faces and roads, which are in the goaf, well timbered and secure. At short distances, according to the strength of the roof, they set props, placing a cap or head (a flat piece of wood) between the props and the roof. When there is a good roof, it is generally necessary only to advance the same props, care being taken to place them opposite to the intervals or spaces between the props in their former position. When however the roof is bad, it becomes necessary to place good and new props more frequently and nearer together or else to build packs of stone or chocks of wood at intervals. Iron props have been much used. The coal having been thus got, the smaller coal and refuse remaining are thrown behind into the goaf or waste, often completely filling it, and as the roof breaks or bends down, a solid mass is formed.

This minute description of working may appear to some to be unnecessary, as almost all persons connected in any way with collieries are conversant with hewing coal; but the Longwall system, well carried out, differs so materially in management, that it is necessary to call attention to the smallest details. In some districts where the coal is cubical in structure, and pillar work is adopted, the hewing process is done in a very slovenly and wasteful manner, the hewers hacking and cutting in all directions (commonly termed "scalloping"); but in strong coals worked by Longwall, this cannot be done.

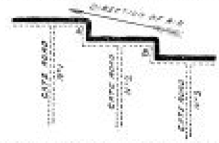
Where two or three seams are to be worked one after the other, the whole success of the undertaking depends on the soundness and good packing of the goaf, together with the entire extraction of the coal. The proper construction of the pack walls for supporting the main goaf roads is of great importance. The circumstances which are favorable to Longwall working are, a good roof and a hard stratum below the holing. Sometimes the holing is made in the middle of the seam, when a more convenient pricking is not found underneath, but if this is to be done in the coal it is wasteful, inasmuch as it breaks it up into small pieces. Wherever these favorable conditions are found, the

Longwall method is to be recommended, both on account of the simplicity of arrangement, the ease and efficiency of ventilation, and the economical manner in which the coal may be got.

The method of ventilation may be described in general terms, as the passing of an adequate amount of air in a continuous stream along each face, and which, entering at one end passes out at the other and then through a length of generally goaf road (the return air-way) and so on to the upcast shaft. The main road is used as the main intake, and the air is distributed from this to the different faces. Stoppings and regulators and doors and air crossings are placed in the necessary positions. When the seam is fiery the return air may be carried to the upcast shaft by a dumb drift, entering the pit some distance above the furnace. Such is the very simple method of ventilation usually adopted in Longwall workings; of course there are cases where necessity compels a modified plan, but that now stated may be considered the one generally in use.

Many modified forms of Longwall working have been adopted in various districts, such as the long work of the Yorkshire coal field, in which the coal is worked in faces of various widths, separated from each other by thick pillars of coal, which are afterwards taken out while working back. Another modification, called narrow bords and long work, is where two narrow and parallel bords are driven, a pillar of coal of about 30 yds. in width being left between each pair of bords. These having been driven the required distance, a communication is made between the pairs of bords, and the coal worked similar to Longwall towards the pit. By this means the goaf is left behind, and there is no necessity of keeping it up by walls or packs.

WOODEN-CHOCKS.—Square pillars built of slabs of wood.
WARRANT.—A tough fire-clay underlying the seam of coal.
PACKS.—The walls built along each side of the gateways to support the roof.
FAST SIDE.—In accompanying sketch three working places or

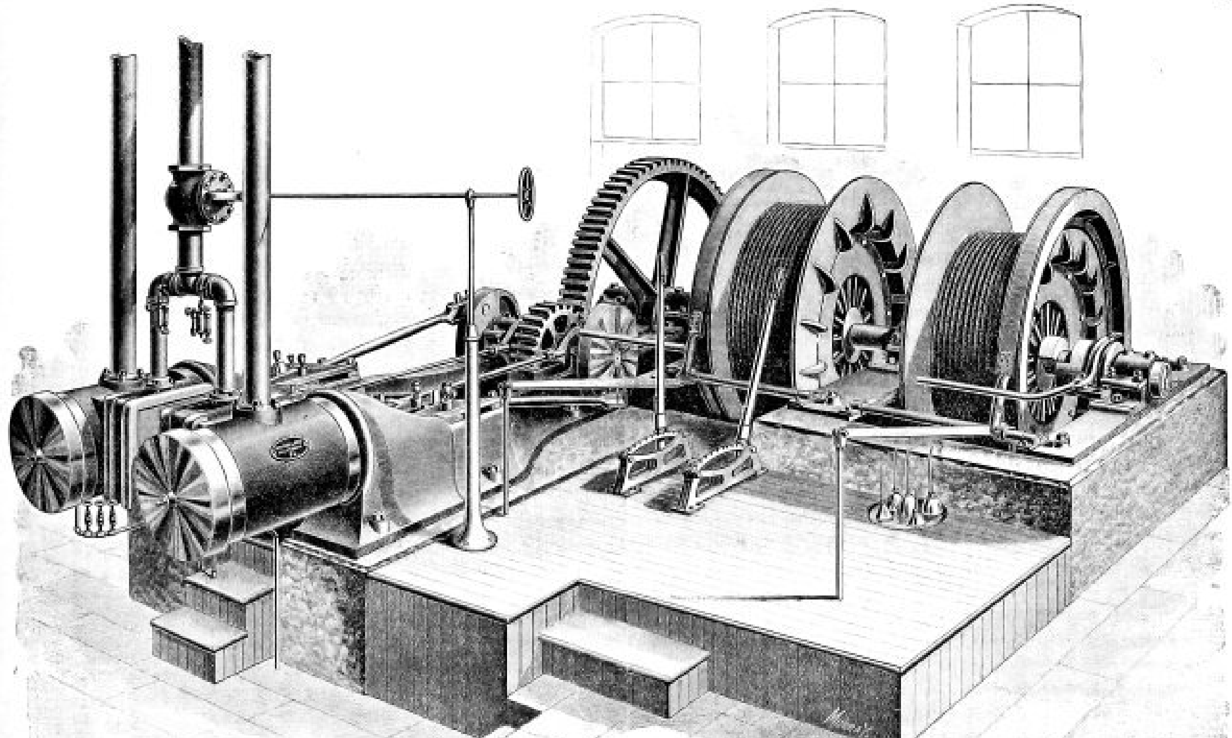


stalls are shown with a "fast side" or "cutting" between each A is the "fast side" to No. 1 because they have to nick or shear it as they advance their face. B is "fast side" to No 2 while A is "loose side" to No 2 and B is "loose side" to No. 3.
PRICKING.—Soft coal or earth for holing in.
BORD AND PILLAR.—Pillar and chamber.
BORD.—A chamber of work.

WIRE ROPE HAULAGE ENGINES AND PLANT.

In Operation at Lonaconing, Md.

With this we give an illustration of a complete plant of a pair of wire rope haulage engines and apparatus designed to haul mine cars through a distance of 2½ miles on a grade of 4 feet in 100, the load consisting of 40 to 60 mine cars, each weighing 6,200 pounds. The engines have cylinders 14 inches diameter; stroke of piston, 24 inches. The connecting rods, piston rods, and valve stems are made of hammered steel; and phosphor bronze bearings are used in all the boxes.



WIRE ROPE HAULAGE ENGINES AND PLANT.

The drums are 5 feet in diameter, width of faces 36 inches, with flanges on drums 12 inches deep; they are turned all over. A brake is attached to each drum for controlling the motion of the mine cars during the descent on grades. These brakes are operated by the quadrant levers on the platform shown in front of the drums. The throttle valve is operated by the small wheel placed at some distance from the valve, so as to bring it and the quadrant levers within convenient reach of the engineer.

The power is transmitted from the engine to the drums through the spur gearing, having a proportion of 3½ to 1. The ropes, which will be eventually 2½ miles long, are arranged so that a rope is wound on one drum while the other is unwound.

This plant has been erected at Lonaconing, Md., in the Georges Creek District, for the American Coal Co., of New York City, and has been in operation for several months, working very satisfactorily. During a trial, 45 mine cars were hauled up the 4 per cent. grade through a distance of 5,000 feet in 8 minutes with comparative ease.

This plant is equipped with all the modern appliances, including sight-feed lubricators, drain pipe connections, and all such as will be conducive to convenience and durability, and no pains have been spared in making it durable, convenient, and modern in design. Although the builders of this plant, Messrs. J. & J. B. Milholland, of 240 Fifth Avenue, Pittsburgh, Pa., have now over one hundred haulage plants in successful operation, they take particular pride in this one, and believe it to be one of the best haulage plants that has been erected. In connection with this plant, they have two steam boilers, of the return-tubular make; 85 horse power each, which can be worked together or separately, at the will of the operator. Messrs. Milholland are at present erecting a very large haulage plant in the same district for the New Central Coal Co., of New York City.

On consideration it will be seen, that as the output in bord and pillar working is limited by the number of working places open, so in Longwall work it is limited by the length of faces open, and the number of gateways open in such faces. Taking a case where the coal lies tolerably level, loaders will be at work on each side of the gateways; and as under ordinary circumstances, where the coals are properly prepared for the loaders, by what is called turning the coal out, or splitting them up ready for the loaders, thirty tons per day may be sent from each side; each gate will produce sixty tons per day, which multiplied by the number of gates at work, gives the quantity of coal which can be produced. Of the comparative merits of the Longwall and bord and pillar system it is not difficult to decide. Supposing all the seams were of the same quality and structure, either one mode or the other would be adopted, without any question being raised as to its merits; but as the component parts of the roof and floor vary in innumerable ways, the mode of working must be adapted to the circumstances.

GLOSSARY.

SPRAGS.—Short wooden props placed in a slanting direction against the bottom of the solid coal face to support it during the operation of holing.
STAYS.—Somewhat similar to sprags, only longer.
GATEWAYS.—Parallel roads running through the goaf from the main haulage road to the working face.
WAGONWAY GATEWAYS.—Auxiliary haulage roads running through the goaf parallel to the main haulage roads. These wagonways are set out to cut off great lengths of gateways.

Packing.

Every engineer knows the importance of having his engines, pumps, etc., properly packed. How to do this tight enough to prevent leaks of steam or water, and not at the same time cause unnecessary friction is a problem that many have attempted to solve with varying degrees of success.

A good packing should be tough and elastic, not affected by heat, and so made that it can be easily applied.

For many years the Gould Packing Co., of East Cambridge, Mass., has been studying this question, and, after putting their work to severe practical tests, has produced a packing which is a sure cure for leaky stuffing-boxes, whether the motion is rotary or reciprocating, or whether the rod is round or worn oval or hollow.

This packing is self-lubricating, thus economizing oil and enabling the pistons, etc., to be made steam and water-tight with very slight friction. It is practically indestructible, as it does not become hard with use, and hence does not have to be removed from the stuffing boxes; and, as it contains nothing of a hard or gritty nature, it does not wear the rods or cylinders.

The company has done a remarkably good business during the past year, and is in receipt of many testimonials as to the solid worth of its goods. The packing is largely used in government work, and a large number of electric light and power stations are using it for high speed engines.

Parties troubled with leaky stuffing-boxes in engines or pumps will do well to write to The Gould Packing Co., 36 Cambridge St., East Cambridge, Mass. They can obtain a supply on thirty days trial, and if not satisfactory, it can be returned at the manufacturer's expense.

A Large Company.

The *Manufacturer's Record* states that the broadest plan of development in the South ever undertaken which will involve the initial investments by New York and Pennsylvania capitalists of many millions of dollars, has been consummated by Alex. A. Arthur, who founded the English town of Middlesborough, Ky.

The operations of this company include the purchase and development on a very large scale of extensive coal and Bessemer iron ore properties in East Tennessee, the purchase of furnaces and coke ovens already completed, the building of furnaces, steel works and coke ovens, the establishment of two manufacturing towns and the construction of several important railroads to tap extensive systems now in operation.

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

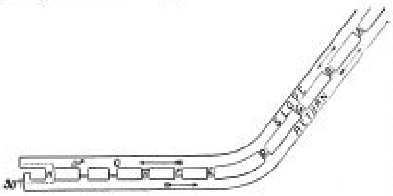
☞ *Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.*

Ventilation.

Editor Colliery Engineer:

SIR:—I will be greatly obliged if some of your able correspondents will furnish me with an explanation of the following phenomenon:

A slope and air way are each 2,000 ft. long. At the foot of the slope a lift turns off, forming a gangway and air-way about 700 ft. long each.



REFERENCES.

Course of air is shown by finished arrows.
Dips are shown by unfinished arrows.
Stoppings are shown by parallel lines.
Brattice is shown by dotted lines.
Beginning of grade in gangway shown by O.

All the headings above A were walled and plastered with mortar, but below A they were only bratticed across with boards, the last heading not being quite through. The fan had to be stopped for two days, therefore no air circulated except what was produced from the difference of temperature caused by the heat of a pump situated at A and exhausting into the return. While the fan was stopped, the gangway and air-way were filled from their faces down to the point O, or for a distance of 400 ft. with fire-damp. When the fan started, I was under the impression that the gas would all clear away in about 12 hours' time. But, 3 days elapsed and the fire-damp held the same position. I then thought a "cave" or something similar had occurred in heading or cross-hole H, as the pressure of the air current was very marked upon headings or cross-holes A, B, C, D, E, F, and G. The headings A, B, and C were walled up and plastered with mortar. The pressure, then became very marked on headings D, E, F, and G. In 24 hours after this, about one-third of the fire-damp was cleared away. D and E were now walled up again and plastered with the result that the pressure became more distinct on F and G, and in thirty-six hours afterwards all the gas was cleared away. But, what attracted my attention most, was the fact that the pressure upon the headings F and G had so diminished that it could hardly be detected, even by sitting down quietly to listen. The return was found to be in good condition and free from falls.

The mine was easily kept free from any standing gas before the fan was stopped, but after the fan started the gas could not be swept away and the pressure became very distinct upon the stoppings in the headings. After the gas was cleared away, no pressure could be observed on the closed headings. Has such a case been met with before, and what explanation is there for it?

Yours, etc.,
PRACTICAL FACT.

Plains, Luz. Co., Pa., Feb. 1st.

Pumping.

Editor Colliery Engineer:

SIR:—I notice that there have been several different answers to "S. W.'s" pump question, which was only to be expected, because certain assumptions have to be made before an answer was given. These assumptions being different in each case, the answers do not agree. Each anwer under the mentioned assumption is correct, and pumps of dimensions given under these conditions would, no doubt, do the work.

Some one wrote "More Light is the Soul of Ambition," and no doubt many of your readers are desirous of "more light," and are seeking it diligently in the correspondent's column of your valuable paper, and on this same pump question many may be a little confused, owing to the several results.

A careful study will make the matter clear, and in order to help a little farther I will reason the question out on my supposition, using Mr. Percy's rule given on page 165 of The Colliery Engineer Pocket-Book.

$20' \times 20' \times 10' \times 6\frac{1}{4}$ gals. = 25,000 gals. each 30 minutes, or 50,000 gals. per hour; 50,000 gals. $\times$ 276 = 13,800,000 cubic inches $\div$ 60 = 230,000 cubic inches per minute $\div$ 70 total height of delivery = 2,875 cubic inches per foot of pump $\div$ 12″ = 240 sq. inches nearly; to this add 10% for slip of pump, and we have 266·66 square inches; and 266·66 $\div$ ·7854 = $\sqrt{339 \cdot 5}$ = 18·4″ diam. of water cylinder.

Now let us consider the power required to move this resistance. The area of 18·4″ diam. is 266·66 sq. inches, then what is the pressure per sq. inch of 70 feet vertical water column?

$$70 \times 15 = 1{,}050 \div 34 = 30 \cdot 9 \times 266 \cdot 66 = 8239 \cdot 8 \text{ lbs.}$$

total pressure on pump. Effective steam pressure taken at 60 lbs. per sq. inch. Therefore 8239·8 $\div$ 60 = 137·33 sq. inches as area of cylinder.

We have already made one assumption, viz.: that effective steam pressure is 60 lbs. per sq. inch; now that we have found the theoretic area of cylinder required to raise the water, we must make another assumption, viz.: the amount of power required to overcome inertia of water in pipes, and overcome friction of pump and give extra power, etc., etc. Mr. Percy adds 50% and others follow his rule (it is a safe one) but would it not be extravagant in this case with only 70 feet of a discharge column? I think it would, but, at the same time, the addition of 50% in this case would make the pump available for a heavier duty if required at another place, and in this light it would be commendable, but the question only desires to know the power for the present duty. A margin of 10% I think would be sufficient even with the discharge column 9″ diam. as the increased head equal to the amount of friction generated by water traveling 300 feet per minute in 9″ diam. pipe would be less than one foot, making the whole resistance equal to weight of water in 71 feet of water column.

$$137 \cdot 33 + 10\% = 152 \cdot 6. \quad \text{And,}$$
$$152 \cdot 6 \div \cdot 7854 = 194 \cdot 3$$
$$\sqrt[2]{194 \cdot 3} = 14''$$

nearly as diameter of steam cylinder.

Mr. Percy, on page 165 of The Colliery Engineer Pocket-Book, says: "*Pipes should be at least as large as the pump.*" This does not agree with American builder's practice, as an examination of any catalogue will show.

Yours, etc.,
H. L. D. W.

Bon Air Mines, White Co., Tenn., Jan. 18th.

A Strong Endorsement of "The Colliery Engineer" as an Educator in the Theory of Mining and Kindred Subjects.

Editor Colliery Engineer:

SIR:—You are aware that the examinations for candidates for mine managers are now in progress in this state. As I am largely, if not wholly, indebted to THE COLLIERY ENGINEER for my theoretical knowledge relating to mining, and it has enabled me to pass a creditable examination, I deem it my duty to render an acknowledgement of the benefits received through a careful study of its pages.

I venture to say that nearly all, if not all, of the candidates who passed the examination in this district (including five counties) were subscribers to THE COLLIERY ENGINEER. A great many expressed themselves as being glad that they had subscribed for the journal a year or two before the law was passed, thus taking time by the forelock; others were free to admit that they were sorry that they had not heeded the warning given them by friends to prepare for the inevitable.

I also wish to say by way of encouragement to others who may be seeking to qualify themselves to pass the examinations for mine managers that some of those who passed this examination had little or no education until a few years ago, when they were induced to read THE COLLIERY ENGINEER. They commenced at the foot of the ladder. Beginning at addition they have kept on improving themselves until they have mastered arithmetic as far as is necessary to work out the formulæ used in ventilation and mine mechanics and, to their credit, some of these same parties obtained the highest grades at the examination.

I take pleasure in commending THE COLLIERY ENGINEER to all who wish to inform themselves in mining; especially those who have not had the advantages of early education. I freely concur in the opinion on the "Intelligent Miner," from Allegheny Co., Pa., who stated "if miners remain ignorant on subjects relating to mining when they have such opportunities as your journal presents it is their own fault."

Yours, etc.,
PETER JEFFREY.

Carterville, Ill., Jan. 25th.

Ventilation.

Editor Colliery Engineer:

SIR:—I submit the following in reply to question (1) by "J. W. S.," of Westville, N. S., in your last issue.

(1). An air-way 10′ $\times$ 10′ and 2,000′ long is passing 60,000 cu. ft. of air per minute, what would be the required area of an air-way to pass 15,000 cu. ft. per minute its length being 1,800′ the pressure remaining the same?

Since air-ways will pass quantities of air in proportion to their areas, the area will be in proportion to the quantity, other things being equal. As the length differs in this case, so will the rubbing surface in the proportion 9 : 10. Then, we have the following compound proportion:

$$\begin{matrix} 4 : 1 \\ 9 : 10 \end{matrix} :: 100 : x, \text{ or } 27 \cdot 7 \text{ sq. ft. area.}$$

The volume passing is as 4 : 1, and the length as 9 : 10.

Yours, etc.,
L. P. H.

Avoca, Pa., Jan. 13th.

Pumping.

Editor Colliery Engineer:

SIR:—I would say relative to the question asked by "Beginner," in the August issue, as to whether more or less power is needed if the suction be 5′ or 20′ and the discharge 95′ or 80′, the shaft being 100′ deep, that as the 15′ more suction needs no power to bring the water up to the pump, only the power to overcome the extra friction of the extra suction, that the weight of water being less in the discharge pipe would need less power to discharge it and would result in a shorter steam line.

Yours, etc.,
C. WALTERS.

Leisenring No. 1, Pa., Jan. 25th.

Surveying.

Editor Colliery Engineer:

SIR:—Please insert in your next issue the following question:

A main entry running 1,000′ due East has a furnace at the East end. Through carelessness the entry has been closed; desiring to get back to the furnace we go into the main entry 250′ from the West end and turn to the North 25° and run 250′, then turning 35° still further North, we run 250′ more. Now, I would like to know the degree of bearing from last given point and what the difference of travel would be from mouth of entry, *workings are level.*

Yours, etc.,
MINER.

Elk Garden, W. Va., Jan. 26th.

Miscellaneous Questions.

Editor Colliery Engineer:

SIR:—Please insert the following questions in the next issue of your journal:

(1.) What is the meaning of the following equation? Please work out fully.

$$\frac{1}{\dfrac{\sqrt{\left(\frac{1}{a}\right)^2 \times s}}{a}}$$

(2.) An inlet of a mine, 4,000′ long, with a return of the same length, shows a water-gauge of 0·5 of an inch at the entrance, what would be the pressure 2,000′ farther in? Please give the rule to find the pressure at any given distance.

(3.) What would be the limit in distance of discharge of a siphon dipping $\frac{1}{4}$ of an inch per yard, without considering friction? State fully and give rule for any angle of dip.

(4.) The main entry of a mine divides into two entries, each of which extends to the surface, if the pressure is four pounds per square foot in the single drift, what is the pressure in the two drifts? State fully.

Yours, etc.,
ALBERTO.

Wall, All'y. Co., Pa., Feb. 8th.

Ventilation.

Editor Colliery Engineer:

SIR:—I notice in the January issue an answer by "J. S. K.," of Canon City, Colo., to question (1) asked by "J. M.," of Morrisdale Mines, Pa., in which he states that the quantity of air is found by proportion, thus—

$$\sqrt{80} : \sqrt{160} :: 40{,}000 : x, \text{ or } 56{,}445\tfrac{1}{4}'.$$

This answer in my mind cannot be correct. While it is theoretically true that the quantity of air varies as the square root of the pressure; still I think there is a manifest difference between the amount of air that would be obtained from a fan increased to twice the speed, and that which would be obtained from double the pressure.

A fan making 80 revolutions per minute, and producing 40,000 cu. ft. of air, if the speed is increased to 160 revolutions per minute, will produce 80,000 cu. ft. of air, but, of course, would take eight times the power to double the speed. Hence I think the quantity would be found to vary directly as the speed of the fan, which in this case would be 80,000 cu. ft.

Yours, etc.,
PETER JEFFREY.

Centerville, Ill., Jan. 25th.

Mechanics.

Editor Colliery Engineer:

SIR:—I submit the following in reply to Thomas M. Brown, of Pinckneyville, Ill.:

If the pressure of an engine is 44 lbs. per sq. in., diameter of cylinder 1′ 8″, length 6′, and paddle-wheel make 20 revolutions per minute, what is its power?

In finding the horse power of an engine, we will let

P = pressure.
L = length of stroke.
A = area of cylinder.
N = number of revolutions per minute.

Then, we have

$$\frac{P \times L \times A \times N}{33{,}000} = 50 \cdot 26 \text{ H. P.}$$

Substituting their values we have

$$\frac{44 \times 6 \times 20'' \times 20 \times \cdot 7854 \times 20}{33} = 50 \cdot 26 \text{ H. P.}$$

Yours, etc.,
T. K.

Mt. Olive, Ill., Feb. 10th.

Relative Efficiencies of the Force and Exhaust Fans, as Suggested by the Escape of Natural Gas from Broken Mains into the Mines below.

Editor Colliery Engineer:

SIR:—I have been considerably interested in reading the review of the mining report of Mr. Henry Louttit, Inspector for the First Bituminous District, given in your January issue. Mr. Louttit refers to the laying of gas pipes or mains by the natural gas companies over certain mines in his district and speaks of the danger to the mine, arising from breaks in the pipes, and the gas finding its way into the mine below. The subsidence of the surface, incident to extraction of coal, renders a break in the gas mains liable at any time. The same cause also opens a crevice by the fracture of the overlying strata that permits of direct communication between the mine and the surface.

His views, as expressed in his report, will find very general endorsement, in regard to the possibility of the natural gas from the broken main finding its way into the mine below. But a better reason can be given than the one he suggests, viz., the increased weight of the gas due to the pressure in the main. He reasons that a cubic foot of air at a temperature of 32° and a barometric pressure of 30 inches, weighs ·080977 lbs., giving a pressure of 14·72 pounds per square inch, due to weight of the atmosphere. Also, under the same conditions, a cubic foot of natural gas will weigh ·04421 pounds. But under the pressure of 60 pounds per square inch or the pipe pressure, he figures the gas will weigh ·1768 lbs. per cubic foot. This is true. He continues: "This weight is for the gas at the moment of exit from the pipes, and this will be maintained for quite a distance after leaving them owing to the great velocity with which the gas travels."

It is quite evident this last assumption, that the weight of the gas is the same for even a second of time after leaving the pipe is wrong; because such a condition could only exist when the covering of clay and earth over-laying the pipes is practicably air-tight. And again assuming the pipes to be laid at a depth of four feet below the surface, this clay and earth covering would have to weigh 2160 pounds, or more than a ton, per cubic foot to hold the pressure of 60 pounds per square inch.

Mr. Louttit means to say that the velocity of the gas is great at the pressure of the pipes. But it could not be greater than the tension of the gas under the same pressure. It is in point of fact equal to it, for it is the tension of the gas which produces such velocity, or which measures it when produced. The instant the gas issues from the broken pipe the tension and the velocity react against each other equally, and this takes place practically at the opening of the pipe. The gas under 60 pounds pressure has been compressed so that its atomic particles are practically ¼ as far apart as they were under the ordinary atmospheric pressure. When the pipe pressure is relieved, these particles spring back to their original relative, position, and their velocity in so doing is equal to the velocity of the escaping gas; because, they react against each other. But the space through which each particle can move is infinitesimally small, and hence the gas has assumed its original volume and weight practically at the opening of the pipe.

Nevertheless this does not destroy the tendency of the gas downward through the crevice and into the mine in particular cases, viz., where the "vacuum" system of ventilating is being used in the mine. If, on the other hand, the "plenum" system is used, the gas will be forced upward and out through the escape pipes he mentions as connected with the trench.

This brings us to a discussion which I have long wanted to see brought up, viz.: The relative merits of the force and exhaust fans. The former is the representative of the "plenum" system of ventilation and the latter represents the so-called "vacuum" system. Formerly the expression of opinion was almost wholly in favor of an exhaust fan as compared with the force fan, no adequate reasonable such choice being given. An old miner once explained his preference for the exhaust method by laying a piece of hemp rope on the ground and taking it by one end said: "Boys, I can pull that rope all right, but I cannot push it." The arguments seem to be principally in favor of the force fan as far as our experience teaches us. But perhaps some of the readers of THE COLLIERY ENGINEER can enlighten us as to the merits of the exhaust fan. If so, we shall be glad to hear from them.

Let us compare the two methods by supposing them to be applied successively to the ventilation of the same mine, under like conditions of temperature and barometric pressure.

Let Fig. 1 represent the "plenum" system or ventilation by a force fan; and Fig. 2 the "vacuum" system or ventilation of same mine by an exhaust fan. Let

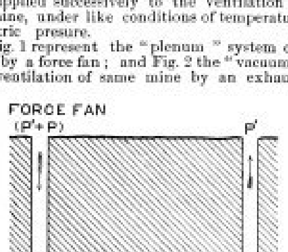


FIG. 1.

Actual pressure $= (P^1 + P)$.
Effective pressure $= (P^1 + P) - P^1 = P$.

p = unit of ventilating pressure.
p^1 = like unit of atmosphere pressure.

It is evident that in Fig. 1 the actual unit of pressure in the down-cast must be $(p^1 + p)$, while the actual unit of pressure in the up-cast is p^1 due to the atmosphere. And the difference of these two pressures or p will be the unit of ventilating pressure. Now the total resistance of the mine $K S V^2$ or $\frac{K S Q^2}{a^2}$ is the same in both cases, the quantity Q being the same. Hence the ventilating pressure $P = p\,a$, necessary to overcome the resistance, must be the same in both systems; and the unit of ventilating pressure p is the same in each case. By referring to Fig. 2 we see the unit of pressure at the down-cast is p^1 or the unit of atmospheric pressure. Hence since the unit of ventilating pressure p is the difference between the units of actual pressure at the two shafts, the unit of actual pressure at the up-cast

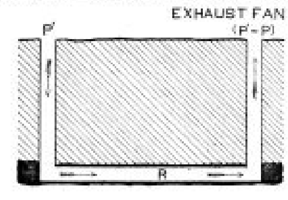

FIG. 2.

Actual pressure $= P^1$.
Effective pressure $= P^1 - (P^1 - P) = P$.

must be $p^1 - p$. That is to say, an exhaust fan of like efficiency as a force fan must be capable of reducing the atmospheric pressure in a shaft as much as the force fan increases it. The expression $(p^1 + p)$ denotes the efficiency of the force fan; while $(p^1 - p)$ denotes the same for the exhaust fan. The first of these expressions is a positive value and shows the efficiency of the fan to be limited only by the power of the engine and the strength of the fan. The expression $(p^1 - p)$ becomes zero when $p = p^1$. Hence the power or efficiency of the exhaust fan can never exceed the atmospheric pressure. This limit however to the efficiency of the exhaust fan is so high as to meet all of the demands made upon it for mining purposes, especially as the velocity of the ventilating current is necessarily limited.

But there is a very important advantage that the force fan has over the other, viz., the maintaining of a higher actual pressure, in distinction from the effective pressure of the pit. The effective pressure is the surplus or ventilating pressure p, and is the same in both systems of ventilation. The actual pressure per square foot, at any point in the mine is, in either system, equal to the resistance still ahead of the current, divided by the sectional area of the air-way, plus the actual pressure per square foot in the up-cast shaft. In the plenum system, the actual pressure per square foot in the pit is always greater than the pressure of the atmosphere per square foot. The practical effect of this is to convert every crevice or fissure, reaching to the surface, into an outlet for the air of the mine, driving out whatever gas is present in such fissure. Also, to drive back the gases which would otherwise issue from old works, by establishing a small leakage of air through such old works to find vent in the open air. In the vacuum system, on the other hand, the actual pressure per square foot in the pit is always less than the outside pressure, for the same unit of surface, and hence the above beneficial results are reversed; and every crevice and fissure pours its gas into the pit. If such fissure communicates with the atmosphere, the outside air will be drawn or pressed into the mine through it. Every crevice or fissure becomes an inlet to the mine when the exhaust fan is used, but an outlet when force fan is employed.

This we would suggest is the case where the gas from broken mains finds entrance into a mine. These gases would not enter were the force fan used. If the experiment mentioned by Mr. Louttit, which is a good one, should be applied to a mine ventilated by a force fan, we venture the assertion that the gas would not have been found to have entered the pipe at all.

Respectfully
J. T. BEARD.

Ottumwa, Ia., Jan. 23d.

TRANSMISSION OF POWER BY ELECTRICITY.

How It Is Done at the Edison Works, at Schenectady, N. Y.

The transmission of power in mills by means of costly belting, pulleys, and shafting, and, in hundreds of cases, by steam pipes radiating from a boiler house to scattered auxiliary engines, has long been considered a costly and more or less unsatisfactory method. This consideration is becoming stronger and more widespread as the adaptation of electricity for the transmission of power progresses towards further development and becomes better known. Mill owners, iron masters, spinners, carpet weavers, and others engaged in manufacturing, who are now obliged to depend upon engines, with their accompanying evils of loss of power, dust, oil, strong smells, dangers from fire, etc., are asking themselves if it is not possible to adopt some other method of power generation and transmission which will do away with the various disadvantages inseparably connected with this system. Various minor attempts at the utilization of electricity to operate mill and mine machinery at a distance, have been made within the past few months, but no experiment on a really grand and extensive scale has been undertaken until quite recently. The Edison General Electric Company seems to have the honor of being the first to solve this problem in a comprehensive manner. The transmission of power from one central power house, containing all the boilers and engines, to the forty or more different buildings which go to make up the Schenectady works of the Edison Company, has attracted attention from all sides. A New York publication, *Power*, chiefly devoted to mechanical interests, considers the matter of so great importance, that, in its February issue, it gives a full and graphic description of the manner in which the elimination of the various defects, mentioned above, is effected.

The power house, is situated almost in the middle of a piece of land twelve acres in extent, and is surrounded on all sides by the different buildings to which it supplies the necessary power. This house contains a battery of boilers of over 2,000 H. P. capacity, the engines necessary to drive the electric generators and the generators themselves. Radiating in all directions run the conductors through special Edison underground tubes to the different buildings where they are connected to Edison motors, which in turn are connected by belts to the shafting serving to operate the machinery. By the adoption of this method, the general aspect of the interior of the buildings is entirely changed. Formerly, there stood in a corner of each building a small independent engine connected by steam piping to the boiler house, giving off its superfluous steam, smelling of lubricating oil and raising the temperature, occasionally, to an unbearable degree. Now, in the place of the engine, and occupying, perhaps, less than a quarter of the space, is a small motor, a switchboard, and a regulator. One throw of a small switch lever, the motor is running noiselessly, and the whole machinery in the building is in motion. There is no trouble, no engine on center, no steam, no smell, and no dirt. The attention required by the motor is very slight, and one of the workmen looks after it without allowing it to interfere with his ordinary occupation to any appreciable degree. The machinery in the forty odd buildings, operated by the motors, drawing their motive force, electricity, from the central power house, gives employment to over 3,500 men. Electricity is also conveyed along the wires to the different testing rooms where all kinds of electrical power apparatus is continually under delicate test. In addition, the two largest machine shops, properly so called, where the big Edison dynamos and their smaller brothers are assembled, and the foundry, are each equipped with traveling cranes, which are operated exclusively by means of electrical motors. These are so constructed that they respond immediately to the slightest desire of the motor man, and are capable of raising and transferring immense weights with ease and rapidity. Here also are to be found the huge shears for cutting iron, and the large and small trip-hammers, all owing their working ability to electricity generated at a point many hundreds of yards distant.

In addition, *Power*, gives the following facts in figures: The power plant comprises an Armington & Sims 10 x 12 engine of 150 H. P., driving on 100 Kilowatt Railroad Generator and two 100 Kilowatt Standard Generator, and another Armington & Sims engine of same proportions, in reserve, coupled to one 50 Kilowatt and one 100 Kilowatt Generator. A small engine of same make of 25 H. P. drives three 8·5 Kilowatt generators. There are also two 300 H. P. Edison Triple Automatic Engines, each driving two of the new Edison 100 Kilowatt Multipolar Dynamos, and a 150 H. P. Triple Automatic engine driving two 60 Kilowatt Generators of former standard Edison type. The boiler battery consists of three boilers of 500 H. P. each, and three of 250 H. P. each, making a total of 2,250; this will eventually be raised to 3,000 H. P., when the three additional 250 H. P. boilers are put up. The present generator or dynamo capacity is about 1,000 Kilowatts. This will be increased to 1,400 Kilowatts as soon as possible and the normal capacity of the power station will then be 1,900 H. P. The normal output is about 950 H. P., at the present moment, but this is increasing as the new shops go up. The present floor area of the Schenectady Works is 11·84 acres. Current is distributed to 43 motors of standard Edison type, which would represent a capacity of 1,324 Kilowatts if run to their full capacity. About 20,000 feet of single conductor wire is used to convey the power from the central house to the motors and this does not include the wiring of the buildings or the conductors laid in Edison underground tubes. The voltage of the motor circuit is 250 volts, the lights running on 125 volt circuits. The loss of power in transmission is small when compared with the enormous loss when steam was conveyed to the small independent engines in the scattered buildings.

Thus it will be seen from the foregoing that from the points of view of both economy and expediency the days of the universal use of steam alone in power transmission, are numbered. The impetus has been given to a new departure, and the progressive Nineteenth Century ideas will effect the rest.

PERSONALS.

MR. JOHN WEAR, Ex-Superintendent of the Coleraine colliery of W. T. Carter & Co., died at his home at Beaver Meadow, Pa., on the 29th inst. Mr. Wear was well and favorably known in the Schuylkill region, where he had resided for a long time. The Hazleton *Sentinel* recently published a sketch of his life.

MR. MORGAN D. ROSSER, who has been superintendent of the four collieries of the Kingston Coal Co. for the past twenty-five years has resigned.

MR. E. B. LEISENRING, the well-known coal operator, and one of the most prominent citizens of Mauch Chunk, Pa., was married to Miss Annie May Wickham, of New York, on the 16th instant.

Mr. W. L. Bellis of Cleveland, Ohio, writes us that his patent mine collar is rapidly winning its way into still greater popularity, and all mines that once use them become regular customers.

MINING THIN COAL SEAMS IN MISSOURI AND KANSAS.

BY ARTHUR WINSLOW, STATE GEOLOGIST, AND LEO GLUCK, ASSISTANT, MISSOURI GEOLOGICAL SURVEY.

[From a Preliminary Report of the Coal Deposits of Missouri.]

The fact of the prevalence of thin coal beds in some parts of the State has already been referred to in the preceding chapter on the coal industry of the State. Some of the reasons why such beds can be worked with profit were there given. It is here proposed to describe the processes by which these beds are mined, in order that their entire availability may be appreciated and understood.

The data from which the following article is prepared are derived chiefly from a study of the mines in Lafayette County, Missouri, where the coal bed is about 20 inches thick, and from an inspection of such at Leavenworth, where the coal is 22 inches thick, and at Osage City, Kansas, where it is only 14 inches thick; these three localities being in the districts in which such thin beds are most extensively operated.

The general system of mining adopted is the Longwall method. The prominent recommendation of this method is that it admits of all the coal in the mine being excavated, none being lost in pillars, as in the pillar and room method. Hence the amount of coal taken out in the former case, from any given area is greater than in the latter case.

In the past the belief was general that a tough and somewhat flexible roof was an essential condition for the successful use of the Longwall method. The conditions in Missouri and adjoining States necessitated, however, a removal of this restriction and, as mining progressed, a system of Longwall working has developed by which the coal is taken out from under comparatively weak and unstable roofs. We hence recognize a division of the process of mining these thin beds into the following two parts:

First, where the roof is strong and flexible.

Second, where the roof is comparatively weak and brittle.

The former condition is, of course, the preferable one and, under the latter conditions, work cannot be prosecuted when the roof is extremely soft and weak, and it is always more expensive and somewhat more dangerous than with the first. An essential condition, with either method, is that there be enough material available, either from the roof or floor, to supply the packing necessary for partially supporting the roof. This will be better understood after the following description of the methods of work is read.

The ideal location in these flat beds, where the question of drainage is not the preponderating one, and when the system of mining alone is considered, is at the center of the property, or, more properly, in the center of the coal area.

METHOD OF MINING WITH A STRONG AND FLEXIBLE ROOF.

With the most approved practice, when the roof is strong and flexible, the following is the general line of procedure when the mine is operated by a shaft:

From the bottom of the shaft four entries are driven in the coal at right angles to each other for a distance of from 20 to 50 feet, this distance depending on the character and strength of the roof, the depth of the coal beneath the surface, upon the nature of the underlying clay and also upon the anticipated period of operation of the shaft. From the ends of these rudimentary entries cross-cuts are then driven connecting the former with each other, as is illustrated in Fig. 1. From the exterior sides of these cross-cuts the coal is next mined radially from the shaft, the main entries advancing with the face and being kept open by gob walls and packing. This process continues until the face has advanced some 800 feet, and until the distance between the ends of each two adjacent entries is about 1200 feet. When this stage is reached the face is still pushed forward in the same direction as before, but instead of one entry being open and left packed, two are now left, which radiate from the main entry, one on the right-hand side, one on the left-hand side, each at an angle of 45° with the original direction of this main-entry. In the angle between these two new entries a triangular gob wall is built as a permanent pillar, and beyond it the mining of the coal continues as before. When this has proceeded to such a distance that the haul along the face of the coal to the entries again becomes excessive, bifurcation of the entries is again resorted to, although the angle at which the new entries separate from the original direction will be different from what it was in the first case.

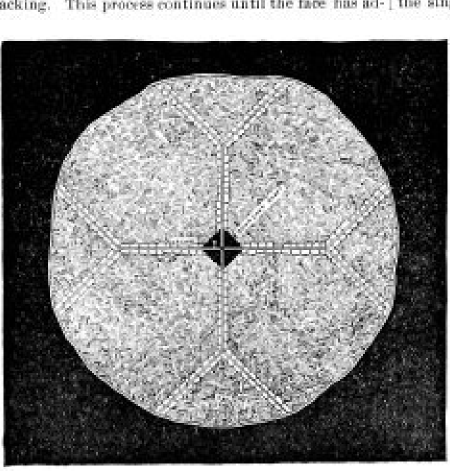

FIG. 1.

Plan of mine operated by Longwall method in strong and flexible roof.

The process continues until the limits of the property are reached, unless the coal be at such a shallow depth that it is more economical to sink a new shaft than to have a very long underground haul.

In illustration of the general process of mining above directed the preceding outline sketch of the map of a mine operated by this method is presented in Fig. 1. The position of the shaft and of the adjacent pillars will be readily recognized, the packing of gob is indicated by the irregular shading, while the face of the coal is plainly shown by the black band surrounding the whole.

METHOD OF MINING WITH A WEAK AND BRITTLE ROOF.

When the roof is comparatively weak, and brittle, a method of mining is pursued which differs from the last described in that less space is left between the advancing face and the packing which follows it. Thus, while in the former case, a track is laid along the face between the entries, over which the coal is pushed in boxes, in the latter case no track is laid along the face, but the coal is removed directly along numerous subordinate entries. By this means much less open space need be left at any one time between the packing and the face, with consequent less strain upon the roof.

The general mode of proceeding is as follows: From the foot of the shaft entries are driven in opposite directions for a short distance in the coal. As soon as a sufficient length of face is exposed for mining operations to proceed, the coal is attacked on both sides of the entry along the whole length. As the face advances the waste material or gob is thrown behind and, at the same time, ways are left with packed walls on both sides at intervals of about 40 feet. With the best practice these passage-ways are run at right angles to the main entry. Between two passage-ways, along the main entry, walls of packing are carefully built. The interval between two such is known as a room, and is generally operated by one miner.

The general plan of thus starting such work is shown in Fig. 2.

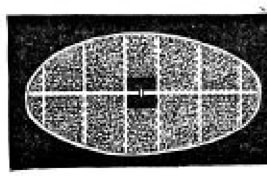

FIG. 2.

At a distance from the shaft of about 100 feet cross-entries parallel with the room-ways, are started, on each side of the main entry, which are kept open by packed walls continuously to the limits of the workings.

Between these cross-entries the rooms are continued in a direction at right angles to the main entry, while, beyond these cross-entries, rooms are now started parallel to the main entry. Each room is made about 200 feet long and beyond this cross-entries are opened from which new rooms are started. This method is more difficult to describe than the last. A study, however, of Fig. 3 will make the method of work plain. The double broken lines there shown are entries, whereas the single solid lines are room-ways. Between these are the packing and gob. The heavy black band around the margin is the face of the coal. The object in having the various entries and in not running the rooms to an indefinite length, is manifestly to limit the distance which the miner has to push his boxes of coal, and to gather the various boxes into entries at frequent intervals.

The two methods of work above outlined are both with shafts. With drift mines the method of working is the same, only the length of face subtends a smaller angle than with the shaft mining.

DETAILS OF LONGWALL MINING.

Having now given a description of the general principles of mining in these thin coal beds, we will proceed to a discussion of the details.

Methods of driving entries.—The method of entry-driving in these coal beds, varies with local conditions.

As the coal bed itself is not sufficiently thick for a traveling way to be confined to it, it is generally necessary to cut down the roof, or to take up the floor in order to acquire the requisite height. The section of such an entry is illustrated in Fig. 4. In the larger mines a height of about 6 feet is usually desired in the main-entries. In the mines at Osage City, however, the entry is cut only 4 feet high and 4 feet wide, but here the roof is a soft shale and generally falls down so that a height of 6 to 8 feet prevails. The entry is driven narrow here so as to prevent heavy roof falls. In the Leavenworth Mines the dimensions of the entry are 5 feet wide at the base, 4 feet at the top, and 6 feet high. In Lafayette County the height of the entry is about 5 feet and the width varies up to 12 feet with the double track entry; the roof here is self-supporting and there are not the same restrictions to the width of the entry that prevail in mines with weaker roofs. In minor entries and room-ways, and also in very small mines where mules are not used, very little roof or bottom is taken out and the height in many cases is only about 3 or 4 feet.

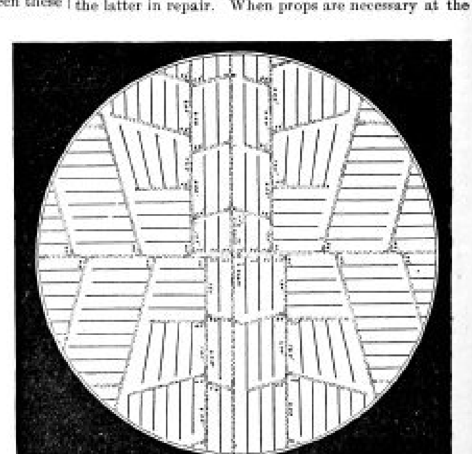

FIG. 3.

Entry driving in the solid coal is only done at the beginning of the work, through the pillar at the foot of the shaft. Beyond this the entry work consists in packing the walls on each side, brushing down the roof or taking up the floor and laying the track. The method of doing this and the attendant cost vary with different conditions. In the vicinity of Lexington the entry is driven through the pillar by first undercutting the coal to a distance of 18 or 24 inches and then shearing the coal on each side of the entry to a corresponding depth. The rib of coal thus left is then wedged down and removed. The coal bed here is less than 2 feet thick and, between it and the overlying limestone roof rock, there are only a few inches of shale. Hence, in order to acquire the requisite height for hauling in the entries, the clay underlying the coal is lifted to a depth of 2½ feet. In places, where there is more shale between the cap rock and the coal, less of the underlying clay is taken up, and the roof shale is brushed down. Elsewhere, as in the Leavenworth Mines, where there is no roof rock, but a large body of shale immediately overlying the coal, the requisite height of entry is obtained entirely by brushing the roof. Under conditions such as sometimes obtain near Corder, in Lafayette County, where the overlying shale and the underlying clay are both thin, the roof rock is shot down in part. This lifting of the bottom clay, or brushing and shooting of the roof is necessary both in the entry beyond the solid pillar as well as in the latter.

The cost of thus driving an entry varies with the different conditions. In the vicinity of Lexington the removal of the coal in the entry through the pillar costs about $5.00 a running yard. The lifting of the tough, hard bottom clay to a depth of 3 feet in entries cost about $2.50 per running yard. In the vicinities of Corder and Higginsville, where the roof rock is shot down to a height of about 3 feet, the cost is about $2.00 a running yard.

At Leavenworth and about Osage City, where fissile shale overlies the coal, $1.25 a yard is paid for brushing down the roof, in the main entries, to a height of about 4 feet above the coal. In the short room-ways, in these mines, the miner brushes down the roof to a height sufficient for man haulage, without extra pay. Track-laying is done by the companies in the main-entries; and such props as are necessary there are also furnished by the company. In the room ways the miner lays the temporary track there used, and the company furnishes the necessary material.

Method of Mining Coal.—The method of mining the coal is essentially the same in both of the systems previously defined. The coal is undercut along the whole face, to a depth of about 18 or 24 inches, and is wedged down, or falls from the weight of the superincumbent strata. These general conditions are illustrated in Fig. 5. The practice is for a certain length of face to be assigned to each miner and he is paid at a fixed rate for the amount of coal which he gets out. The under-cutting is done, in almost all cases, by hand, no machine cutter having been successfully used in such mining in the districts examined.

In addition to the work of undercutting and wedging the miner has, further, to load the coal and sometimes to push it to the entries; to pack the gob, to keep his room-way open, and to lay the track in these room-ways, and to move it along as the face advance. He, further furnishes his lamp oil and all tools, and keeps the latter in repair. When props are necessary at the face he puts these in place, but they are furnished him by the company ready for setting. The undercutting is generally done in the clay under the coal and is about 4 inches high at the face, tapering towards the end. Where the underlying material is excessively hard, however, or where there is little or no clay the cutting is done directly in the lower bench of coal. This is, of course, objectionable in that it causes waste of coal. The length of face worked by one miner varies from 20 to 60 feet, and the length of cut per shift varies 10 to 40 feet, according to the character of the underlying material, the thickness of the coal, and other minor conditions. A cut of about 20 feet is perhaps a fair average. With the strong roof, where a track is layed along the face, the distance between the face of the coal and the gob packing is generally about seven feet, and this must be kept clear by the miner.

With the weak roof, where no track is layed along

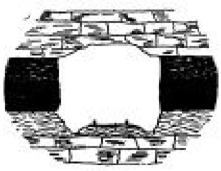

FIG. 4.

the face, the space is generally not more than three feet. In Lafayette Co., and in the Leavenworth Mines, the miner is paid at the rate of about 4c. per bushel ($1.00 per net ton) for the clean coal which he mines. In the Osage district about a cent more per bushel is paid in consideration of the thinness of the bed and the consequent increased difficulty of mining.

Methods of building pillars and packing gob. The method of supporting the roof is different in the two systems described in the preceding pages. Where the roof is a strong one a heavy and well packed wall is carried along by the miner on each side of the entries. Between these, continuous pillars, less carefully packed, are carried along at right angles to the face, as the work advances. These pillars are built of the heavier and larger blocks of waste material, and in between them the smaller and loose material is shoveled.

The plan of work above described is well illustrated in Fig. 6.

The distance between each pillar is generally about 6 feet, the wall itself is usually about two feet thick and it is tightly wedged with the roof at the top. The miner who works adjacent to the entry builds the entry wall, generally without extra pay. The difference between this wall and the others is that it is made of the larger blocks, is more carefully, packed and is built with a smooth face towards the entry. The proximity of the miner to the road head is thought to be a compensating consideration for the extra work of building this wall; in some cases, however, a small extra allowance of pay is made for this work.

In mines with weak roofs pillars are carried only along the entries and in the room-ways between these, props are placed in rows running vertically to the face. In the Osage district, of Kansas, each prop in such a roof is 18 in. apart, and each row is 2½ to 3 feet from the adjoining one. As the work proceeds the entry walls are built of the larger material and the loose material is thrown in around these rows of props. In Fig. 7 this plan of work is illustrated.

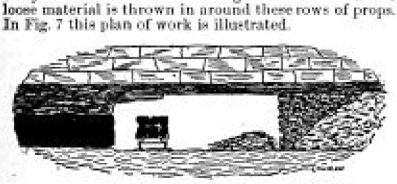

FIG. 5.

Cross section illustrating the method of mining coal.

The method of hauling. In the larger mines hauling in the entries is generally done with mules. They haul the coal in trips of several cars, the number being dependent upon the grades encountered in the entries. In some large mines, where the grades are very slight, or the coal dips towards the outlet, the cars are run out singly by the miner, and this is generally the case in small mines. The capacity of the cars is generally about one-half a ton or less, they being small and low on account of the limited working space. The track in the entries is generally a light T-rail, spiked to wooden ties. Where the track runs along the face, the rails are the same, but they are tied together by iron bars. As the face advances the whole track is moved forward by the miners. This track between two entries is not connected at the middle, but has loose ends. As it advances with the face, the distances between the diverging entries necessarily increases, and to allow for this additional lengths of track are added from time to time. The entry track and face track are connected by a flat iron plate on which the cars can be readily transferred from the one to the other. In some mines, where the entry is wide, a switch is laid at each road-head, where empty cars or boxes are stored and full cars can pass each other. Further, in mines with soft roofs, where the cars come from a large number of different points, turn-outs are provided in the entries, where empty trips coming in can pass the full ones going out. The transfer plate at the road-head is not advanced with each moving of the face track, but, generally, remains in the same place for two or three days, the face track being curved back to meet it. Along the room-ways, in mines with weak roofs, only temporary tracking is laid of wooden strips 1½″ x 3″ in section.

In mines with strong roofs the empty cars are all run in along the face track, to the various places of work, by the "pusher," and are then filled by the miner. After the cars are filled they are removed successively from the face track to the entry track by the "pusher," beginning with the car nearest the entry. As each full car is removed an empty one to replace it is brought in and is temporarily turned up off of the track so as to allow the full ones beyond to pass by, as they are pushed out.

In mines with weak roofs the car is run to the end of each roadway and is then loaded by the miner, who either shoves each block of coal separately to the face of the roadway, or slides it in on small sled-like buggies to such roadways, and there loads it on to the cars.

Methods of ventilating and draining. The system of ventilation in these mines is extremely simple; in fact it is one of the points recommending these methods of Longwall work that, when properly prosecuted, the mines are so easily ventilated.

In some cases the entire fresh air current is carried from the downcast shaft out one of the entries to the face, it is then split to the right and left and carried around the whole face to the end of the opposite entry, along which it returns to the upcast shaft. In other cases the air current is split at the beginning, at the foot of the downcast shaft, and is then carried in opposite directions to the face, where each current is again split to the right and left. These currents then pass along the face around a quadrant of a circle, where two from opposite directions unite and pass back along one entry to the upcast shaft. The entries which are off the line of the main currents are generally cut off from these currents by brattices or doors, and are generally ventilated by the occasional opening of the doors or by the leakages through the brattices. In some cases small side-currents are kept up constantly along side entries which are much used.

The draining of many of the mines, in which this system of work is carried on, is a very simple matter, inasmuch as little or no water accumulates in them. Where water exists it is drained towards a sump located at a low point, and is thence pumped to the surface. For drawing the water to these sumps, small ditches or drains are dug along the entries, and, in some cases, small drain tile is used. A large amount of water in connection with such mining is an especially

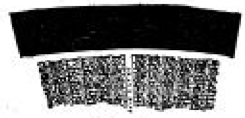

FIG. 6.

Plan illustrating pillar work and gob packing with a strong roof.

serious objection, inas-much as it tends to weaken the roof, to soften the underlying clay, and to produce excessive settling and squeezing throughout the mine.

Concluding remarks. The fact that, with the methods of mining which have been described, all of the coal can be removed from the ground, has already been referred to as the chief recommendation. The ease of ventilation has also been referred to and the simplicity of the plan of work further recommends it to use. It is desirable, however, in order that the best results may be reached, that the work be prosecuted regularly and uniformly, so that the face advance equally in all directions and preserve approximately the shape of a circle. If this is not done the coal will not split off freely at some points along the face, while elsewhere it will split off before a sufficiently deep undercut has been made. Further, unequal settling resulting from this irregular work will produce inequalities in the floor and roof, which become obstructions in hauling the coal along the face. A greater fracturing of the roof is also liable to result, accompanied by all of the attendant difficulties. All of such Longwall mining, however, causes a greater or less fracturing of the roof. On this account, it is not generally practicable to carry it on when the mining is near the surface, and when the surface is a wet one. An excessive amount of water is admitted to the mine in such cases. It can also not be practiced at a shallow depth when the overlying property is of great value, for the reason that the effects of the settling may be transmitted to the surface and cause serious damage.

A number of suggestions might be made in the nature of improvements upon the methods of mining these beds, both in this state and in Kansas. Among these are the introduction of rope and power haulage, and the use of machine cutters. In the direction of rope haulage nothing has yet been done. The reasons generally given, are that the properties worked are too small and the amount of coal available too little to

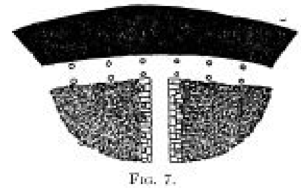

FIG. 7.

Plan illustrating pillar work and gob packing with a weak roof.

warrant the introduction of an expensive plant. Further, the shallow depths at which the coal is found in many places, make it cheaper to have frequent openings from the surface than to haul the coal far underground, by power or otherwise. In the future, as the industry develops, and as the demand becomes greater and more regular, some of the conditions will change, and improvements in these and other directions will probably be made which will lessen the cost of production. At the Mendota Mine in the northern part of the state, where the coal bed is nearly 3 feet thick, rope haulage is already successfully used, but here both the pillar and room as well as the Longwall method are practiced.

Machine cutters have been experimented with to a limited extent in Lafayette County, but not with success. The Harrison machine was used. The chief reasons given for the failure of the experiment are the lack of competent and willing labor, and the excessive amount of refuse which the cutters made. The coal bed here was only about 18 in. thick, however, and the cutter took out nearly a foot of clay. This together with the overlying shale which came down with the coal was more than could be disposed of in the mine, and hence had to be hauled to the surface at excessive cost. At the same Mendota Mine in the northern part of the state, in which rope haulage is practiced, machine cutters have also been introduced and are successfully used. We do not feel, at present, at all convinced that with some form of machine especially adapted to these thin beds, machine cutting may not be in near future successfully prosecuted.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED [illegible], INCORPORATED [illegible].

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
ALEX. DICK, MINING ENGINEER, ASSISTANT EDITOR.
THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed

IT IS NECESSARY AND WILL BE BENEFICIAL.

Since the close of the war the Anthracite coal trade has been in an anomalous condition. The production has increased from ten million to forty million tons, but for nearly the whole period the mines have been in condition to produce more coal than could be profitably marketed, and prices have fallen from $10 per ton, the retail price in Philadelphia in 1866, to $5 per ton, the retail price at present. The wages paid for mining have been reduced one-half and because it is necessary to restrict production to obtain even $5.00 per ton at retail in Philadelphia, the collieries are only worked from three-fourths to one-half time. All classes interested in the production of coal are suffering because of this unnatural condition. The capital invested in the collieries is not profitable; the mine officers are not paid as well for their services as the same class in other branches of industry not requiring as great technical knowledge and executive ability, and the Anthracite miner earns less than other workmen who perform the same amount of work and run the same risk of injury or death from accident.

The causes of this peculiar condition are, First: Too much capital has been invested in the production and transportation of coal. More railroads than can be operated profitably have been built to distribute the product of the mines and more mines than are necessary have been opened to supply these roads with tonnage. Second: With the object of cheapening the cost of production in order to realize profits on the low prices for coal which have prevailed for many years, the operators have largely increased their output. Many new collieries have been opened and the capacity of those already opened has been largely increased. The result is that the capacity to produce is far ahead of the demand for consumption, and for years it has been impossible to obtain prices for coal that will pay the operators reasonable interest upon their investments and the miners fair wages for their labor.

An association was first formed to prevent the ruinous effects of over-production and to secure a remunerative price for coal in 1872. This association was dissolved the first of September, 1876, because one of the companies was shipping more than its proportion. The history of the trade in 1877 and 1879 (when unrestricted competition prevailed) shows how far in advance of the requirements for consumption the development of colliery property is maintained. It also proved that without restriction of production and regulation of prices both mining and transportation interest must be ruined. At the New York auction sale of the D. L. & W. Co. in November, 1877, prices fell to the lowest point as yet reached. The average price obtained, that year by the P. & R. C. & I. Co., for lump coal at Philadelphia was $2.40 per ton. In 1878 there was a new association formed which expired by limitation at the end of the year and 1879 was another season of unlimited production. The losses suffered that year by the coal producing interests have been estimated at thirty million dollars. Coal was sold on board vessels at Philadelphia at $2.00 per ton. At the September auction sale in New York the price realized for broken coal was only $1.97½ per ton. These prices are less than cost in the cars at the mines.

This lesson was a severe one and it has not been necessary to repeat it. Since 1879 the Anthracite interests have acted with sufficient harmony to prevent the ocurrence of another such disastrous experience, but there has been a great deal of friction because of the failure of the parties interested to act in good faith, and it has been found impossible to advance prices to a remunerative point, when there is no penalty for violating the mutual agreement as to the amount of coal to be mined and the price at which it is to be sold.

The pooling of interests by the owners of the Philadelphia & Reading R. R. Co.; the Lehigh Valley R. R. Co., and the New Jersey Central R. R. Co., and the purchase by the capitalists interested in them of a large interest in the D. L. & W. R. R. Co. is a movement to control the Anthracite coal trade and by introducing economies and regulating production to make the business of mining Anthracite coal remunerative. It will be better if the leasing of the Lehigh Valley and New Jersey Central properties by the Reading Company shall not prove unconstitutional since if the three roads can be placed under one management great economies in the administration of the properties can be effected. The more economical the management of these large companies the greater will be their earnings and the more liberal they can afford to be to the individual operators and to the employes of their mining departments, and the less it will be necessary to advance prices to make the business pay. If the leases are declared unconstitutional plans will be devised to accomplish the end aimed at. It is not necessary to discuss what action will be taken should such a contingency arise, but if the owners of the four largest companies interested in the Anthracite coal trade wish to do away with the ruinous competition that has so long ruled they can do so. A saving of 25 cents per ton in the cost of mining, transporting, and marketing the Anthracite coal product of forty million tons (or an advance in prices of that much) will add ten millions of dollars per annum to the earnings of the companies to be divided between the capital invested in transporting and mining the coal and the labor engaged in producing it. The proportion of this which will fall to the operators and to labor will be so considerable as to largely benefit the whole population of the Anthracite coal counties.

That the effect of this agreement by the owners of the coal carrying companies to act together will be to raise the price of Anthracite to exorbitant figures, as is so freely predicted by the New York and other journals, is ridiculous. As we have shown, Anthracite coal has been sold at prices so low that there has been no profit in mining, and both operators and miners have suffered. Hereafter it will not be mined if it cannot be sold at a profit, and the operator and miner will be benefited. Exorbitant prices will not be asked for it. Bituminous coal is plentiful and cheap and if the price of Anthracite is placed too high the public will use soft coal.

The attitude of certain men, high in position in labor organizations, in opposition to this pooling of interests is something we cannot understand. It is certain that the prices obtained for coal will be higher and more regular than in the past, and as the wages of the Schuylkill miners are fixed by a sliding scale regulated by the rise and fall in the price of coal, it is also certain that their earnings will be increased. If the earnings of the Schuylkill miners are greater the wages of those in the Lehigh, Wyoming, and Lackawanna regions will also be better. For twenty-five years every effort of the miners and laborers of the Anthracite coal regions to prevent the many reductions in wages which have been rendered necessary by the decline in the prices of coal, due to over-production, or to secure advances in wages has resulted in defeat, because it has been impossible to get good pay out of an industry which could not afford to pay high wages. In plain language it has been impossible "to milk a dry cow." This movement to control the trade and advance prices is the first encouraging rift in the gloomy outlook for labor in the Anthracite coal regions for many years, and yet we find men, whose occupation it is to advocate measures to secure better pay for the workmen, antagonizing it.

THE COLLIERY ENGINEER SCHOOL OF MINES.

It is only four months since we enrolled our first student in The Colliery Engineer School of Mines, and we have now 275 in our books. The course is meeting with success beyond the most sanguine expectations, and the school has every prospect of becoming one of the largest and most popular institutes for technical education in the United States. Our students reside in every state in the Union, from Pennsylvania in the East, to Washington in the West and Alabama in the South, while Nova Scotia and British Columbia each supply a few. We also number on our roll men in all positions from the mining engineer, mine superintendent, and mine foreman, to the miner.

We believe that few have an adequate idea of the completeness of the Lesson Papers or the thoroughness of the method of instruction. We do not supply the student with a superficial text-book, and leave him to flounder through it alone. We take right hold of each scholar and stick to him until he is proficient, whether it takes weeks or months.

When we first introduced this system of study we made the fee low in order to place it favorably before the public, because as it was something new it was natural some people should doubt the success of the system. Now, however, the continued approval of our students and the rapid progress they are making are sufficient evidence of its worth, and on the 1st of June the fees will be increased to $35 for a complete mining or complete mechanical scholarship, payable in advance, or to $40 if paid by installments. The partial scholarships will be each raised to $20.

We wish to announce to our students that the Instruction Papers on Surveying will soon be ready. The first class for field practice, at Scranton, will start on June 1st, and those who intend taking advantage of it should apply for their Surveying papers, so as to have them studied previous to that date.

ILLINOIS MINING INSTITUTE.

We are pleased to record the inauguration of a State Mining Institute for Illinois. It would be to the advantage of every man interested in mining if similar associations were started in every State in the Union. There is nothing better for the perfecting of a mining engineer's or mine manager's education than periodical meetings for the reading of papers and friendly interchange of views.

The first meeting of the Institute was held at Springfield, Ill., on February 19th, when the following officers were elected: President, J. C. Simpson, of St. Louis; First Vice-President, Richard Ramsay, of Braceville; Second Vice-President, Walter Rutledge, of Alton; Third Vice-President, Hugh Murray, of Sparta; Secretary, J. S. Lord, of Springfield; Treasurer, Thos. R. Stockett, of St. Louis; Executive Council, Wm. Scaife, of Coal City; G. C. Simpson, of Springfield; J. D. Peters, of Murphysboro; Robert Lee, of Cable; R. D. Fletcher, of Streator.

The object of the organization is educational, and as all the members are in positions of responsibility as to life and property the Institute will embrace within its scope all matters relating to safety and economy in mining. The next meeting will probably be held in May.

During the meeting Prof. Joshua Lindahl, the State Geologist, drew attention to a circular he had issued to all the Illinois coal operators regarding a proposed State mining exhibit at the World's Fair. The Illinois Board of Commissioners refused to allocate any money for this purpose. Prof. Lindahl thereupon wrote to every coal operator in the State asking them to send, at their own expense, a specimen of their coal to be exhibited, along with an analysis. The person to do the sampling for the analysis was, however, not to be of the operators, but of Prof. Lindahl's selecting, and we are not surprised to hear that out of eighty operators who troubled to reply to the invitation only five of them showed any inclination to respond. We should say these five happy mortals must have gems of coal seams. The guilelessness of Prof. Lindahl's circular is highly typical of a true student of nature—not human nature.

THE NEW CAMBRIA LIBRARY BUILDING AT JOHNSTOWN, PA.

AMONG the many buildings which were utterly destroyed by the flood of May, 1889, few had been better appreciated than the Library Building which was erected by the Cambria Iron Co. in 1879.

A new building enlarged and improved, has now taken the place of the old erection.

It was an act, unique in the annals of ordinary human nature, that prompted Andrew Carnegie to defray the entire cost of such a restoration.

There are not many people who would, even with the means at their command, write out a check for $55,332 to pay for the re-establishment of an institute to be devoted to the educational advancement of the workmen of a business competitor. This is just what Mr. Carnegie did, however, and is another verification of the fact that his generosity recognizes neither country nor nation, sect nor creed, but is in everything thoroughly cosmopolitan. He is known alike on both sides of the Atlantic, and his fellow countrymen of the kingdom of Fife are as ready to swear by the name of Carnegie as the Moslems are by the beard of the prophet.

One of the features of the inaugural ceremony of February 19 was the speech by Mr. John Fulton, General Manager of the Cambria Iron Co. Mr. Fulton dwelt on the work which had been done in the old building towards the technical education of the young men of Johnstown. The speech was a fine *resumé* of the advantages of such a training and the worth of his advice was evidenced by the fact that of former students many had risen to high positions, one being a State Inspector of Mines, while others were now Mine Superintendents.

EDITORIAL NOTES.

THE State Board of Examiners sat at Springfield Ill., on February 15, and succeeding days, to examine applicants for certificates of competency as mine managers. Fifty-two were successful in passing the examination. Of this number thirty-three are subscribers to THE COLLIERY ENGINEER, and four of these hold scholarships in The Colliery Engineer School of Mines.

PREVIOUS to the Reading Company taking possession of the L. V. R. R., the officials and clerks in the latter corporation's Philadelphia office were furnished with their midday lunches by the company The day after the deal was made, each officer and clerk was notified that from that time forward he would have to buy his lunch himself. One of the clerks, of a poetic turn, thereupon relieved his mind in the following stanzas:

Quickly following the Reading's coup,
They cut off dessert, and then the soup,
The warming broth, the cool ice-cream,
Are things as seen in a fleeting dream;
And now they all will have to go,
(Officials high and Dinkeys low)
Without the nourishing consomme,
For which they now will have to pay;
And missed along with the loved tureen,
Are pies, puddings, baked apples, and cream;
They all must go, their weight to lend,
To help the guaranteed dividend.

Penney. isn't in'it,
Reading made the scoop,
Navi. doesn't give a pin,
And we are in the soup.

The Anthracite Trade.

The past month witnessed the most important combination of Anthracite coal interests ever consummated. The Philadelphia and Reading Railroad became the lessee of the Lehigh Valley Road; and the Port Reading Railroad, under the same management, became the lessee of the Central Railroad of New Jersey. This naturally placed the Lehigh Valley Coal Co., and the Lehigh and Wilkes-Barre Coal Co., also, under the same management. The Delaware, Lackawanna and Western Railroad, at its annual election, admitted to its directorate Messrs. Maxwell and Baker, and it is announced that it will act in complete harmony with the Reading management, and its relations will be closer than they have ever been. This practically put under one management nearly 70% of the entire Anthracite output. The balance is produced by the Delaware and Hudson Canal Co., the coal companies of the Pennsylvania Railroad Co., the Pennsylvania Coal Co., the New York, Ontario and Western R. R. Co., and the New York, Lake Erie and Western R. R., or other operators on the lines of their roads. Of the above, the Delaware and Hudson Canal Co. controls about 10% of the output. What action it would take in the matter has been under speculation for some days, and the recent activity in trade in its stock gives credence to the rumor that it will be brought into close relations with the new combination.

The Reading management will handle the output of the individual collieries on the lines of the Lehigh Valley and Jersey Central roads on the following terms: When coal sells at $4.00 per ton f. o. b. New York, or less, the operator to get 60%, and the railroad 40%. On all over $4.00 and less than $4.50 per ton, the operator to get 40%, and the railroad 60%. All over $4.50 per ton the operator to get 30%, and the railroad 70%. President McLeod, in this arrangement, virtually guarantees a minimum price for stove coal at $4.00 per ton, f. o. b. New York, such price to be based on the average monthly prices of the Wyoming coals of the Lehigh Valley R. R. Co. and Delaware Lackawanna and Western Co. An additional inducement offered the operators, is the establishment of a board of arbitration for the settlement of all possible disputes, and of a system for the inspection of coal. This arrangement of prices can be readily seen in the following table:

Selling Price.	Operator's Share.	Railroad's Share.
$4.00	$2.40	$1.60
4.10	2.44	1.66
4.25	2.50	1.75
4.35	2.54	1.79
4.50	2.60	1.90
4.60	2.63	1.97
4.75	2.67½	2.07½
4.85	2.70½	2.14½
5.00	2.75	2.25

This arrangement is considered a liberal one, and is being accepted by the operators generally.

Coxe Bros. & Co. have secured control of the three mines of Pardee Bros. & Co., at Latimer; of the mines of Pardee, Son & Co., at Mt. Pleasant, and of Calvin Pardee & Co., at Hollywood. The product of these mines will hereafter be shipped over the Reading's line from Bethlehem to Philadelphia, instead of being sent over the Belvidere Division of the Pennsylvania R. R. from Philipsburg to Philadelphia.

There is naturally considerable uncertainty in the trade regarding the future policy of the combination regarding prices, but the arrangement with the individual operators, mentioned above, makes it evident that prices are lower now than they will be when all the new plans are in operation. That the policy will be conservative is evidenced by the fact that at the meeting of the sales-agents on the 26th ult., the March output was fixed at 2,500,000 tons, and there was no change in prices.

The demand for coal is light. Stocks in retailers' hands are also light, but there seems to be no desire to increase them.

The Bituminous Trade.

The Bituminous trade is dull and featureless, and the trade is now considering the character and policy of the Seaboard Steam Coal Association, that seems to be an assured fact. It is believed that this association will be more effective this year, and rate cutting will not be so freely indulged in. It is too early in the season for new contracts to be made, and as old contracts are about filled, the trade is confined to the wants of the smaller buyers.

A rise in the Ohio enabled the Pittsburgh River operators to send nearly 5,000,000 bushels to Cincinnati and Louisville, and the Pittsburgh harbor is comparatively bare of coal. The markets usually supplied with river coal, all have an abundance of coal now. The local demand in Pittsburgh is active. The trade in Chicago is suffering from an over supply, and, as a consequence, prices suffer.

The Coke Trade.

The coke trade is a trifle duller than it was last month, and considerable coke is being stocked in the yards. The car supply is ample, and prices are well maintained at same figures as quoted last month. The future, at this writing, is uncertain, as there is at present a depression in the iron trade, and this always has a corresponding effect on the coke trade.

Anthracite Coal Statistics.

Statement of shipments of Anthracite coal for month of January, 1892, compared with the corresponding period last year. Compiled from the returns furnished by Mine Operators.

	January 1892.	January 1891.	Difference.
Wyoming Region	1,520,927 06	1,684,307 05	Dec. 163,379 19
Lehigh Region	353,347 00	499,421 12	Dec. 146,074 12
Schuylkill Region	935,592 04	955,232 07	Dec. 19,640 03
Total	2,809,866 10	3,138,961 04	Dec. 329,094 14

The stock of coal on hand at tide-water shipping points, January 31, 1892, was 790,932 tons; on December 31, 1891, 637,668 tons; increase 153,264 tons.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since our Last Issue.

The International Mining Co.,	Pueblo, Colo.
The C. O. D. Gold Mining Co.,	Colo. Springs, Colo.
The Lou P. K. Mining Co.,	Denver, Colo.
The Condon Mining and Milling Co.,	Denver, Colo.
The Salmon River Placer Mining Co., Ltd.,	Denver, Colo.
Bessemer Iron Co.,	Duluth, Minn.
The American Turquoise Co.,	Chicago, Ill.
The Snowstorm Consolidated Gold Mining Co.,	Chicago, Ill.
Loretta Gold and Silver Mining Co.,	Milwaukee, Wis.
The Belle Vernon Coal and Coke Co.,	Belle Vernon, Pa.
The Connecticut Free Stone Quarry Co.,	Cromwell, Conn.
The Monserrat Silver Mines Co.,	New York City, N. Y.
Albion Phosphate Mining Co.,	Martinsburg, W. Va.
Dead Medicine Mining Co.,	Spokane, Wash.
New York and Middle Coal Field Railroad and Coal Co.,	Philadelphia, Pa.
East Palestine Coal Co.,	Pittsburgh, Pa.
The Crescent Coal Co.,	Wilkes Barre, Pa.
Hidden Treasure Gold Quartz Mining Co.,	San Francisco, Cal.
Virtue Mining, Milling & Development Co.,	Stockton, Cal.
Antelope Crystal Salt Co.,	Salt Lake Ranch, Cal.
Union Gold Mining Co.,	New Orleans, La.
New Jersey Iron Ore Co.,	New York City, N. Y.
Mississippi Cotton Oil Co.,	Meridian, Miss.
The Union Mining Co.,	Neihart, Montana.
Good Luck Mining Co.,	Helena, Montana.
Consolidated Silver Crown Mining Co.,	Spokane, Wash.
The Washington Consolidated Mining & Milling Co.,	Seattle, Wash.
Bliss Salt and Oil Co.,	Bliss, Wyo. Co., N. Y.
The Buffalo Stone Co.,	Buffalo, N. Y.
The Consolidated Mica Co.,	Hot Springs, S. D.
Pacific Star Coal Co.,	Chicago, Ill.
The San Luis Prospecting & Mining Co.,	San Luis, Colo.
The Gold King Mining Co.,	Colo. Springs, Colo.
The Summit Gulch Mining and Milling Co.,	Denver, Colo.
The Highland Mining & Tunneling Co.,	Aspen, Colo.
The Pueblo-Creede Mining Co.,	Pueblo, Colo.
Campfield Coal and Mining Co.,	Des Moines, Iowa.
The Clarendon Marble Co.,	Rutland, Vt.
Bertha Zinc and Mineral Co.,	Jersey City, N. J.
Jefferson Coal Co.,	Piedmont, W. Va.
Coal Harbor Coal Mining Co.,	San Francisco, Cal.
Lead Placer Mining Co.,	Lead, S. D.
The Lone Rock Marble & Mineral Co.,	Chicago, Ill.
Detroit Iron Co.,	Duluth, Minn.
Tar Springs Asphalt Co.,	Los Angeles, Cal.
The Asbestos Mining and Manufacturing Co.,	Denver, Colo.
The Della S. Consolidated Mining Co.,	Aspen, Colo.
The Bull Mountain Gold Mining Co.,	Colo. Springs, Colo.
The Black Hawk Mining Co.,	Denver, Colo.
The Menlo Park Mining Co.,	Ouray, Colo.
The Eureka Coal and Coke Co.,	Dun's Branch, W. Va.
Huntington Improvement Co.,	Huntington, Ark.
Silver Mountain Mining Co.,	Walla Walla, Wash.
The Moore & Blunton Gas Co.,	Noblesville, Ind.
Shear Oil & Asphalt Co.,	Hueneme, Cal.
San Antonio Oil Co.,	Hueneme, Cal.
Lion Oil and Asphalt Co.,	Hueneme, Cal.
29 Palms Mining and Milling Co.,	Riverside, Cal.
Consolidated Santa Rosa Mining Co.,	Riverside, Cal.
Charleston Iron Co.,	Duluth, Minn.
Phoenix Mining Co.,	Paint Creek, W. Va.
Hope Mining Co.,	Paint Creek, W. Va.
The Silver Basin Mining Co.,	Denver, Colo.
The Cripple Creek Syndicate Mining & Milling Co.,	Denver, Colo.
The Western and Eastern Investment Co.,	Denver, Colo.
El Vadelesta Mining Co.	Jersey City, N. J.
Everett Gold Mining and Milling Co.,	Tacoma, Wash.
Fulton Fire Brick and Mining Co.,	Fulton, Mo.
The Harden Placer Co.,	Colo. Springs, Colo.
The Phillips Land & Gas Co., of Alexandria,	Alexandria, Ind.
Henrietta Coal Mining Co.,	Philadelphia, Pa.
The Globe Powder Co.,	Allegheny, Pa.
Temperance Flat Mining and Milling Co.,	San Francisco, Cal.
The Scotia Mining and Milling Co.,	Colo. Springs, Colo.
The Montezuma County Development Co.,	Cortez, Colo.
The Saturn Mining Co.,	Aspen, Colo.
The Miller Creek Contract Mining Co.,	Denver, Colo.
The Mansfield Lead and Zinc Co.,	Mansfield, Ohio.
Sunset Coal Co.,	Tacoma, Wash.
Compromise Natural Gas Co.,	Windsor, Ind.
The Glen Falls Coal and Coke Co.	Clarksburg, W. Va.
Gold Eagle Mining Co.,	Cerrillos, N. M.
Columbia Building Material Co.,	Alexandria, Va.
Chicago Iron Co.,	Duluth, Minn.
Kanawha Iron Co.,	Duluth, Minn.
Liberty Mining Co.,	Great Falls, Mont.
Vulcan Mining Co.,	Elkhorn, Mont.
The Lost Creek Fire Brick and Silica Co.,	Anaconda, Mont.
Black Swan Coal & Mining Co.,	Des Moines, Iowa.
Rowena Mining Co.,	Keokuk, Iowa.
J. P. Pierce Co.,	Santa Clara, Cal.
The Idaho Mining Co.,	Salina, Kan.
The Bompy's Hook Stone Co.,	Bompy's Hook, near Alpine, Bergen Co., N. J.
Enterprise Mining, Milling and Smelting Co.,	Seattle, Wash.
The Acoparra Mining Co.,	Colo. Springs, Colo.
Big Kanawha Coal Co.,	Chicago, Ill.
The Augusta Gas & Oil Co.,	Augusta, Ill.
Sunset Mining Co.,	New Orleans, La.
Black Hills Mining and Developing Co.,	Hill City, S. D.
Consolidated Quarry Co.,	Alexandria, Va.
Washington Marble Co.,	Alexandria, Va.
Pink Granite Co.,	Alexandria, Va.
United States Contract Co.,	Norfolk, Va.

Orkney Springs Hotel and Improvement Co.,	Alexandria, Va.
The U. S. A. Tunnel Mining and Milling Co.,	Denver, Colo.
The Cleopatra Mining Co.,	Colo. Springs, Colo.
The Omaha and Grant Smelting Co.,	Denver, Colo.
Hardin Baker Gold Mining Co.,	Milwaukee, Wis.
The Robinson Mining Co.,	Baker City, Oregon.
The Lemhi Placer Gold Mining Co.,	Salmon City, Idaho.
Dubuque Ore Concentrating Co.,	Dubuque, Ia.
The John Young Silver Refining Co.,	Chicago, Ill.
Patton Vitrified Brick Co.,	Chicago, Ill.
The Minnesota & New Mexico Reduction Co.,	Gold Hill, Grant Co., New Mexico.
The Creede Prospecting and Mining Co.,	Denver, Colo.
The Mountain Side Mining and Milling Co.,	Great Falls, Mont.
Frisco Mining Co.,	Great Falls, Mont.
Tomasso Hill Mining Co.,	San Francisco, Cal.
Missabe Mountain Iron Co.,	Duluth, Minn.
Centralia Mining and Improvement Co.,	Centralia, Wash.
The Argent Mining Co., of Idaho,	Chicago, Ill.
The Bethlehem Natural Gas, Oil & Mining Co.,	Noblesville, Ind.
Cynthiana Natural Gas, Oil & Water Co.,	Cynthiana, Ind.
The Golden Star Mining Co.,	Chicago, Ill.
The Ohio Land & Coal Co.,	East Palestine, Ohio.
The Weurich Lead & Zinc Co.,	Mansfield, Ohio.
The Magnetic Ore Milling Co.,	New York City, N. Y.
The Rapid River Mining Co.,	Spokane, Wash.
Arctic Placer Mining Co.,	San Francisco, Cal.
Long Creek Co.,	Richmond, Va.
The Maid of Erin Silver Mines, Ltd., London, Eng.,	Leadville, Colo.
The Antlers Mining & Milling Co.,	Colo. Springs, Colo.
The Jessie Gold Mining & Milling Co.,	Breckenridge, Colo.
The National Ore Reduction Co.,	Pueblo, Colo.
Helena Mining Co.,	Great Falls, Mont.
The Silver Pass Mining Co.,	Olden, Tex.
Rowland and Lacy Petroleum and Land Co.,	Los Angeles, Cal.
Farview Natural Gas and Oil Co., Ind., Howard Co., Ind.,	Kokomo, Ind.
Silver Belt Mining Co.,	Albuquerque, N. M.
Manhattan Gold Mining & Milling Co.,	Silver City, N. M.
Odgen Electric Power Co.,	New York City, N. Y.
The Greiner Economical Cupola Co.,	Chicago, Ill.
Porter Creek Consolidated Mining Co.,	Porter, Wash.
Mammoth-Garfield Gold Mining Co.,	San Francisco, Cal.
Bush Gold and Silver Mining Co.,	Marietta, Wis.
Carpenter Bar Gold Mining Co.,	St. Croix Falls, Wis.

The Enterprise Mining and Land Co.,	Colo. Springs, Colo.
The Chief Mining Corporation,	Pueblo, Colo.
Vulcan Iron Co.,	Duluth, Minn.
Dayton Iron Mining Co.,	Duluth, Minn.

STRIPPING ANTHRACITE SEAMS.

Methods of Procedure to Secure Best Results, and Accurate Estimates of Material Removed.

BY H. W. ALTHOUSE,
Asst. Mining Engineer, Consolidated Coal Co., of St. Louis.

Stripping, whether applied to coal measures, ore bodies, or phosphate beds, literally means the removal of the covering, earth, rock, etc., from the material sought after, and often brings to mind the idea of cheap work. This is true in many instances; such as where earth alone overlies the seam, and it can be removed by dredge, figuring as low as six cents a yard. Under certain adverse circumstances where power shovels cannot be used, the cost is double or treble that amount. The latter is the cost of stripping Anthracite, when the topography of the country and nature of the material are such as to prevent the use of power shovels. When the crops of the seams are low in the valley, on the hillside, and on the mountain top, as in the cross section, Fig. 1, they indicate erosion in addition to upheaval. It will be noticed that much of the coal measures have been lost by the former agency, which is the case throughout the entire coal region, more especially prominent in the mountain country where the strata frequently is "turned on end." The wash met with usually, is inconsiderable compared with that found in the lower elevations, where it is so great as not to warrant removing. At times, where the seam conforms to the surface, and has not too much rock overhead, stripping is employed. Generally the crop is sought, which in most places is well defined by benches and ridges, and also by crop falls, shaftings, and borings. The engineering data at hand being so complete, as a rule, to determine the exact location.

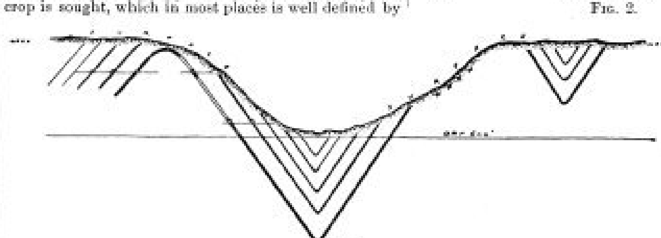

Fig. 1.

The preliminary survey connected with the stripping depends upon the knowledge of the engineer. The question of location is a study; and practice and experience demonstrate the fact that even without classifying the materials removed it would be exceedingly difficult to estimate the amounts removed, unless a system is adopted.

In laying out the confines of the work, the crop being known, a base line, the foundation from which the work is planned, should be located in the field. This base line should be straight if possible, parallel to the strike of the seam, and 100 ft. away from the excavation. Having driven a stake every fifty feet and numbering them from 0, 0 + 50 and so on, call this base, line 0; from it lay off, parallel to it, a line of stakes one hundred feet distant, number as above and mark this, line 1. Then stake off the remaining portion in fifty ft. squares or as judgment dictates. The *lines* run with the crop, those crosswise are called sections as is shown in plan, Fig. 2.

Let all the work be based on one common meridian and datum, agreeing with those of the mine workings,

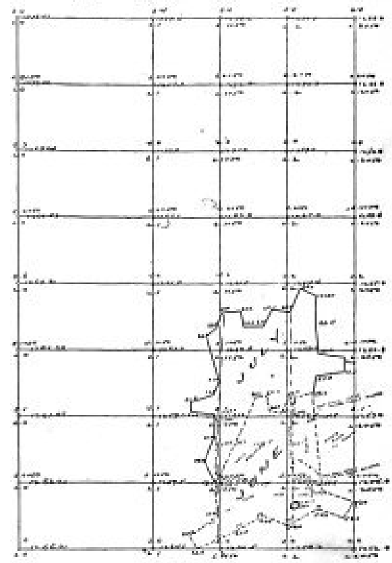

Fig. 2.

if known. Establish levels along the base line at each stake on plugs driven flush with the surface and take elevations of the natural ground at all other stakes. It is also advisable to have a few good bench marks throughout the work. By means of this method of laying out strippings, the engineer, between estimates, is enabled to watch the progress of the work in detail, not only on the ground but in the office as well. The mapping should be on good heavy paper as there will be considerable pencil erasure.

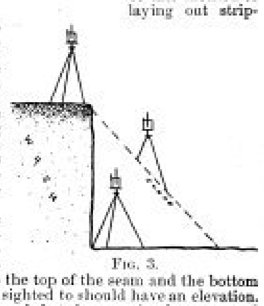

Fig. 3.

In surveying the work, use the vernier, accurately locate the top and bottom of the cut, also the top of the seam and the bottom slate. Every point sighted to should have an elevation. Occasionally it is found that the seam has been grooved deeply by glacial action.

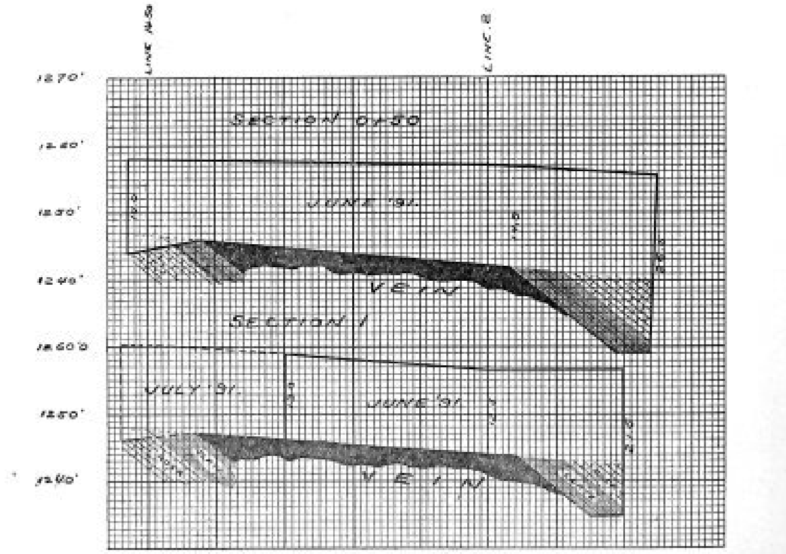

Fig. 4.

On the working plan, mark all surface elevations in black, those at the bottom of the excavation in red, which in the drawing, Fig. 2, are heavy and light respectively. Different months work should be represented by colors. (In the figure June and July, for example, are in dotted and solid lines.)

The excavation should continue, if possible, in one direction. This is of advantage to the contractor as well as the engineer, especially where there are four classifications. Much the engineer will become acquainted with. He may have to notice when, where, and why the method of "plunging" the cut is adopted, which nationalities work better together, how many shovels should be worked to a pick, and how many barrows, carts, etc., for each group of men. He also learns why under force account there are so many men hired as foremen, blacksmiths, repair men, and last, but not least, water boys, and why the poor labor and small shovels are used; and why on a haul for barrows, carts are employed, and he must remedy expensive practices whenever possible. Where possible steam shovels, ditchers, plows and scrapers are used, but when owing to the grades and material to be removed these are impracticable cars and carts should be used.

The estimate connected with different classification is interesting. Rarely is the method of double areas by traversing employed, on account of the nature of the cut. It being impossible in such excavations, where the cuttings are perpendicular, to obtain the area unless the perimeter is run or by lengthening certain sights. On light slopes the perimeters could be obtained, and also by running an average line on the slopes, (Fig. 3) it might be done, but to determine such point would require so much labor and detailed calculations as to condemn it. This method could be employed by taking a final estimate, but then it would not be thorough unless the principle of Graphostatics to a certain extent is used, and in no case would it be exact for any other estimate but the final one without such additional employment.

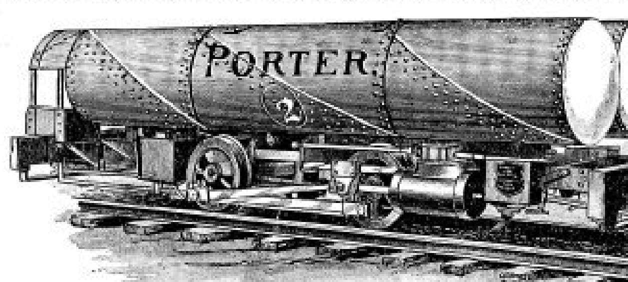
In the sectional method of estimating excavations, the survey should be platted as in plan (Fig. 2), all elevations marked, and the depth of wash and height of rock known. Then on prepared cross section paper in tenths, construct the sections, showing the classifications, etc. In Fig. 4, 0 + 50 and 1 are cross sectioned in detail. These cross sections should be kept on file and completed as the work advances.

By this system of planning, etc., stripping estimates are complete at the last excavation, no final estimate being necessary unless requested. It will be found that after the adoption of the foregoing method, the work will be pleasing, as nearly correct as is possible, and entirely satisfactory to all concerned.

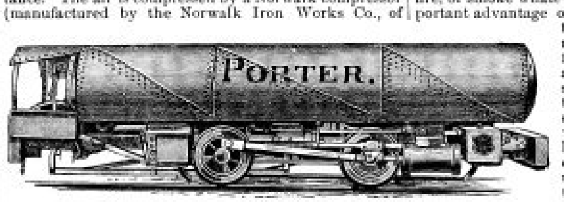
COMPRESSED AIR MINE LOCOMOTIVE.

Its Advantages over Steam or Electric Locomotives for Mine Use.

H. K. Porter & Co., of Pittsburgh, Pa., builders of light locomotives, have constructed a locomotive operated by compressed air, for use inside coal mines. This locomotive has been in use some months very satisfactorily, and is fully as powerful as a steam locomotive of the same size cylinders. The general construction is the same as a steam locomotive, with the boiler and water tank omitted, and two large cylindrical tanks added, for holding compressed air. These tanks are 33″ diameter and 16′ long. By means of a very simple method of connecting the air reservoirs with the engine cylinders no difficulty whatever is experienced from freezing either in summer or winter. The locomotive is constructed to carry air at 500 to 600 lbs. pressure, but thus far the output of the mine, 15,000 bushels per day, has not been large enough to tax the locomotive to anywhere near its full power, and usual charges of air are 250 to 450 lbs. This locomotive makes alternate trips on different cross-entries. One entry is 1,925 ft. long, with a number of curves 25 ft. radius, and the longest up-grade for loaded cars 1,200 ft., averaging 1½% grade, but very irregular, so that for short distances the grade runs as steep as 5%. The other entry is 1,550 ft. long, with grades of 1% for loads to be hauled up, and very crooked, many curves being 25 ft. radius, and one curve only 17 ft. 3 in. radius; curves being measured to centre of track. An ordinary day's work, not developing more than about half of the full power of the locomotive, is 31 round trips, or about 20·5 miles total daily mileage. Over the longer entry, up maximum short grades of 5%, from 8 to 11 cars are hauled each trip; weight of car 1,250 lbs., and of load 3,360 lbs. The average charge of air doing this work



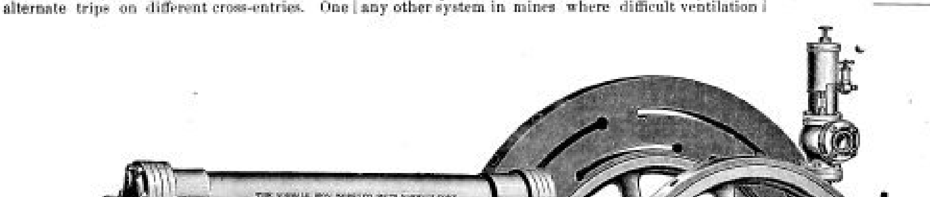
was 334 lbs., running the pressure down 193 lbs. and having 141 lbs. pressure left at the end of each trip—equivalent to a distance run of about 20 ft. for every pound of pressure used up. Over the shorter entry from 14 to 18 loaded cars are hauled up 1% grades, the average charge being 314 lbs., using up 146 lbs. and having 167 lbs. pressure left at end of each round trip, making distance run per pound of pressure exhausted about 21 ft. Of course on easier grades and curves one charge of air would run the engine a much longer distance. The air is compressed by a Norwalk compressor (manufactured by the Norwalk Iron Works Co., of



South Norwalk, Conn.) situated for convenience 2,400 ft. from the point where the locomotive is charged, and no loss of pressure is noticeable, conveying the air this distance through 3 in. pipes. The locomotive is charged inside of one minute. If charged to 500 lbs. it can make two round trips, a distance of about 1½ miles, hauling longer trains, than can at present be taken care of at the sidings or on the tracks at the tipple, and have considerable air to spare. It is entirely practicably to build an air locomotive with capacity to run 4 miles or more with one charge of air, doing heavy work. So little time is required to charge the engine, the compressor is usually run to a light pressure and the engine charged oftener. The locomotive can be charged Saturday night and left standing till Monday morning and not show perceptible loss of air by leakage, and there would be nothing to prevent its starting off at a mere touch of the lever after a rest of weeks, or even months.

The compressed air locomotive has advantages over any other system in mines where difficult ventilation or danger from gas makes steam locomotives undesirable. The cost of an air locomotive is nearly the same as of a steam locomotive of the same size, and the cost of a compressor plant large enough to operate two locomotives is usually a little more than the cost of one locomotive. The running expenses are light, and the air is also used to good advantage for running a pump, the air being conveyed a long distance, where steam would not work satisfactorilly. Compressed air coal digging machines may also be operated by the same plant. As compared with electric systems the compressed air locomotive involves about one-third the outlay, and the operating expense is less, and the danger of naked electric wires is avioded, and also danger of electric sparks causing fire-damp explosions. As compared with rope haulage, the cost of plant and of operating is less, and it can be used without any trouble on entries too crooked to be operated by rope systems.

The air locomotive is simple and not liable to get out of order, and requires less skill to operate than a steam locomotive, and is safe and reliable. One of these air locomotives has been in use seven years with not over $50.00 cost of repairs, and without losing a trip. It improves the air in the entry, and there is no steam, gas, fire, or smoke whatever. In this respect it has an important advantage over the only cheaper system that there is—the steam locomotive. In mines where the main entry is used for the return current of foul air, any smoke or gas made by the steam mine locomotive cannot reach the working parts of the mine, and so can do no harm. In mines where the locomotive entry must be used for the intake of fresh air, or where the locomotive is to be used for gathering from cross entries and rooms, the air locomotive is the cheapest and most efficient system. These air locomotives are built of various sizes of cylinders, from 5 in. to 10 in. diameter, and to suit the dimensions of the mine entry and gauge of track. The smaller sizes will run on 16 lb. rail and in entries 4 ft. high, and are specially useful in cross entries. The larger sizes require 20 to 30 lb. rail and entries 4½ ft. or more in height. These air locomotives may be seen at work at the old Eagle Mines on the Monongahela River, near Pittsburgh. Compressed air system is also the best possible system of transportation for many places where steam or other systems are dangerous or objectionable, such as powder mills, rope and cordage works, lumber yards, saw mills, etc. Compressed air is also well adapted to street railway purposes, and many street railway companies who are looking for some cheap and satisfactory power, without smoke or steam, and without the intolerable screech of the electric motor, and free from the pole and wire nuisance, will find it in compressed air.



NORWALK AIR COMPRESSOR USED IN CONNECTION WITH PORTER LOCOMOTIVES.

(Built by Norwalk Iron Works' Co., South Norwalk, Conn.)

An Unsolicited Opinion.

Mr. Thomas Middleton, of Middleport, Ohio, writes, "I have been a subscriber to The Colliery Engineer since 1881. Of course, it had then an additional name (Mining Herald). I wouldn't part (of my own choice) with the information and pleasure received from it in that time for thrice the money it has cost me."

A Unique Calendar.

One of the most unique and neatest calendars issued this year, is that issued by The Lunkenheimer Brass Mfg. Co. of Cincinnati, Ohio, to advertise the "Handy Gate Valve." It has embossed on it a perfect representation of a "Handy Gate Valve" that opens or shuts by moving the lever.

"I have taken The Colliery Engineer for four years and was therefore enabled to pass a successful examination and gain a certificate of competency at the examination for mine managers in this state."

John Westwood,
604 Barnhart Ave.,
Streator, Ill.

A WELL MADE STEAM ENGINE,

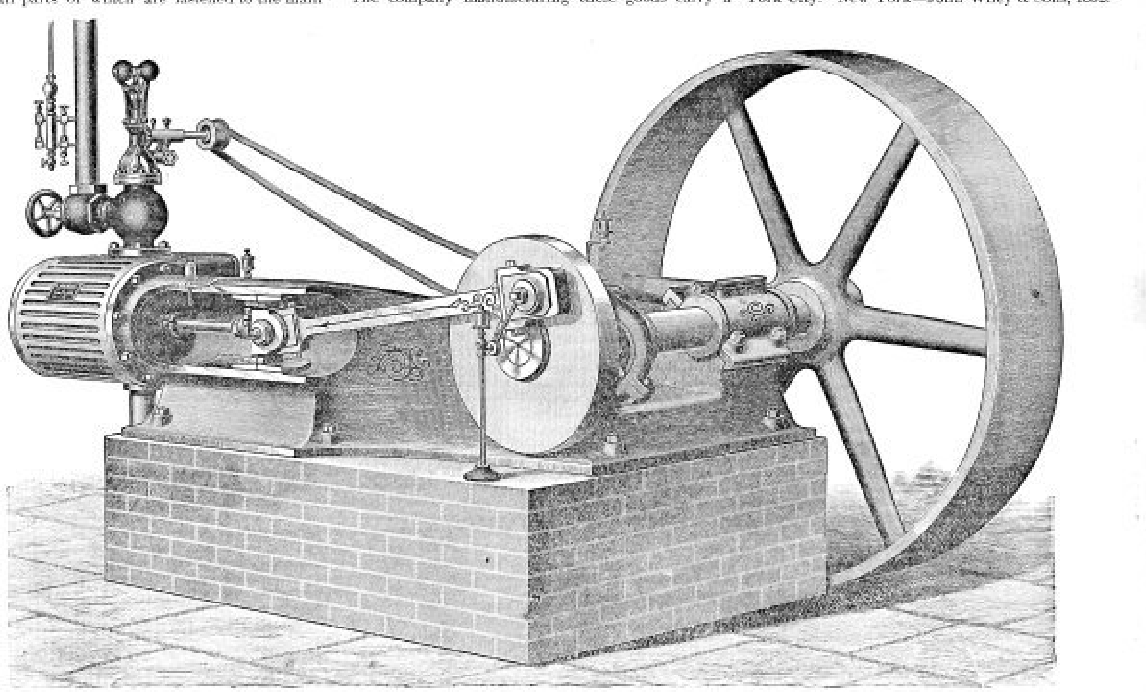
And First-Class Boilers of Guaranteed Strength.

The engine shown below is one of the most modern of steam engines. Its proportions and arrangement conform to the latest engineering practice and its neatness and adaptability of design are evident to the most casual observer.

The company building these engines claims not only these points for the engine but also strength beyond all ordinary requirements, first-class material and workmanship and construction on the interchangeable plan so that in case of breakage duplicate parts can be immediately ordered of the factory by number and the damage repaired with a minimum loss of time.

Every engine is subjected to thorough tests before shipment, under full steam pressure and brake load, by competent inspectors at the works of the makers, a certificate of which accompanies each, thus giving assurance to the purchaser not only of the capabilities of the engine but also as to the result of its individual preformance. The bed of this engine is also one of its distinguishing features. In it the metal is so distributed as to present the greatest resistance in the line of motion between the cylinder and crank shaft, and furnishing within itself both of the bearings for the crank-shaft, which brings it absolutely and permanently square with the other working parts. This point cannot fail to be appreciated by steam users generally and especially in countries which are subjected to earthquakes and other terrestrial disturbances.

The two bearings for the crank shaft being a part of the main bed of the engine, of which the guides are also a part, makes the whole a thoroughly rigid machine, all parts of which are fastened to the main



bed.

Under these conditions it is only necessary to set the main shaft of the engine parallel to the shaft which it is to drive, fasten it in position, attach the steam connections, and then the engine is ready to run.

The separate pedestal which is used on ordinary side crank engines to support the outer shaft journal is dispensed with and all chance of the engine itself getting out of line is entirely removed. Such a shock as an earthquake might, and in fact would be likely to throw the engine out of line with the shaft it drives, but never out of line with itself.

This engine, while not especially placed on the market as a high-speed engine, is nevertheless designed for quick motion and may be run at almost any desired speed as it has all the elements of endurance. Its bed frame is rigid, its ports ample, and it has large bearing and wearing surfaces, adapting it to long and continuous runs under heavy duty. It is heavy, compact, durable, and a marvel of simplicity. The self-contained feature of its bed, which sustains the crank shaft in perfect alignment commends itself to every one, its quick motion and sensitive spring governor insure close regulation, and there is no room for doubt that it will show results in power, durability, and economy rarely surpassed.

These engines are used in almost every kind of industry and in every case are rendering the utmost satisfaction.

The builders of this engine are also manufacturers of a complete line of both Stationary, Tubular, and Firebox Boilers, Circular and Muley Saw Mills, which are of the same modern designs and upon which they exert the same care in the choice of material and in the workmanship and devices for meeting the demands of the machinery buying public that they do upon their engines.

The plate used in these boilers, which are supplied in connection with the above described engine, is the best Open Hearth Homogeneous Steel, capable of being turned down double cold without fracture.

All tubes are made lap welded and of charcoal iron from a mill whose reputation is beyond question and are properly expanded in the heads and beaded over in both ends by skilled workmen.

The Burden Rivet is used exclusively. The holes in the heads for tubes are accurately drilled in all cases by means of special cutters, which not only causes no injury to the metal of the head but also produce a true hole into which the tube can be thoroughly fitted and expanded. The bracing is in excess of the requirements of modern boiler practice. All flat surfaces are strongly and substantially stayed with braces of the best refined iron properly distributed throughout the boiler.

The heads of stationary boilers are braced by bolts running from head to head with double nuts on each end.

The arrangement of the tubes is in horizontal and vertical rows, and is such as to give free and perfect circulation within the boiler as well as being easy of access for cleaning.

Before shipment each boiler is thoroughly inspected and tested to 150 lbs. hydrostatic pressure, by the authorized inspector of a reliable boiler insurance co.

This inspector renders weekly reports to his company of the inspection and test of each boiler, and upon these certificates a policy of insurance for $300.00 is issued on each boiler by said company.

This policy is assigned to the purchaser of the boiler in due form, giving a substantial guarantee that the boiler has been properly made, inspected, and tested.

The company manufacturing these goods carry a stock of them on hand at all times for immediate delivery, the only delay necessary after receiving the order being that required for thoroughly packing such machines for shipment.

Those who are interested in this subject and who desire a special descriptive catalogue can receive same by applying direct to the makers, Messrs. Chandler & Taylor Co., Indianapolis, Ind., U. S. A.

THE McALESTER EXPLOSION.

Some Additional Notes Regarding Its Cause.

BY WHITFIELD FARNHAM.

It is proper that a few words should be added to the account of the mine disaster at Krebs, near McAlester, Indian Territory, as published in the February number of The Colliery Engineer. That report was written hurriedly, soon after the accident, and some additional facts have since come to light. It was stated that no powder cans were found exploded, but it now appears that some miner had (contrary to rules) smuggled his 25-pound can of powder down the slope, and hid it in the air course, nearly opposite entry O. This can was exploded, but was afterwards surreptitiously removed from this location to the proper place and locked in a box between two other powder boxes, thus successfully hiding the fact from the "pit boss" and the committee at the first examination. This explains how the explosion gained such force in its travel up the slope.

The men who escaped safely from entry N, opposite and so near entry O, the initial point of the explosion, did not pass out to the slope at once, as might be inferred from the account, but waited for the after-damp (that filled the slope and blocked the mouth of the entry) to be cleared away, which required about one hour. They tested it frequently, and only ventured out when their lights would burn. Similar precaution saved many others.

The mine was examined and the causes of the disaster inquired into at the request of the general manager of the Osage Coal and Mining Co., by Walton Rutledge, mine inspector of the 4th district of Illinois, C. C. Woodson, State Mine Inspector of Missouri, and John T. Stewart, State Mine Inspector of Kansas, during the first week of February. Their report will probably soon be published, but it may be well to say now that they locate the start of the explosion in the same place, and ascribe the same cause (viz., blown-out shots caused by reckless mining) as given in my report, except that they think a small quantity of carbureted hydrogen gas (fire-damp) may have been liberated from the coal by one of the shots—not being willing to admit that an explosion can occur in coal dust in the entire absence of gas. They condemn in the strongest language, not only the shots in upper entry O (described last month) but also the shot fired at the same time that fatal afternoon in lower entry O and which was also a blown-out or windy shot—necessarily so from its depth and location.

BOOK REVIEW.

A Manual of Mining based on the course of lectures on mining delivered at The School of Mines of the State of Colorado. M. C. Ihlseng, C. E., E. M., Ph. D., Professor of Engineering Colorado State School of Mines, formerly of Columbia College School of Mines, New York City. New York—John Wiley & Sons, 1892.

This book of 428 pages which has just been issued is got up in an attractive form. It is liberally illustrated with cuts of a high class type. Part I., entitled *Mining Engineering* consists of sixteen chapters embracing all the subjects which come within the scope of the mining engineer. The chapter on Methods of Mining embraces not only coal and iron-ore working but includes metalliferous, gypsum, salt, and other mines.

The mechanics of mining are fully dealt with in chapters IV. to X., and ventilation is treated in chapters XI. to XVI.

The illustrations of the various types of pumps and more especially the cuts descriptive of the details such as valves, suction pipes, clacks, etc., will be found of great value to students in a mining engineering course.

Part II., entitled *Practical Mining*, gives details of the various forms of shafts, the methods of sinking, the modes of driving tunnels, adits, levels, etc. Boring is fully treated in chapter V. The illustrations on timbering under varying conditions are very clear and distinct. The new and more powerful types of explosives such as ammonite, tonite, etc., are well explained and their analyses given in Chapter VII. This is in itself a good recommendation for the book in the light of recent investigations, regarding coal-dust, which call for an explosive which will be sharp and flameless.

The various types of mining drills and machines are fully described, and a considerable amount of space is given to a discussion of the best positions for bore-holes to secure the best results.

Altogether this book will form a useful addition to the library of the expert and to the table of the student, and possesses this additional great claim to popular favor that it is the only American work treating on both coal and metal mining.

EASY LESSONS FOR BEGINNERS

IN THE STUDY OF THE

ART OF MINING

AND THE

SCIENCES RELATED TO IT.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the theory of mining and to learn how to answer the questions in ventilation, mine surveying, and mechanics which are asked at the examinations for mine manager's and mine foreman's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine manager's and mine foreman's certificates and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and the calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

In the study of penmanship the most important thing to be acquired is to be able to write plainly, for characters that cannot be read are of little use. After this has been accomplished rapidity in writing may be obtained by constant and long continued practice; and finally, if one would become a graceful writer, beauty of writing must also be acquired. A page plainly written is satisfactory, but one beautifully written is not only satisfactory but praiseworthy.

Continuing in the order of the alphabet, we have for consideration this month the capital letters P, Q, and R. Letter 1, Fig. 37, numbering from the left, shows the letter P written correctly. Its development consists of the capital stem, left curve, and a right curve. The capital stem begins at five-sixths of the full height of the letter; at the base line it merges into a full left curve which, with a broad turn making a right curve, crosses the stem vertically at the top and recrosses it at right angles at the middle, where it terminates. The

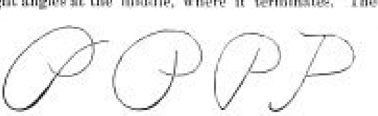


FIG. 37.

second letter, counting from the left, shows a common mistake made in writing this letter, viz., that of making the general shape of the letter round instead of oval. In letter 3, the capital stem is drawn too far to the left, giving an angular turn at the base which destroys its symmetry. The fourth and last letter shows a careless way in which this letter is often written. The oval is not completed and the loop on the right hand side of the stem is too wide.

The capital letter Q, as shown by Fig. 38, consists of the capital loop with its terminating curve drawn to the left forming a horizontal loop at the base, ending with a curve one-third of the full height of the letter. In the second letter from the left the capital loop is too angular and is a violation of the fourth law of penman-

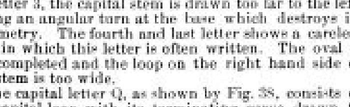

FIG. 38.

ship, namely, all curves should be elliptical. The third letter represents an easy but incomplete way of writing this letter. Letter 4 shows several causes of deformity; the curves are not elliptical, the strokes are not parallel, and in completing the letter an extra curve is made, which spoils the looks of the letter and prevents its union with the following letter in writing a word.

In Fig. 39, the first letter R conforms with the requirements of the four laws of penmanship and is pleasing to the eye. It consists of a capital P with a small loop made across the capital stem, and a curve extending to the base line, uniting there with a curve extending upwards one-third of the full height of the letter. When

FIG. 39.

R is combined with other letters this last curve changes to suit circumstances. In letter 2 the ellipse is made too circular, and although the inclination of the major axis is correct, it is imperfectly developed. The ellipse in letter 3 is too narrow and on a wrong inclination. Letter 4 is loosely constructed, and is a direct violation of the laws of penmanship.

ARITHMETIC.

In this issue we will explain the process of pointing off the decimal in numbers that are added, subtracted, and multiplied.

Pointing in the addition of decimals is of the most simple character, because it is evident that if ·5 be added to ·5 the result is 1; and if 5 is required to be added to ·5 the result is neither 10 nor 1, because ·5 cannot be added to the integral or whole figure 5; consequently the simple rule in addition is to place the figures over each other, according to their numerical values, for example, ·5 must be set over ·5;

·5
·5
1·0

and when 5 is added to ·5

5
·5
5·5

Again, if ·5 has to be added to ·05 we have

·5
·05
·55

The rule for pointing in addition can be expressed as follows: The numbers to be added, are to be set over each other in such order that the separate figures stand to each other, in the same relationship that they each bear to the decimal points, for example, add the following numbers together: 1·03, 27·84, ·005, 2002, ·001.

1·03
27·84
·005
2002
·001
2030·876

In short the, common rule might be expressed as follows: Keep the decimal points above each other, in the order of a vertical line. But a statement like this is very unsatisfactory, and it is very much better for the student to first discover the reason why the decimal points are so kept in order. The position of the points, in the subtraction of whole and fractional numbers, is precisely similar as in addition, and the explanation given for one will equally apply to the other. Now pointing off decimals in multiplication involves a little difficulty, which we will try to remove. It is clear that the half of a half must be a fourth. Therefore, ·5 × ·5 = ·25, and the principle to be understood is simply this, that if you multiply a whole number by less than a whole number the result must be less than the whole number multiplied, for example, the half of 20 is 10, and if you multiply 20 by ·5, the result must be 10·0. Now, when a cipher stands alone, on the right-hand side of the decimal point, it has no value; ciphers also on the right-hand side of a decimal number have no value, because ·5 and ·50 express the same thing. Consequently the cipher in the last case may be dispensed with. At this point we would like to warn the student against acquiring the absurd practice of speaking of ·25 as decimal twenty-five. The term twenty-five can only practically be applied to a whole number. And what is true in this example is equally true in all others. The rule for pointing off in multiplication is as follows: Add the number of decimal places in the multiplicand, to the number of decimal places in the multiplier, and the sum is the number to be pointed off in the product, for example, multiply 26 by ·6, then the product will be 15·6. In this case there was one decimal in the multiplier, and none in the multiplicand; consequently one must be pointed off in the product. Again, multiply 2·6 by ·6, the product will be 1·56, as we have one decimal place in the multiplicand, and one in the multiplier, making two places of figures to be pointed off in the product. Therefore the only difficulty that can arise in this case, is in the confusion that may exist in the mind of the student, with regard to what is meant by the term "the number of places." Multiply 345·345 by 543·002 and the product will be 187,523·025690; now observe there were three decimal places in the multiplicand, and also three in the multiplier, making in all six places to be pointed off in the product. It will be seen that the last decimal figure is a cipher, which being at the right-hand side of the decimal figures has no real value; the product can, therefore, be expressed as follows: 187,523·02569. With the aid of a few exercises out of an arithmetic, the student cannot fail to be correct in his pointing.

MISCELLANEOUS PROBLEMS SOLVED.

Q. If the area of an air-way be doubled, the velocity remaining the same, how much will the frictional resistance be increased on the total quantity, and how much will the frictional resistance be decreased per square foot of section?

A.—Friction varies directly as the rubbing surface; to explain this we will take two air-ways, one twice the area of the other. The small air-way 5′ × 5′ = 25 sq. ft. area, the large air-way 6′ 3″ by 8′ = 50 sq. ft. area, each are 3,000′ long. The perimeter of the small air-way is 5′ + 5′ + 5′ + 5′ = 20′; for the large one 6′ 3″ + 6′ 3″ + 8′ + 8′ = 28·5′. The perimeters multiplied by the length in feet gives the amount of rubbing surface for each air-way, thus: 20′ × 3,000′ = 60,000 sq. ft. of rubbing surface for small airway; 28·5′ × 3000 = 85,500 sq. ft. of rubbing surface for large air-way.

Then, 85,500 ÷ 60,000 = 1·425, or the frictional resistance in this case will be increased from 1 to 1·425. The amount of rubbing surface per sq. ft. of section may be found as follows:

60,000 ÷ 25 = 2,400 for small air-way.
85,500 ÷ 50 = 1,710 for large air-way.

Then,

1,710 ÷ 2,400 = ·7125, or the resistance per sq. ft. of section will in this case be reduced from 1 to ·7125.

Q.—The pressure per square foot producing ventilation is equal to 66·56 ounces, what is the height of the water-gauge?

A.—We will first reduce the ounces to pounds, thus,

$$\frac{66·56}{16} = 4·16$$ pounds, and 4·16 pounds pressure per sq. ft. are equal to a water-gauge of

$$\frac{4·16}{5·2} = ·8 \text{ inches.}$$

Q.—How many cubic feet of air are there in a circular shaft 1,680 feet deep and 18 feet in diameter; also what would be the rubbing surface of this shaft?

A.—To find the number of cu. ft. of air in a shaft of the above dimensions we proceed as follows:

The rule is square the diameter and multiply the result by the constant ·7854, to find the area, thus—

18 × 18 × ·7854 = 254·4696, and this multiplied by the depth in feet, 1,680; will give the cubical contents, thus—

254·4696 × 1,680 = 427,508·928 cu. ft.

The rubbing surface of the shaft is obtained by first finding the perimeter and multiplying it by the depth or length, thus—

18 × 3·1416 = 56·5488′ perimeter and 56·5488 × 1,680 = 95,001·984, rubbing surface.

Q.—The form of an air-way is that of an arch with a semi-circular top, it is 8 feet high and 8 feet wide, and begins to circle 4 feet from the bottom, what is the area of the section?

A.—Up to the point where it begins to circle we have a rectangle 8′ × 4′ which has an area of 32 sq. ft. Treating the top part as half a circle, whose radius is 4′, and diameter 8′, we find the area of the whole circle by squaring the diameter and multiplying the result by ·7854, thus—

8^2 × ·7854 = 50·2656 sq. ft.

Then half of this would be the area of the circular part of the air-way, or 50·2656 ÷ 2 = 25·1328 sq. ft., which added to the bottom gives the whole area,

32 + 25·1328 = 57·1328 sq. ft., the required area.

Q.—A circular shaft is 16 feet in diameter, and during the course of sinking from some cause the shaft feeder has flooded the shaft with water to a depth of 312 feet; how many gallons and cubic feet of water are there in the shaft?

A.—To find the cubic feet of water in this shaft we square the diameter 16, and multiply the result by ·7854, thus—

16 × 16 × ·7854 = 201·0624 the square feet in the area of the section of the shaft. Now, if the area of the section be multiplied by the depth of the shaft in feet, the result will be the volume of water in the shaft in cubic feet:

201·0624 × 312 = 62731·4688 cubic feet of water. Now, as there are 7·4805 U. S. gallons in a cubic foot, then

62731·4688 × 7·4805 = 469,262·75 + gallons the answer required.

Q.—How long would it take to pump the shaft dry in the previous question if no feeder continued to run into it, the pump being twelve inches in diameter, and having a 5 feet stroke, and making 6 strokes per minute?

A.—First, we will find the cubic feet the pump can lift per minute, as follows: The diameter being 12″ = 1′, then

1 × 1 × ·7854 × 5 × 6 = 23·562 cu. ft.

Now, if the cubic feet of water in the shaft be divided by the cubic feet of water the pump can lift per minute, the result will be the time in minutes the pump will empty the shaft.

Thus,

$$\frac{62731·4688}{23·562} = 2662·4 \text{ minutes, or } 44·37 \text{ hours}$$

This is a correct answer theoretically, but in practice there is a loss by leakage from the bucket and the valves.

POWER IN MINING.

The Elementary Principles of Mechanics—Steam—Boilers—Engines—The Machinery Employed in Mines.

1. What is a force?

It is anything that tends to change the state of a body. Either to move it or to stop it.

2. How is it measured?

Always in pounds.

3. What is velocity?

Its rate of motion.

4. What are the laws of motion?

If a body is at rest it will remain so. If in motion it will move forever uniformly in a straight line till some other force acts on it.

5. Is that perpetual motion?

Yes, but nobody ever has perpetual motion. The nearest to it is that of the stars.

6. Why does not a body go on forever?

Because of friction, or the resistance of the air or some other force.

7. What is the measure of a force?

We measure it in pounds only if it is a pressure and in its ability to move a certain weight a certain distance in one second. Thus, if a force produce a velocity of one ft. per second in a body weighing about one-half an ounce.

8. If a force moves a 20-pound weight at a rate of 40 feet per second, how much is that force?

Well 20 pounds is 320 ounces or 640 half-ounces and that multiplied by 40 feet gives 25,600 as the value of the force.

9. Will you name some of the forces?

Steam acting on a piston; air in an air drill; water moving a wheel; the falling weight of a clock; the explosion of powder; and the muscular power of a man or horse.

10. Are all of these forces measured in the same way?

Yes. In each case the force is only capable of producing a given quantity of power, no more, no less. No scheme has yet been found for increasing the value of any power. When you have multiplied the velocity by the number of half-ounces, you have the total value of which the force is capable. *Remember no kind of machine can give you any more.* For in example, question 8 above, the force can give 25,600 units of force whether it is steam or a mule that furnishes it, and whether it is in a hoister or on a canal, no more than 25,600 units can be obtained. If you increase the speed you cannot move so heavy a body or if you try to force a heavier body, it will travel slower.

11. Give me some examples.

With 25,600 units you can move a 4-pound body 200 feet a second, because if it is all used on the body, then 25,600 must equal the number of half-ounces multiplied by the velocity.

$$25{,}600 = 4 \times 2 \times 16 \times 200$$

There are two half ounces in an ounce and 16 ounces in a pound. If you want to find how fast this force will move a body weighing 20 ounces you must divide the 25,600 by 20, which gives 1,280 feet per second.

12. Do you mean that no matter what kind of a force or what kind of a body you have that this is always the rule?

Of course I mean only on this earth are these things true. On the moon it may be different. Again this does not take into account friction or the resistance of the air. Of these we will speak later.

13. Suppose all of the force were not acting on the body? You spoke as if that had something to do with it in question 11.

By that I meant simply that friction did not act. And that the forces balanced each other. When they do we call them in equilibrium. I will use the term *balance* instead of equilibrium.

14. What is a machine?

It is a piece or contrivance for producing an effect at one point by a power operating at another.

15. Name some of the simple machines?

A crowbar, a pulley, spur wheels, windlass, screw, and so on.

16. How is a crowbar a machine?

By it you can lift a weight or move a car.

17. How does it act?

One end rests on the ground and that point is called the fulcrum (pronounce the u as you would the u of tub). Then with your hand at the other end you lift the weight at some point C, Fig. 1. Have you ever tried the

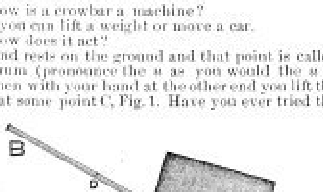

Fig. 1.

crowbar by holding it somewhere else than at the end? If so, have you noticed that it is harder to lift a weight that way than if you held it at the end? Again, where would you prefer to hold the crowbar in Fig. 2, if it rests on a stone at A? At C, nearer to A, or at B far away? At B, yes that is right. I would rather take hold at B and pry the weight up with the point C than to hold it at C and lift the weight from B. Now that suggests a rule.

18. What is the rule?

Look back to question 10. We saw there that if you increase the speed, you can not move so big a weight. Here is the same thing; a large weight can only be moved a small distance. Now the rule is this: The power multiplied by its distance from the fulcrum balances the weight multiplied by its distance from the fulcrum: Power $\times$ A B = weight $\times$ A C. Take an example I can pull 60 pounds and the crowbar (Fig. 1) is five feet long. How much of a weight can I raise if it rests on C, one foot from A? Here 60×5 = weight $\times$ 1 and the weight is 300 pounds. Suppose I held my hand on the crowbar at D, Fig. 1,3 feet from A, then I could only raise 180 pounds because 60×3 = weight $\times$ 1.

19. Do this example now: Suppose in Fig. 2 the same crowbar rests on a stone 15 inches from one end and I used 50 pounds at the other end B. What could I lift at C?

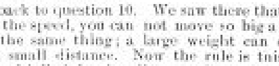

Fig. 2.

Well now A is the fulcrum. Then as the crowbar is 5 feet long, or 60 inches, the end B is 60 — 15 inches from A (= 45).

50 pounds $\times$ 45 inches balances weight $\times$ 15 inches.

Therefore,

Weight $\times$ 15 = 2,250 and the weight is 150 pounds.

20. But suppose I wanted to raise 300 pounds with this bar, how could I do it?

Your only way would be to move the stone under the crowbar until

50 pounds $\times$ A B = 300 pounds $\times$ A C.

That is, when A B is six times as long as A C. As A B + A C must equal 60 inches, then A C must be $\frac{1}{7}$ of B C = $8\frac{1}{7}$ inches.

21. Is that the only way?

Yes, unless you could put on more muscle.

22. But do not we gain power in this way?

Yes, but you will also see that you lose distance Don't forget question 10. The point B must swing further than the point C. So you do not raise the weight as far as you move the hand.

23. How can I arrange to gain distance and to gain power too?

No way whatever can be found by which you can do both. It often is claimed but it can not be done. Don't believe any one who pretends this.

24. Can I arrange so as to gain distance then?

Yes, by using more power. Look at Fig. 2 and imagine your hand at C and the weight at B. Then you can raise the weight at B fast but the point C travels slowly.

25. Suppose I want to raise a 300 pound weight nine inches high so I can put a block under it. What must I do?

To raise the point B nine inches high I must move the point C down a certain distance. If the stone at A is 15″ from the end C, then C will go down $\frac{1}{3}$ as fast as the point B, which is three times as far off from A as is C. So C goes down 3 inches while B goes up 9 inches.

300 $\times$ 9 inches balance power $\times$ 3 inches.

So the power must be 900 pounds.

26. But I can give only 50 pounds push. What then?

Well, you must get a longer crowbar or else give it up. You would need a crowbar so long that

300 $\times$ 9 inches = 50 $\times$ distance swung by your hand which is 54 inches. If then the length A B were 45 inches your crowbar would have to be 270 inches.

27. I can't get so long a crowbar. What could I do?

Then you must use some other kind of a machine. For example a jack-screw or a block and tackle, or windlass.

28. Is a windlass a machine?

Yes, it is a double machine. It has a crank-handle B on which you apply your power that goes to a shaft A then to the barrel on which the rope winds (Fig. 3).

29. How does it act?

In Fig. 4 I have drawn the end view of a windlass

Fig. 3.

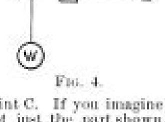

Fig. 4.

The rope hangs from the point C. If you imagine the barrel to be cut away except just the part shown, we have a crowbar like Fig. 2. Power at B, fulcrum at A, and weight hanging at (instead of resting on) at C.

Then the weight multiplied by the distance A C (the radius of the barrel) is balanced by the power multiplied by the distance A B (the length of the crank arm).

30. But does not the round barrel of the windlass have anything to do with it?

No, it makes only this difference: Instead of having a large number of arms alike, A C (Fig. 4) close together, they are put solidly together and the barrel as it turns always has the rope hanging from an imaginary arm.

31. Let the barrel be 9 inches across and the crank 15 inches long, how much can I move with the windlass?

Your power being, say, 50 pounds, we have 50 times 15 balancing weight multiplied by the half distance across the barrel

$$50 \times 15 = \text{W times } 4\tfrac{1}{2},$$

so the weight is nearly 167 pounds.

32. Is the principle the same with the crank arm of a direct-acting hoister?

Yes, the drum of the hoisting engine winds rope on it just as the barrel of the windlass does. Instead of a crank-arm for the hand to take hold, the piston of the steam engine is connected by a "pitman" to the crank arm on the same shaft as the drum. (See p. 153, of February, 1892, number of The Colliery Engineer.)

33. Let a drum be 10′ in diameter and a crank on the side be 10″ long, how would you calculate it?

The weight of the cage, car, ore, and rope is hanging from the drum. So if these all weigh 9,000 pounds then 9,000 times 5 feet must be balanced by the steam pressure acting on the crank pin times its crank arm.

So 9,000 $\times$ 60 inches = P $\times$ 10″.

Whence the rotary power on the crank pin must be 45,000 pounds.

34. Suppose the arm was at a dead point, what then?

There is no force to turn the pin.

35. Then the engine could not start from a dead point?

That is why two cylinders, one on each side of the drum, are used, the pistons of which are connected to the cranks which are so set, that both cranks can never be at dead points. They are usually set at quarters. Later I will discuss the effect of the pitman and crank combination.

[to be continued.]

GEOLOGY

In Its Relation to Coal, Iron, Oil, Gas, and Ores.

1. What is coal?

Any mineral substance containing sufficient carbon to supply its own fuel and be capable of burning. The line between the various fuels is not easily drawn. There are all grades of coal with vegetable matter at one end of the series and graphite at the other, including peat, lignite, soft bituminous hard coal, and graphite. (See p. 18, August, 1891, number of The Colliery Engineer.)

2. What is the difference between these varieties?

If you read the lectures on chemistry you will notice that every piece of organic matter, leaf, wood, flesh, etc., has carbon, hydrogen, and oxygen in it in different proportions. According as these elements (See p. 18, August, 1891, number) differ in quantity, so they produce wood, grass, or flesh. For example, wood is made of minute particles of carbon, of hydrogen, and oxygen. The same is true of the coals, of which here is a table to show their composition. For simplicity we put C. for carbon, H. for hydrogen, and O. for oxygen.

	C.	H.	O.
Vegetable matter has about	·49	·06	·45
Flesh has about			
Peat has about	·56	·07	·37
Lignite has about	·70	·06	·24
Block coal has about	·75	·10	·15
Soft coal has about	·88	·06	·06
Hard coal has about	·95	·03	·02
Graphite has about	1·00	·00	·00

3. Why are they so different?

Because these coals were made at different times.

4. How do you know that?

Because they never occur near each other and they look so very much unlike one another.

5. Please explain what you mean?

Graphite is a pure carbon just like the diamond, and has a fine grain, is smooth and shiny, like steel. It leaves no ash after burning.

Anthracite is a hard stone coal, with a very little ash, and burns without smoke.

The bituminous coal is soft, blazes up with a flame, swells, and finally bakes into a spongy mass called coke. There are many varieties called cannel, coking, cherry, splint, or block.

Lignite is a poorer quality of coal that leaves behind a great deal of ash, and is brown in color showing often the fibres of wood in it.

Peat is a matted mass of rotting vegetation.

6. Where are these varieties found?

Graphite is not very common, and occurs in thin seams.

Anthracite is found in Pennsylvania and Colorado, where the rocks have been disturbed, or broken up.

Bituminous coals are found all over the world, as a wise provision of nature for the comforts of man.

Lignite, or brown coal, is mined in the Western States.

7. Is there any theory to account for them?

Yes, it is one which the geologists have formed from their observations and knowledge of the behavior of the forces of nature.

8. What is it?

Have you ever noticed the marshes and bogs, how they are the rotting masses of vegetable and organic matter? If they are not disturbed for a number of years the marsh becomes deep and large. In the swamps of Louisiana, Arkansas, and Mississippi are very deep bogs, in which also grow large trees, close together. When these die, fall, and rot, a thick bottom of carbonaceous matter is deposited. When the water is absorbed, or if the bog becomes dry, a peat is formed, which can be cut and burned. Throughout Ireland, and in many countries are thick, rich bogs of the peat, some quite compact and dry. In any swamp we can find a depth of this black, half decayed wood. Then the land sinks, or the sea rises, and covers the peat with sand and mud, just as we have seen off the shores of Guernsey and off Devonshire. The peat becomes buried, pressed together by the materials above it, and in time it assumes the shape like lignite, light, and having one-tenth of its weight in water. A further change, as time wears on, produces the forms of bituminous coal. With greater time, pressure and heat anthracite is formed. If it is still longer heated graphite or plumbago is formed.

9. How long has this change been going on?

Geologists cannot tell but it must have taken ages. The amount of coal that supplies U. S. inhabitants alone, is 150,000,000 tons every year, and men tell us that there is sufficient under ground to keep up the supply for an indefinite period. The time required to make all this coal out of wood is very great.

10. What evidences have you of this theory?

First, the microscope shows coal is full of leaves, fibres, and bark of trees. Then near Richmond we see a bituminous bed of coal that has been changed in place to anthracite where a thin sheet of lava has touched it. And we can make coal by putting sawdust under heat and great pressure.

11. Have those "coal pipes" that occur in the roof any connection with coal formation?

Those are called "sigillaria." They are tree trunks that were standing when the mud formed around them. You will notice them in the roof as saucer-shaped. As they are the base of trees near the roots and taper thinner upward they are liable to drop down, so always stand from under and prop them at once. In looking for coal (prospecting that is called) the finding of sigillaria is a sign of being above the coal. Here is a picture of them, Fig. 1. The scars are where leaves once grew.

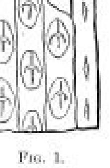

Fig. 1.

12. There must have been immense forests to furnish so much timber and vegetation?

There were. If you have seen the large and dense swamps of the Southern States that hid so many negroes during the Rebellion; or the illustrations of Brazilian and African woods you will readily see that the illustration, Fig. 2, (on next page) is simple in comparison. It shows what the geologists believe to have been the forests of the coal period.

13. Now there are three things troubling me. First, how does this theory come to have been formed? Second, what do you mean by coal period? Third, I do not understand what you say about the mud forming around the "pipes?"

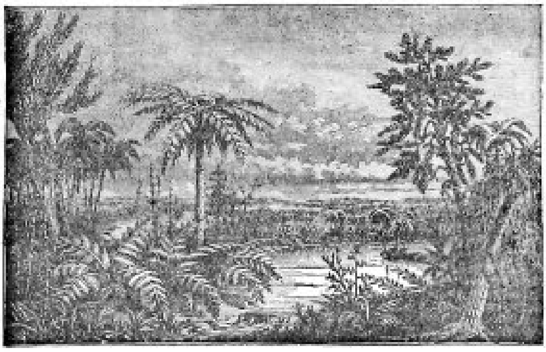

FIG. 2.

That is a long story, but I will answer your second first. Have you noticed that coal contains different kinds of leaves, roots, etc.? Well they indicate to us that these plants existed at the time that the trees were growing. We call that the coal period.

14. How was the theory formed?

It followed the same ideas as are now going on. A leaf falls into the stream and becomes imbedded in its mud. A twig falls on the ground and is covered by sand. An animal dies on the plains, its bones are bleached. A rain washes them into a creek, and they are covered with sand. If in time these are buried under the soil, they give form to the sand that packs around them and a "fossil" is produced. That explains the coal pipes that had been growing in a marsh and stood many hundreds of years after the marsh had been covered by a stream that had deposited mud around the tree. We know that old forest trees live perhaps a thousand years.

15. Did animals live during that time?

Yes; there were beetles, spiders, and other insects. There were some air-breathing, back-boned animals, like our water dogs. There were no birds, no serpents, no fruits, no flowers. Fishes were plenty.

16. Are there any of these in the coal?

Occasionally they are found, to give life to the dead waste, but they are generally found in the slates and clays above and below the coal.

17. Is that the reason that certain rocks are called carboniferous, or of coal period?

We always know how and where to look for coal. The finding of fossils is our guide. For example if I find in a certain rock, remains of the five-fingered leaves, like that shown in Fig. 3, I know I am too high to look for coal and must go down. And if a rock is found with the lower forms of life, like those of Fig. 4, I am too low down in the rocks. Carboniferous rocks will have shells like those shown in Fig. 5.

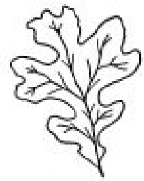

FIG. 3.

18. What do you mean by saying "too low down?"

The question involves the whole history of the earth's formation. All the rocks are in layers which occur in the same order wherever you go. Some

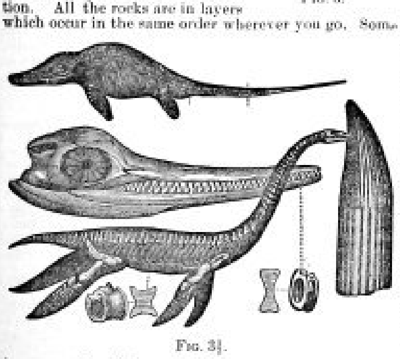

FIG. 3½.

layers may be missing or very thin, and in other places they will be thick. The order is, however, the same.

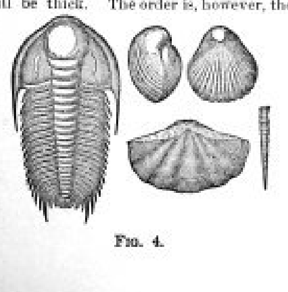

FIG. 4.

Granite is always at the bottom and is called the basement of the earth. Then come a variety of sandstones, slates, clays, and limestones, of different colors and natures.

Some of the bottom layers of these have fossils like those in Fig. 4, and are called *Silurian*. Above them will come layers having fishes, called *Devonian*; corals were also numerous. On top of these, never below them, came again series of slates, limestone, etc., (carboniferous) that are full of plants, fossils, or shells like Fig. 5. Above them came layers and layers of these same rocks carrying corals *in sizes, not in forms* as were those of the *Devonian*, and *equally split* tailed fishes, and above all reptiles like those in Fig. 3½.

These layers included the *Jurassic*, *Triassic*, and *Cretaceous* periods. During the last-named there also existed great forests to produce the coals of the Western States. After the *Cretaceous* we had birds appearing in the *Tertiary* rocks, and finally mammals.

So you see there is perfectly uniform order which can always be identified by the kind of fossils the rocks contain. The more nearly the animal or plant resembles those of our day the higher up the rock is.

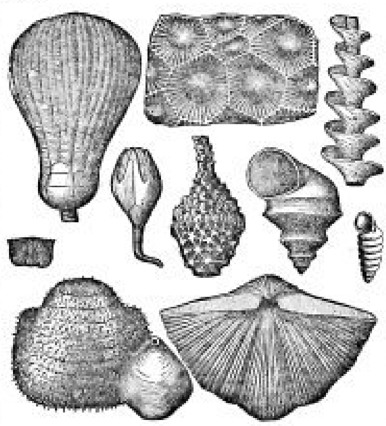

FIG. 5.

19. Are these rocks always of same thickness?

No, for they were made under different conditions of the earth and may be one foot thick in Pennsylvania and 50 feet thick in Germany. The carboniferous does not exist at all in Colorado.

Again the rocks were formed like the peat as mud deposits of a creek, or lake, or ocean, so they will be thin near the banks and thick in the deep water.

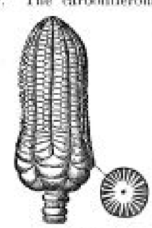

FIG. 6.

20. What are strata?

That is a term for several layers. One is called a stratum. Two or more are strata.

21. Is that where "stratified rocks" comes from?

As the rocks like limestone and slate are flat layers we call them stratified. (See p. 286, July, 1891, number of THE COLLIERY ENGINEER.)

22. Is granite stratified?

No it is a massive rock.

23. Then it was not produced by seas or creeks?

No, granite is the foundation rock of the earth and when as the Bible says, this earth assumed form, it began to be worn away by frost and water. The coarse heavy material was washed to the bottom of the hill and there it was left while the sand and mud were carried further on. Soon the current became too slow and the sand accumulated while the lime grains were carried along with the clay mud. Afterwards the lime settled out and the mud formed a bottom way out in deep water. If the operation continued long we had

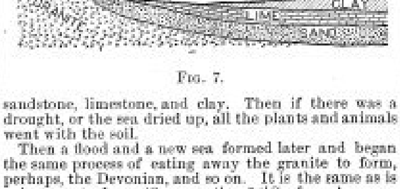

FIG. 7.

sandstone, limestone, and clay. Then if there was a drought, or the sea dried up, all the plants and animals went with the soil.

Then a flood and a new sea formed later and began the same process of eating away the granite to form, perhaps, the Devonian, and so on. It is the same as is going on to-day. (See question 8 "Surface Arrangements.")

24. What are the slates made of?

They are the same as clay but they have been hardened more than the clays. (See page 287, July, 1891, number.)

25. Then, the coal must have been formed in very quiet water, a pool or ocean?

Yes, how did you come to see that?

26. Because usually our coal seams have clay or slate roof and floor. Then in years to come will we be fossils for future geologists?

Yes, drowned sailors lying in their wet graves are being slowly buried with whales and corals in the ever-settling sediment. The whole history of the earth has been one ceaseless action of rain and sea that carries everything to the ocean the bottom of which is and has been a cemetery in which lie the dead from the three kingdoms of nature—the earth, air and water.

27. How long has this been going on?

We can not tell, certainly a long time.

(TO BE CONTINUED.)

METHODS OF MINING.

Shaft Sinking—Tunnelling—Systems of Working Coal and Metals—Timbering in Mines.

1. What are the methods of reaching veins or seams?

By shaft, slope, tunnel, or adit.

2. What is a shaft?

It is a vertical opening sunk from the surface.

3. What is a slope?

It is a passage that is inclined. Some call it *incline*, others a *plane*.

4. What are the other two?

These are horizontal openings. A tunnel, properly speaking, is a passage driven *through* a mountain, or from daylight to daylight. In mining this term means a passage from daylight through the country rock *to* the vein. An adit is a horizontal opening on the vein from daylight in.

5. Then only slopes and adits are on the vein?

Yes. The first follows the dip of the vein and the other follows the strike of the vein.

6. Which is the best method of opening a vein?

That depends upon the surface features. If the vein crops out to daylight, one may have the choice of all four methods. Undoubtedly it is cheaper and more advised to follow the vein by slope or adit, for then you know what your vein looks like. With coal this is not of so much consequence, because the coal is so even in quality and the bed of uniform thickness. With lead or silver it is different, the vein changes in direction and in thickness. The vein is rarely ore-bearing throughout, but only has streaks of ore that must be followed. Generally speaking, "stick by the ore" and follow it. If on a hillside the vein crops out, running up and down, then surely you have the best and cheapest method—by adits. These are driven every 100′ apart in height and offer the simplest mode of transportation.

7. How about slopes; are they not cheap?

Slopes are good for following the vein down and thus give you an idea of its value, but they are expensive to keep up. The wear and tear of hoisting is great, and the timbering is more expensive than for the same style in shafts. But there is another objection. If the vein should "knuckle back" hoisting would be dangerous. For example, veins in the lead and silver districts are not regular in their pitch, as you will see later, under geology of this department. Sometimes they double back. You may imagine what danger and trouble there is in hoisting up a shaft like that in Fig. 1. I could name several. But when the company started out on the slope, they did not know what to do when they reached the point A. I believe there are a dozen such shafts in Colorado. Their owners sooner or later must change. They can not hoist fast through them. And you know the speed of hoisting and the amount of the load fixes the output of the mine; no matter how much ore is broken down, only a small amount can be pulled out.

FIG. 1.

8. Do you prefer a vertical shaft?

By all means. It is safer, you can hoist quicker, the timbering is better preserved and watched, and even the hoisting rope lasts longer.

9. How would you sink it?

I'd prefer to put it on the side shown in Fig. 2, so as to cut the vein. I would drive across to cut the vein every 100 feet or so in height.

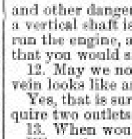

FIG. 2.

10. Are not these cross-cuts expensive?

I grant you they are.

11. Would this plan not cost too much?

This must be determined by the owner. It is dearer than a slope at first. But when you figure up the first cost of slope and then add to it the slowness of hoisting, the extra cost of repairs, the danger of knuckling, and other dangers, you will find that before five years a vertical shaft is cheaper, for it will require less coal to run the engine, and the rope will last so much longer that you would save money.

12. May we not first sink a slope to see what the vein looks like and then after sink a shaft?

Yes, that is surely the best plan, for you would require two outlets sometime anyhow.

13. When would a tunnel be better?

When the country is wet and you know enough about the vein and its ore to know where to find it and what it contains. A tunnel is cheap to operate. It requires no hoisting machinery and the cars and ore can be brought out through it without trouble or great cost. Transportation is the most important, and, in ore mines, the least considered of all branches of mining.

14. Is a tunnel expensive to drive?

Yes, though the cost will depend more upon the difficulties encountered, like water and soft rock. Hard rock is no longer any objection. With machine drills and electric firing the cost of driving tunnels is not so serious an item as it was.

15. Are machine drills and electric firing cheaper than by hand?

Yes, the work is done more rapidly and cheaper.

16. What is the method of using air drills in tunnels?

There are two systems. The "center cut" and the "radial." In the center cut system, known as the American method, the holes are drilled 12 to 14 feet deep and in vertical rows of four each and looking toward each other. The two rows 1, 1, in Fig. 3, the center cross and are fired first. This breaks out a wedge of rock. The others are fired in volleys, marked 2, 3, afterwards. Then the sides are trimmed to shape. For this method, there are two machines at A and B. The advance of the tunnel is 10 feet when the tunnel is 9×16 feet, 20 holes are drilled. The "radial" system is for drifts where the machine is placed at one side of the drift and drills the holes about 4 feet deep, such as in Fig. 4.

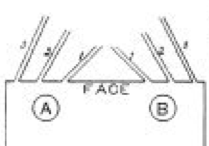

FIG. 3.

In the consumption of powder they are a little higher than in hand work, but the progress is very much faster. It does not pay to arrange the holes in the last way, as a miner would, for the time lost in moving the machine is too great.

FIG. 4.

17. Are tunnels timbered?

Usually not, unless the ground is soft.

18. How are they timbered?

Like galleries and drifts—in sets of four pieces. Sill, cap, and two posts.

19. How are they joined?

If the pressure is only from the top, then the cap may rest on the posts, as in Fig. 5. If there is any side pressure the joint should be cut, as in Fig. 6.

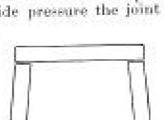

FIG. 5.

FIG. 6.

Never hollow out the post to rest the cap on for the post will soon split. Always dress off the ends to a flat face. Some miners dress and hew off the cap and the posts like Fig. 7, but I do not find this a good plan. I have known of cases where the cap fell through when the posts were forced back. This was on account of poor backing.

FIG. 7.

20. What is that?

The timbers and frames should never be allowed to stand long without being well packed behind with waste rock stowed away between the rock and the lagging.

21. What is lagging?

That is close slabs of flat boards, cord-wood, or half round slabs from the saw-mill, which are placed close along-side of one another, like in Fig. 8.

22. What are they for?

To hold back the waste packing and to prevent any movement. Remember this one principle in timbering and mining generally—that timbering is not for a bad roof merely. *It is intended to prevent a good roof, so called, from becoming bad.* A stick of timber will hold a heavy load or stand a very heavy pressure *so long as it is quiet*, but the moment that movement begins, there is no timbering on earth strong enough to prevent disaster. So always close up spaces in the waste and pack them as tight as you can to prevent movement. The talk about "rock of ages" is all well enough but it is cracked, some will soften on exposure to the air and little of the rock of the earth is so solid as to stand the jars of blasting without loosening up and falling. The man who will not timber up because the roof looks good, will be fooled some day, and be brought home on a stretcher. Therefore, I pray you, be over-cautious in your timbering. Think of it! One man out of every four hundred miners is killed every year by falling roof.

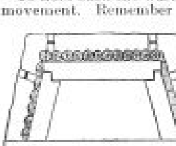

FIG. 8.

23. Is there no remedy against this?

No. Men who live with the constant threatening dangers of mining all around them, become hardened and careless. They say that "I am more lucky," or "more careful." But to-morrow is their day. I have picked men out of mines crushed by rock, and yet they had to crawl over loose timbers supplied to them, to reach their working faces. They are anxious for a big turn-in, and do not want to lose the time necessary to prop the timbers. The use of machines for drilling and coal cutting will remedy this somewhat. For then certain men will do nothing but attend to the machines; others will only put up timbers, still others will do the blasting, and so on. This is a big improvement, and is much safer for everybody.

24. How far apart are the sets you mentioned in 18?

Three feet, ordinarily, but they may be farther apart or nearer together, according to the greatness of the pressure.

25. How are the sets held together?

Nails or spikes should never be used. Straps are sometimes used. But I advise you to get along without any iron, all the pressure is inward toward the gallery or drift and if the joints are carefully made the pressure will hold the pieces of frame together without any fastenings. Often wedges and wedge-blocks are placed at the caps and heads, as in Fig. 8, but a tight backing of waste rock will be sufficient.

26. Will this do if the ground is soft or crumbles?

No. The lagging may help, but generally, soft ground requires heavy sets. The lagging, by the way, should *always be weaker than the timbers* of the sets, so that when crumbling takes place and anything must give away, the lagging will do so first and relieve the sets. The lagging can be so easily replaced when quiet is restored.

(TO BE CONTINUED.)

SURFACE ARRANGEMENTS.

The Preparation of Coal and Ores for Market.

1. Why need ores be prepared?

Because minerals and ores as they come from a mine are never pure. They are found mixed with material of no value. Often, also, there occur with the valuable portion of the ore, material which is injurious to the ore, while in use. Of this we will speak later.

2. How about coal?

The same is true there. No matter what may be the uses to which coals are to be put, there are impurities that injure the coal. Iron pyrites and slate, besides clay, are the most common. The first occurs all through the coal in fine grains and sometimes in balls that break up in the hewing or shooting. The slate and clay come from the partings, roof or floor. In loading the cars these cannot be picked out quickly in the dark so when they arrive up at the surface they must be separated.

3. What are the objections to pyrites?

Pyrites contain sulphur which increases the percentage of ash for whatever purpose it may be used.

4. Does not coking in the ovens destroy the sulphur and carry it off?

Burning does take off some of the sulphur from the coke but the iron remains in the ash. Pyrites, as you may know, is over one-half sulphur and nearly one-half iron.

5. Is the sulphur injurious?

Yes indeed. A coal with much pyrites in it cannot be used raw in iron manufacture because the sulphur spoils the pig iron. Nor is impure coal fit for burning under steam boilers. It makes a poor heating coal and clinkers badly. The blacksmith cannot use a coal with pyrites, nor one with slate, because of injury to the tools he is forging.

6. How are the pyrites and slate removed from the coal?

Until recently the only means adopted for separating them was by picking. The broken coal was caused to slide down screens made of bars through which the fine material and culm or slack passed and over which the larger coal sizes were carried. Boys, on convenient seats, watched for the lumps of slate or clay, and picked them out as they flew by. This method was crude and not entirely satisfactory. In ore mines, the method is the same except that the ore is dumped on tables. The sorters have less ore to pick over than the boys have of coal.

7. What is done now?

Methods called washing are used. For coal and for ore, the principle is the same.

8. What is the principle?

Watch a creek and you have the plan. When a creek is falling fast and flowing with great speed it can wash away anything smaller than quite large pebbles. When it has emptied into a large river, it moves slower and now the pebbles settle down, but the heavy sand, fine sand, and clay go on. Wherever the river widens the speed of the river is less and now sand will settle. The mud remains and is carried away out to sea before it settles down. Every change in the speed of the river alters the bottom; finer material will settle if the speed is slower and only the coarse stuff will stay on the bottom if the river is faster. So with the washing machines. (See Q. 23, Geology.)

9. Must the coal and the ore be fine for this work?

Yes, and that is the only objection, at least with coal. There is one reason why the material must be broken, besides the one mentioned. Usually the impurities are mixed all through the coal and ore, and unless you break it up, you can not separate them.

10. Is there an objection to making small coal?

Yes, the waste is large and you can not break up coal for screening without losing a great deal. The breaking wastes nearly a tenth; screening loses some and the lip-screens waste a little. It is found that the breaker waste from mines delivering to furnaces is less than that from mines which supply domestic sizes which are all small. This waste is always very large. Later we will discuss means of preventing so much waste.

11. But is not sized coal better for the consumers?

Yes, the consumers prefer sized coal. Grates are planned for the burning of a certain size of coal, and so the screening is all right for the consumer. So, for coke making, small coal is preferred. But the breaking of coal produces so much culm which with the fine coal hoisted up to surface is screened out and lost. At present there is little chance of using the fine coal. Usually, too, it has more impurities than the raw coal. If this slack were washed it would sell better than it does now. It could then be used for coke making. If the dry coals of the Mississippi Valley could be coked there would be more washing of the coal and slack.

12. Is coke better to burn than coal, that you should lay so much stress on it?

For certain purposes, yes. Furnaces for melting iron and lead find coke better than raw coal.

13. Is any coal so good and pure as not to require washing?

I hardly think so. I believe all coals have sulphur, and most of them have slate. But even if it was not necessary to wash the impurities out of the coal, screening would separate the coal into sizes and give cleaner products. So I believe that every coal should be washed for one purpose or another.

14. Is it not expensive?

Oh yes. I grant you it is simply a question of cost as to whether it would pay. As the consumers prefer coal which is clean, and demand it to be screened and sized, it is a question whether a colliery wants to continue to supply trade by putting up a cleaning works, or if it would rather run the risk of losing business. Breakers were found to be necessary and to improve trade years ago. So it will be equally important to build washing-houses for the coal.

15. Is there only one method of washing coal?

No, for air will accomplish just what water does. The farmer of the olden time separated the chaff from the wheat by letting a current of air sweep across the barn and blow away the chaff. Still the air method is not a success, for you have to use a strong blower fan or a suction fan to make the current.

16. Then water is the only means?

Yes. Dr. T. Drown has tried to obtain some other liquid, but, like others, has concluded that water is the cheapest.

17. What is the plan of washing?

You have seen how water can separate lighter particles from heavier? Well, coal is lighter than the slate and pyrites. So a current of water is caused to flow in such a manner and with such speed as to just carry off the coal and leave the heavy impurities behind.

18. Is it the same plan as that of dressing ores?

No, not quite the same. An ore of iron, lead, silver, or gold is heavier than the impurities that are found with ores. So there, the plan is to wash away the lighter materials.

19. Is there any other difference?

Not essentially. In principle there is no difference. But in quantity to be treated there is. You see, with metallic ores, we have to deal with small quantities of rich material, and hence can afford to be more careful with the operation. A *large* ore-washing mill is one that treats 100 tons a day. This is a very small turn-out for a coal mine. A coal washing plant must deal with enormous quantities of a very cheap substance, and one on which the margin for profit is so small that we must use machines that act very quickly and simply.

20. A coal-washer, therefore, is a very large mill of simple and self-acting machines, while an ore-washer is not. Is that so?

Not exactly. The first part of the statement is correct, but the latter part is not. First, a mill for washing ore is called a concentrator, and the process is called concentration. But the mill may be just as simple as the coal washer. All I intended to imply was this, the coal must be washed fast and the ore may be concentrated slowly or even several times before the operation is complete. Ores are, therefore, repeatedly washed in many mills.

(TO BE CONTINUED.)

A Pirate.

THE COLLIERY ENGINEER's estimate of the annual supplies required for an 100-oven coke plant is printed in the *New York Engineering and Mining Journal* and credited to the *American Manufacturer*. The *Journal* acted in good faith. The *Manufacturer* acted piratically.—*Connellsville Courier.*

No More Trouble From Boiler Corrosion and Boiler Scale.

Last month we published an article on the merits of the boiler compound manufactured by the Pittsburgh Boiler Scale Resolvent Co. In our advertising pages of this issue will be found a page of testimonials from those who have used it longest. If it will successfully meet the requirements of all these parties it naturally follows that it will meet yours, and you cannot afford to pass it by without investigating it.

A neat reminder of the Lidgerwood Manufacturing Company, comes to our desk in the shape of a delicately tinted bevelled-edge card, $7 \times 8\frac{3}{4}$ in., upon which is mounted a photograph of a new six-spool Lidgerwood hoisting engine for bridge erectors. There is a brief description of the engine below the photograph. The card is designed to be hung upon a nail.

The Lidgerwood six-spool hoisting engine is portable, serviceable, and thoroughly reliable, and is designed for use in bridge erection and in the construction of iron buildings. It can also be profitably used for hoisting heavy loads generally. It has six spools, independent in action and each having a clutch, lever, ratchet, and pawl. The absolute independence of the spools enables the engine to be operated to great advantage in bridge erection as several members of a truss or girder can be hoisted and held in position while they are being bolted or riveted. The engine has many other attractive features and the Lidgerwood Manufacturing Company will gladly reply to all inquiries concerning it, addressed to the New York office of the Company, 96 Liberty Street.

HOW TO LIVE

Use Hot Water.

The human body, says a writer in *Hall's Journal of Health*, is constantly undergoing tissue changes. Water has the power of increasing these tissue changes, which multiply the waste products, but at the same time they are renewed by its agency, giving rise to increased appetite, which in turn provides fresh nutriment. Persons but little accustomed to drink water are liable to have the waste products formed faster than they are removed. Any obstruction to the free working of natural laws at once produces disease. People accustomed to rise in the morning weak and languid will find the cause in the imperfect secretion of wastes, which many times may be remedied by drinking a full tumbler of water before retiring. This very materially assists in the process during the night, and leaves the tissues fresh and strong, ready for the active work of the day. Hot water is one of our best remedial agents. A hot bath on going to bed, even in the hot nights of summer, is a better reliever of insomnia than many drugs. Inflated parts will subside under the continued poulticing of real hot water. Very hot water, as we all know, is a prompt checker of bleeding, and besides, if it is clean, as it should be, it aids in sterilizing our wound. A riotous stomach will nearly always gratefully receive a glass or more of hot water.

Consequences of Error.

Take care what thou sowest, as if thou wert taking care for eternity. That sowing, of which the Scripture speaketh, what is it? Yesterday, perhaps, some evil temptation came upon you—the opportunity of unrighteous gain, or of unhallowed indulgence, came, either in the sphere of business, or of pleasure, of society, or of solitude. If you yielded to it, then and there did you plant a seed of bitterness and sorrow. To-morrow, it may be, will threaten discovery; and agitated and alarmed, you will cover the sin, bury it deeper in falsehood and hypocrisy. In the hiding bosom, in the fruitful soil of kindred vices, that sin dies not, but thrives and grows; and other and still other germs of evil gather around the accursed root, till from that single seed of corruption, there springs up in the soul all that is horrible in habitual lying, knavery, or vice. The evil deed may be done, alas! in a moment—in one fatal moment; but conscience never dies; memory never sleeps; guilt never can become innocence; and remorse can never, never whisper peace.—*New York Ledger*.

A Paper on the Hidden Causes of Disease, by the Late Sir Morell Mackenzie.

At the solicitation of the editor of *Youth's Companion*, Sir Morell Mackenzie, M. D., a short time before his death, wrote the following article on the "Hidden Causes of Disease."

Age is not always to be measured by years. It has been truly said that "a man is as old as his arteries;" as long as these living conduits retain their soundness and elasticity, the parts which they supply with blood will resist decay.

Overwork, "hard living," prolonged privation and exposure to cold, and generally speaking, whatever makes the fire of life either burn too fast or get low for lack of fuel, will add very largely to the natural wear and tear of the tissues.

Dryden speaks of a man whose restless spirit

> Fretted the pigmy body to decay
> And o'er informed the tenement of clay.

Anxiety and distress of mind also contribute powerfully to hasten the advent of old age. A great sorrow will whiten the hair and make a man look old and worn; adding, in very truth, years to his life in the physiological calendar.

Probably there is no more potent cause of disease than long-continued mental suffering; and the greater part of its effect in this way is due to the fact that it brings on premature old age.

Old age causes disease by setting up changes in the tissues which make them liable to perverted action, as in the transformation of harmless warts into cancerous growths; or less capable of resisting the effects of cold and other external agencies; or more prone to wasting, which the exhausted system finds it more and more difficult to repair.

Organs like the brain and the heart—which are, as it were, banks for the storing up and distribution of vital energy—become worn out, and physiological bankruptcy results.

The special enemy of old age, inflammation of the lungs, is due to weakness of the heart, combined with loss of elasticity in the lungs. The mortification of the feet and ulcers of the legs so frequent in the aged are also consequences of deficient blood supply, associated with local degeneration of tissue.

HOW PARALYSIS COMES IN.

The arteries lose their elasticity and give way under any unwonted increase in the force of the blood current; thus a fit of anger or even a sudden movement may be followed by bleeding into the brain—popularly called "apoplexy" or "paralytic stroke"—or a large vessel may become dilated into a kind of hollow ball, called an aneurism, which causes pain and troublesome complications by pressure on the parts in its neighborhood, and may at last burst, with an immediately fatal result.

The changes wrought by old age in the structure of the brain show themselves at first in subtle alterations of disposition and intellect, such as irresolution, timidity, irritability, unreasonable suspicion, avarice,—that "good old-gentlemanly vice," as Byron calls it,—garrulity, loss of memory, confusion of thought, and all the characters of age," which literature from Homer downward has delighted to portray.

In a more advanced stage these senile changes in the brain lead to various forms of mental derangement, and in the last scene of all to "second childishness and mere oblivion."

The most fatal tendency of old age, however, is to the formation of what are called "malignant" growths. This is distinctively a "senile change," if we are to believe Mr. Jonathan Hutchinson, an English authority on the subject, who insists that cancer is merely chronic inflammation in tissues that have undergone the degeneration characteristic of old age.

PECULIARITIES OF STRUCTURE.

That there are peculiarities of structure and constitution, which predispose to certain diseases is a fact as to which there can be no possible dispute.

A good example of such a proclivity is seen in "bleeders," who suffer from what medical men call hæmophilia. The constitutional tendency to bleed on the slightest provocation is very marked in such persons. After the extraction of a tooth, or a trifling cut, they bleed so profusely and so long that surgical skill is sometimes taxed to the uttermost to keep them from bleeding to death.

The late Duke of Albany (Prince Leopold) was the subject of this peculiarity to such a degree that the lives of his physicians were made a burden by the almost incessant demand for their assistance which it entailed. It was ultimately the cause of his death; and yet the injury which indirectly proved fatal was nothing more serious than a slight twist of the knee-joint, which occurred in dancing.

Nothing has yet been discovered to account for this extraordinary peculiarity except a certain thinness of the blood vessels, which is far from being constantly present in such cases. The theory that the Duke of Albany had "one skin less than other people" is probably a grotesquely distorted version of this slight structural anomaly.

The most noteworthy instance of constitutional tendency to disease is seen in the case of consumption, and what used to be called scrofulous diseases. These are now all classed, together with consumption, under the head of tuberculous diseases.

The peculiarity of structure in these cases shows itself in this—that the real cause of the disease requires a certain condition of the tissues before it can produce its effect. They are more delicate and more easily injured in predisposed subjects than they are in other people. Wounds do not heal kindly, and are apt to fester in persons of this constitution.

HEREDITY.

That heredity is a cause of disease admits of no doubt. It is not the disease itself, but the tendency thereto, that is inherited, just as other physical peculiarities are.

Readers will remember the horseshoe vein on the forehead which was the badge of all the tribe of Redgauntlet; and there is a well-known family in the South of France which for more than three centuries has boasted a white lock of hair. The Bourbon nose, and the thick lip of the Hapsburgs, are other instances in point.

Consumption, gout, insanity, and cancer are the diseases which show the greatest tendency to run in families. Of the hereditary transmission of gout, nearly every noble family in Europe can show the most conclusive proof. With regard to cancer the case is not so clear; but statistics prove that heredity can be more or less distinctly made out in a considerable proportion of those who fall victims to the disease.

The Bonaparte family furnishes a remarkable example of the hereditary transmission of cancer. One of the parents of Napoleon the First died of cancer of the liver or stomach. He himself died of cancer of the stomach, which also proved fatal to his brother Lucien and to his sister, the beautiful Pauline Borghese.

A hereditary tendency to disease may not show itself till an advanced period of life, as Professor Huxley, in his charming autobiographical sketch has lately told us that a peculiar movement of the hands which was habitual in his mother has recently shown itself in him.

The moral to be drawn from these facts is that if a man has reason to suspect that he inherits a tendency to a particular disease, he should be careful to avoid exposing himself to the conditions which favor its development. He should also be mindful of his posterity, actual or possible.

Most people use their bodies as if they were their property in fee simple. This is hardly fair to their descendants. A man should, undoubtedly, treat his body as though it were strictly entailed, and the rights of his heirs should be, as far as possible, respected.

If the attack of the disease can by any means be kept off, it is possible that in time the family taint may be eliminated.

The Mortality of Miners.

This is an old subject of controversy, and the general idea seems to have prevailed that the mortality is above the average. In connection with the frequent mention of the subject lately, attention has been called to Dr. Ogle's views contained in a paper on "Occupational Mortality," which was issued in connection with the Registrar-General's 55th annual report. A contemporary thus summarizes the returns.

While not bearing out the assertion that miners enjoy healthier lives than agricultural laborers, they show that coal miners and the miners in the North Riding of Yorkshire, and in other ironstone districts, aged between 25 and 65 years, were liable in 1871-80 to a lower death rate than the mean rate among all males at the same ages. Taking 1,000 to represent the mortality figure of all males at the above-mentioned ages in the ten years under notice, the figure for laborers in ten agricultural counties was 701; for miners in nine counties where the mining was almost exclusively for coal it was 891; and for miners in the North Riding and other ironstone districts it was 834. Dr. Ogle wrote: "The death rates of coal miners are surprisingly low. In spite of their terrible liability to accident, and their constant exposure to an atmosphere vitiated by coal-dust, by foul air, and by an excessively high temperature, the comparative mortality figure of these laborers is considerably below that of all males." This rule holds good, not only for the aggregate of all the miners in the nine counties dealt with, but for each of the six great coal areas taken separately, excepting only South Wales and Monmouthshire, where the exceptionally high rate from accident causes the mortality to exceed the mean for all males. —*Labor Tribune (England).*

Chauncey M. Depew's Method of Preventing a Break-Down.

To the charge which has been made in connection with the Hastings disaster that Chauncey M. Depew spends too much time outside his duties as President of the Central Road, Mr. Depew makes an extended reply:

He said: "I have closed my twenty-fifth year with the Central Railroad and in that quarter of a century I have been in touch with every part of its business and every condition of its development. Though blessed with physique and health and capacity for work accorded to very few men, I early made up my mind from observing the men who had broken down around me and gone to pieces, that the only safety was in variety of occupation; that unless a man could relieve the strain by excursions into other fields, and especially such things as would keep up his cheerfulness and hopefulness, he was gone."

After citing the means of relaxation adopted by a prominent banker and by a railroad president, Mr. Depew said:

"I care nothing for cards, take no interest in games of chance, and at first used to spend my evenings late in the night in continuing the business of the day. Of course that produced sleeplessness, and in a short time led to an overstrain in one direction of the same brain fibers, which destroyed their elasticity, and resulted in bad judgment and poor work. It is for this reason that the extremely busy man can do better the next day if after his business hours he can switch his mental machinery off to some channel which gives rest and recreation. Happily for my critics, and equally fortunate for my health, my recreation is mental labor in other channels than business, which are public and widely advertised, while the railway president or banker who passes his evening at his club or with the card party in his house is free from criticism, because the public are wholly unaware, and, therefore, they don't care how he passes his evenings."

Mr. Depew spends much time in his office, but he urges that it is a misapprehension to estimate a man's value by hours.

"I know plenty of business managers," he says. "If they were not ably assisted, would ruin the properties which they control, even if they gave 18 out 24 hours to the service. I know others of such comprehensive and executive genius that, with three hours a day, they will make any business a success. Commodore Vanderbilt was the greatest business success the world has ever known. He made about a million and a half a year for every year he lived, counting from his birth. He always closed his business day at 2 o'clock, and there never was any business so important that he would give it any attention after that hour. He drove in the afternoon his fast horses and devoted the evening absolutely to recreation and pleasurable amusements. He always claimed that his judgment was very much better and his success largely due to these habits. I believe that a man of large executive endowments, who is properly educated and trained, has the faculty of selecting efficient and loyal subordinates, and the greater faculty of instantly turning his mind and concentrating all its resources upon the business in hand, can successfully manage several important business concerns and still have time for his family, his friends, and the public."

In conclusion President Depew refers to the large share of New York's traffic handled by his road and then says: "I do not claim that my speeches produced this result or any considerable portion of it, but the passenger agents both of the Central and rival lines, tell me that they notice an appreciable difference in travel by our lines, as the public appearances of the President are more or less frequent."

ELECTRICAL PROGRESS

Electrical Improvements.

Two Germans have each invented a process by which the filaments of the incandescent lights can be preserved from deterioration. One is by depositing chromium upon the filament, either chemically or by electrolysis. The claim is that the melting point of chromium is so high, as to resist the action of the electric current and increase the life of the filament. The second method is to deposit nitrides of silicon or boron upon the surface of the filaments. This is done by heating the filaments to high temperature, in an atmosphere of volatile compounds of silicon or boron, and volatile compounds of nitrogen.

A French engineer has discovered a method of repairing broken filaments economically, so that the bulbs can be used again. He makes a hole in the bulb, carefully takes out the broken filament excepting a small piece, which is left attached to the platinum supports. The bulb is then filled with a hydro-carbon liquid, and a new filament inserted, with its ends just touching the piece of old filament. An electric current is then turned on, which decomposes the liquid; the hydrogen liberated, rises through the bulb and the carbon is deposited, cementing the new and old filaments together. The bulb is then cleaned and sealed ready for use.

The reduction of aluminum from its oxide by means of the electric current, is one of the greatest results in the way of electrolysis. The metal which was only recently a comparative myth, is now produced in large quantities, and is used in the manufacture of many articles, both useful and ornamental. Experiments are being made, with reference to its use in the steel plating of vessels, a small quantity of aluminum in the steel, rendering the latter more uniform and more ductile, with a higher ultimate strength.—*Mining Industry.*

Is Electricity a Manufactured Article?

At first sight this may seem a grotesque question, but it has a very serious financial aspect and in fact more than one law suit to determine this point is at present in progress, one, indeed, in New York City. The point at issue is the taxation of central stations, for many States and cities make a wide difference between manufacturing establishments and others. If electricity is a manufactured article then it should be treated with the same consideration due to the establishment of a new industry, with as much gentleness as if it were a soap factory or a shoe shop. Then, too, the question is likely to arise from time to time whether the electric current is dutiable. It is one of the few things that the redoubtable McKinley did not specifically include in his amiable tariff bill, but it might be levied upon as an unclassed manufactured or unmanufactured article for the benefit of the governmental pocket. A question of opinion such as that involved in this inquiry is one to fill the hearts of our legal friends with unwonted joy, for there are as many sides to the subject as there are human beings to discuss it. Does a change in the form of energy constitute manufacture? Is the electric current a substance or not, and in either case is it in any sense properly manufactured in the central station? If it is a substance, has it been altered in form sufficiently to be classified as a manufacture? If it is not, can it be manufactured at all? These are a few of the pleasant questions that arise for solution before the courts, and the longer one discusses them the more hopelessly abstruse do they seem to be. As a matter of plain straightforward equity, an electric light station and gas works ought apparently to stand on precisely the same footing, but whether under our existing laws this can be permitted is another question. For example, is an establishment for the distribution and sale of power, whether transmitted by cable, steam, or compressed air, a manufactory? If it is not, should the distribution of power by electricity be classified as manufacturing? On the other hand, is not the production by the consumption of coal of an available something for human advantage manufacture, whether it is a current of gas or of electricity? It is one of the cases where appeal cannot be taken to logic, for logic is left out in the cold in such a varying series of analogies; nor can one appeal to ethics, for ethics is not always considered in adjudicating disputes; so after all it may have to be settled on a purely legal basis. If so, no man can tell what the result will be, for the laws are not universally bound by any code of either ethics or logic.—*Electrical World.*

An Electrical Mail Carrier.

A plan to carry the mails by electricity between New York and Brooklyn has been submitted by Mr. A. Bryson, Jr., of New York, to Postmaster Collins, of Brooklyn. It is the result of an act recently introduced in Congress by Mr. J. J. Clancy, which provides for the better transmission of mail matter between the two cities, by means of pneumatic tubes, electrical or other appliances, and authorizes the appropriation of $95,000 for the purpose. A similar bill has also been introduced for experimenting between New York and other cities. Mr. Bryson's system consists of a traveler, say 6 feet long and about 11 by 16 inches in breadth and height, to the back of which is attached an electric motor about 8 inches square; this is acted upon by an electric wire which runs along the bottom of an iron or steel cube, which encloses the whole arrangement. In fact it is the trolley system on a reduced scale, and the live wire which supplies the power is fed from one end or the other of the route. The rapidity with which the traveler is propelled may vary, depending on the amount of energy called for. From 70 to 100 miles an hour, or even higher speed, can be obtained. All the advantages which the pneumatic system could give would be obtained, but with much less expense for the plant and its maintenance.

First Messages by Telegraph.

The Western Union Telegraph Company is searching for the first telegram that went over a wire. It is believed that Maj. Stephen Johnston of Piqua, has it, but he has not been able to find it among his papers.

In 1844, when Morse was experimenting in Washington with a wire that extended to Annapolis, he was visited by Maj. Johnston, who was among the delegates arriving in town on their way to the Whig convention in Baltimore. The experiments were incomplete, and in the course of the explanation Morse said that he had sent to Annapolis a friend who would try to send a message in the characters that he had arranged and gave the slip to Johnston, who considering it the completest sentence ever sent by telegraph, carefully preserved it. The message expressed the pleasure of the sender in reaching the inventor by wire.

In the most trustworthy description of the development of the telegraph, it is related that among the earliest messages, while the line was in its experimental state, was one from Baltimore on May 1, 1844, announcing the nomination of Henry Clay to the Presidency by the Whig convention. On May 11 Morse sent to his assistant, Albert Vail, in Baltimore, "Everything working well," and that became historical.

The most impressive of the first messages was that sent at the public exhibition in the chamber of the United States Supreme Court in the capitol, on May 24, 1844, to which Morse had invited his friends. Miss Annie G. Ellsworth, a daughter of the commissioner of pensions, who had announced to Morse the passage of the bill granting the appropriation to build the line, selected this message from Numbers xxiii: 23: "What hath God wrought?" It was received by Vail in Baltimore and sent back. The strip of paper on which the Morse characters were printed was claimed by Gov. Seymour, of Connecticut, because Miss Ellsworth was a native of Hartford, and is now in the archives of the Hartford Athenæum.—*Chicago Journal of Commerce.*

USEFUL INFORMATION.

Cause of Thunder.

Many theories have been offered in explanation of the phenomenon of thunder. Here is Prof. Hirn's description: "The sound which is known as thunder is due simply to the fact that the air traversed by an electric spark, that is, a flash of lightning, is suddenly raised to a very high temperature and has its volume, moreover, considerably increased. The column of gas thus suddenly heated and exhausted is sometimes several miles long, and as the duration of the flash is not over the millionth of a second, it follows that the noise bursts forth at once from the whole column, though for an observer at any one place, it commences where the lightning flash is at the least distance. In precise terms the beginning of the thunder clap gives the minimum distance of the lightning, and the duration of the rolling of the thunder the length of the column of heated air. Professor Hirn also remarks that when a flash of lightning strikes the ground, it is not necessarily from the place struck that the first noise is heard. Again, he points out that a bullet whistles in traversing the air, so that we can, to a certain extent follow its flight. The same thing also happens with a falling meteorite just before striking the earth. The noise actually heard has been compared to the sound produced when one tears linen; it is due, really, to the fact that the air rapidly pushed on one side of the projectile in front, whether bullet or meteorite, quickly rushes back to fill the gap left in the rear."—*American Meteorological Journal.*

Fecundity of Sea-Fish.

Doctor Wemyss Fulton contributes a paper on this subject to the "Annual Report of the Fishery Board for Scotland" of 1890, wherein he states that the fecundity of over a hundred specimens of fish, comprising thirty-nine species, has been determined. The degree of fertility varies to an extraordinary extent among certain fishes, and according to the sizes of the individual. The ling produces a greater number of eggs than any other fish—twenty to thirty millions being an ordinary average among medium-sized and large specimens. On the other hand, the pipe-fish brings forth each season only a few hundreds, the eggs being taken charge of by the male, which carries them about in a compartment situated on its under surface. The cod produces from two or three to seven or eight millions of eggs; the haddock from two or three hundred thousand to nearly a million; the saithe from four or five to seven or eight millions; the torsk, or tusk, from about one to two or three millions. In the herring the number ranges from about twenty to about fifty thousand, the average for sixteen specimens examined being over thirty thousand, showing a considerably greater fecundity than has been generally supposed. Among flat-fish the most fertile is the turbot, with from three or four to nine or ten million eggs, and the least so, the long, rough dab, which produces from about thirty to sixty thousand. In proportion to its size, the flounder produces more eggs than any other fish, the number ranging from over five hundred thousand to about one and a-half million eggs. The common, or English sole, is also very fertile.

Facts About Our Railroads.

To gather the statistics from the corporations which operate the American railways is not a simple work of a day or so, but takes time. It is only just now that we know, from the government reports, what the railway business amounted to for the year ending June 30, 1890. The mileage at that time was 163,597, an increase during the year of 5838 miles. This increase, it is of interest to note, was greatest in that group of States formed by Kentucky, Tennessee, Mississippi, Alabama, Georgia, and Florida, where were built during the year 1370 miles, or 23 per cent. of the whole increase. In the State of Georgia the increase was 438 miles, and this was more than in any other State in the Union.

These roads are owned and operated by 1797 companies, but about one-half of the mileage is operated by forty companies. The gross revenue of these roads for the year mentioned was $1,051,877,632, but 80 per cent. of this revenue was divided among seventy-five roads. Large roads must do cheaper work than smaller ones, as these seventy-five roads carried 83½ per cent. of the passengers, and 85¼ per cent. of the freight. To operate the railways required the services of 749,301 men. This was an increase of 44,558 men over the previous year, and added an average of twenty men to the operating force on every 100 miles of road in the country.

In arriving at the capitalization of these great properties accurate statistics have been obtained on only 156,404 miles. The capitalization for this mileage is $9,437,333,372, or $60,340 per mile. At the same rate the capitalization of all the mileage would bring the total up to about ten thousand millions. This is certainly a great amount of money; but dividends were not paid during the year on 63·76 per cent. of the capital stock. The surplus from operating these roads was $12,070,383, a decrease of $7,387,155 from that of the year before. The passengers carried were 492,430,865, an increase of 20,250,322 and the average journey of each passenger was 24·06.—*Harper's Weekly.*

Financial Training for Children.

In this, as in all other respects, a child's individuality must be considered. One child requires a different training from another; but generally speaking there are only two wrong natural tendencies to be overcome by such training. These are the two opposite extremes of thoughtless extravagance and selfish hoarding.

Probably the vast majority of parents have the first difficulty rather than the second to contend with. Children are more apt to be thoughtless about money than to overvalue it. How, avoiding each great error, can they be taught its wise use? The school savings bank idea is helping to check the great waste of pennies and nickels which is constantly going on among the children; but parents have a duty and an important one in this connection. Few grown people seem to realize that right habits of both saving and expenditure do not come by nature but must be acquired, and that to assist a child in forming such habits is the truest kindness both to the present child and to the future man. A vast amount of unhappiness and of positive trouble might be prevented if parents would take careful thought about the training of their children in practical finance. There are questions of morals as well as of expediency concerned in it.

In what way can the thoughtless, extravagant little one be trained to prudence? In the first place do not give spending money irregularly, regulated only by the child's demands. Think over the matter and decide on a fair allowance, even if the plan is more trouble than to give according to the impulse of the moment. The amount once settled and stated to the child, on no account exceed it. Thus he may know what to expect and get out of the way of letting the pennies slip and continually teasing for more.

Require an account kept of his expenditures, and look it over each week before giving the next installment of the allowance. Here is an opportunity to give suggestions, but avoid severe criticism. A child will necessarily make some foolish purchases. Counsel rather than carp.

Arrange if possible for a larger allowance as the child grows older, with the understanding that certain personal expenses shall be met from it. These will vary with the age and ability of the boy or girl. One might be required to provide handkerchiefs, ribbons and gloves, another shoes and stockings or school supplies, books, pencils, papers, etc. Most young people would enjoy this responsibility; and the practical understanding of the value and purchasing power of money that comes of such training can scarcely be overestimated. Some instruction will be needed at first with regard to the quality of goods and the fair market price; but young heads are quick to learn. And they see, as they never would otherwise, the necessity of caring for their clothes when they buy them from their own private purse.

Teach the boy to weigh one purchase against another that he may learn to judge of relative importance. Show him that his candy and peanuts for the month would buy the fish-line or ball he wanted; both are merely for pleasure, but good things to eat last only a moment and are worth least of all pleasures. Weigh the expenditures for games with that for books, lectures, and scientific pursuits and show that instruction and amusement are worth more than amusement alone. Make him understand that a dollar may buy one of a dozen different dollars worth, but only one. To select one, excludes all the rest.

We are responsible for what we do not as well as for what we do buy. A good place to enforce this is in connection with the church and charity-giving. If such items are small, it is because others are too large.

Such training as this presupposes thought and time devoted to the matter; and thought and time are the very things parents are least willing to give their children. Yet to rear them to wise and noble man and womanhood, if they would but realize the mighty fact, not money nor luxuries nor even parental fondness is worth a thousandth part as much.

With regard to the selfish, stingy child, the same plan of an allowance, accounts and their inspection should be pursued, but with the different end in view of fostering liberality. Strive to make the child forget his mere personal wants, and draw out his sympathies for those around him and for all noble objects. Show him in conversation, and perhaps in extreme cases by a severe object lesson, how the close selfish theory of life would work toward him were it put in practice in the home. Be what you would have the child become. Surrounded by wide and noble sympathies it is scarcely possible for a child to grow up narrow and selfish.—*Amelia H. Botsford, in Christian Union.*

Scientific Advancement

Mortar Batteries and Long Range Rifles for the Defence of New York.

In addition to the modernizing of the existing forts in New York Harbor a new element of defence will be introduced in the shape of mortar batteries. As is well known, the mortar, or "bombard," was one of the earliest forms of cannon, and dates almost as far back as gunpowder itself. Not only so, but very large mortars were cast, and as long ago as 1857 a mortar was made in England carrying a shell 36 inches in diameter, and weighing with its bursting-charge, 3,000 pounds. A little later Armstrong introduced the *rifled* mortar, which has recently come so prominently into notice on account of its great range and accuracy.

The method of using mortars in sea-coast defence is to mount a large number of them in deep pits where they will be safe from direct fire, and after having obtained with one mortar the range of one or more of the enemy's ships, to fire a volley from the entire battery with the same charge and in the same direction so as to cover several thousand square yards of space, and thus multiply the chances of sinking the ships. This is something on the shot-gun principle, but as the shells weigh over 600 pounds, and fall from a height of from 1000 to 4000 yards, the penetrating effect is very great. As the decks of the heaviest iron clads are only about 4½ inches thick, and have an area of nearly *half an acre* each, the probability of sinking as well as striking a ship with a battery of mortars is excellent, while the mortars themselves and the gunners who serve them are comparatively safe. This is *not* magnificent, but it *is* war.

It is proposed to have mortar batteries so located as to command not only the channels of approach to our harbors, but also the positions likely to be occupied by an enemy's fleet in bombarding our forts or cities.

Another important element of offensive power to be added to our forts is the modern high-power rifle of from 8 to 12 inches calibre, and perhaps larger, these guns being very long, and using slow-burning powder, so as to give a very high initial velocity and a correspondingly long range, without overstraining the gun itself. Some idea of the enormous increase in range obtained with modern guns may be had from the "jubilee shot," so called, because it was fired in July, 1887, at Shoeburyness, during the Queen's Jubilee. This shot was fired from a 9·2-inch rifle, and attained a range of 21,800 yards, or more than 12 miles, and at its highest point was over 4 miles above the earth. This is the longest range on record, and would, of course, be of no practical use except in bombarding a city or some other extensive target. The chances of hitting a ship or a fort at that distance would be very slim; but it is desirable to have at least a few long-range guns to prevent a ship which carries such guns from taking up a position beyond reach of our guns and annoying us from a safe distance. It is to be noted that with guns of equal power a fort would have the advantage of a ship in both range and accuracy of fire. The range would be greater, because guns on ships are seldom so mounted as to allow firing at high angles of elevation, while the accuracy of fire would be greater on account of the more stable platform in the fort. The rolling motion of a ship has been known to cause such inaccuracy of fire that a broadside at close range would do no damage whatever to the enemy, the shot passing harmlessly over, or into the water beneath him.

One of the greatest dangers heretofore has been that an enemy in swift armor-clad ships would disregard the forts, and rush past them into our harbors. But this is now provided against by the use of fixed torpedoes, whose mission it is to hold the enemy in check until the guns or movable torpedoes can get in their work. The torpedoes must be planted, if possible, under the guns of the forts, so that their removal by the enemy would require him to come within the effective range of our batteries. The exact location of the torpedoes would, of course, be unknown to the enemy, and the mere suspicion of their existence would inspire due caution on his part. It is pretty well settled by the best naval as well as military authorities that no commander of a ship or fleet would be justified in disregarding a torpedo-blockade, or in attempting to remove such obstructions as long as their shore connections are held by the defence.—*Harper's Weekly.*

Electricity's Rival.

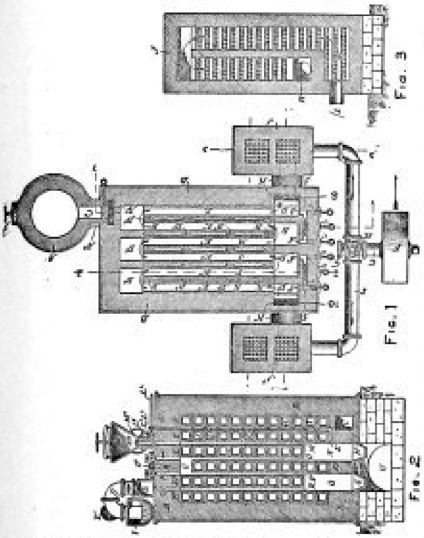
Progress in the development of electricity has been so rapid during the last few years that the public has come to regard it as the motive power of the future, but it appears that electricity is to have a rival in the shape of compressed air. Robert Gillham, an engineer of New York, has recently returned from an extended sojourn in Paris, where he made a thorough study of the compressed air system of the metropolis. The new dynamic agent according to his report, has within an almost incredibly short time fairly revolutionized many lines of industry at the gay French capital. It is at this time propelling surface cars with unequalled ease, furnishing motive power for elevators, and a multiplicity of uses, manufacturing ice and preserving meats of all kind. The air is compressed at a large central station and conducted through mains in the streets to all parts of the city, as are water and gas.

The method of using the compressed air in engines as described by the engineer, is interesting. The air is admitted from the main through a pressure reducing valve by means of which the pressure can be adjusted to any number of atmospheres desired. From the reduction valve the air is conducted to a small coke radiating device in the shape of a hollow cylinder having vertical divisions where the air is heated. The coke is burned in the central space and the air passes up and down the other vertical divisions in succession until it has reached a high temperature. The air is then conducted to the engine, where it operates exactly as steam. Once in the engine it is made to do all sorts of labor, not the least of which is the generation of electricty for lighting and other purposes.

One fact of importance noted by Mr. Gillham on his visit was the preparation Paris engineers are making by means of compressed air with a view to averting the terrors of another siege such as was experienced in 1871. Refrigerator stations can in an emergency to be made to contain enough food to last Paris for over a year. Mr. Gillham thinks that both the smoke and steam nuisances will be obliterated by the encroachment of the compressed air system in every line of dynamic application.—*Chicago Journal of Commerce.*

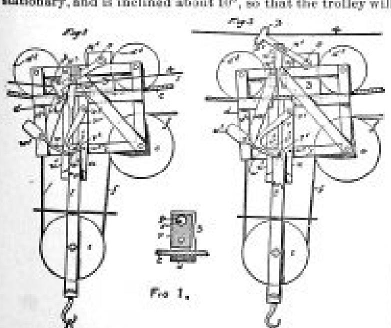
GAS APPARATUS.

No. 463,139. JOSEPH H. COLLINS AND ISAAC N. KNAPP, PHILADELPHIA, PENNA. *Patented Nov. 17, 1891.* This apparatus is designed to make gas for metallurgical purposes from powdered carbonaceous material. A horizontal section near the middle of the height is shown in Fig. 1. Fig. 2 is a vertical cross section near the middle, and Fig. 3 is a vertical section of the regenerator J along the line 3, 3. Ordinary producer gas is supplied by the producer A, through the flue C, Fig. 2, which runs to the front end of the furnace B. Here the gas rises through a vertical flue 8, and runs horizontally along the flues E to the chamber D^4, and back toward the front again, as shown by the arrows—until it finally escapes from the chamber D^3, through the pipe K to the regenerator J^1. To burn this gas, air is let in through the front by the stoppers d, d^1, d^2 d^3 as required to maintain uniform combustion in all the flues. The air comes in by the vertical flues shown in the front in Fig. 1, and through the regenerator J, which heats it to a high temperature. The course of the air is shown in Fig. 3, by the arrows. The flues E are made of hollow square tiles as shown in Fig. 2, which are laid so as to leave narrow vertical spaces or retorts L, M, O, P, R, extending from top to bottom of the furnace. Powdered coal or other fuel is fed from the hopper M^1 into the top of the space or retort M, and as it works downward it becomes highly heated, the gas is liberated and the remainder reaches the chamber N in a state of incandescence. At L^1 it is met by a current of steam blown in from the pipe L^2 down through the space or retort L, which highly superheats it. The steam is decomposed by the glowing fuel at N, and water gas composed of carbon monoxide and hydrogen is rapidly formed and mixed with the coal gas liberated in the retort M. The mixed gases pass upwards through retort O to the chamber C^1, where oil is injected by the pipe O^1. The oil is quickly gasified by the intense heat, and mingles with the other gases, which pass down the retort P to the chamber Q, where they drop any dust carried over from chamber N, into the dust-pan Q^1. In passing through the retorts P and R the gases are practically united and fixed, and they pass out of the furnace by the siphons S^1 and hydraulic main T. The exhausting fan F serves to draw the products of combustion of the firing gas through the regenerator J^1 while the fresh air is drawn in through J. As soon as J^1 is thoroughly heated and J is cooled as far as allowable, the four way valve H is reversed and the air and gas currents are reversed. Another valve not shown changes the current of firing gas from the producer A from the flue 8 to flue 10, and reverses the path of the flame in the flues E. The gas made by this process is without nitrogen and possesses great heating power.



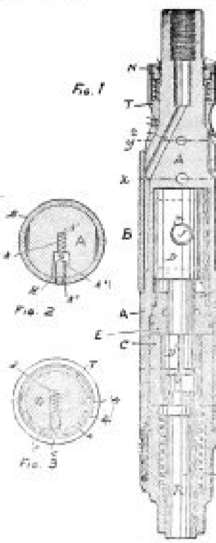
TROLLEY FOR AERIAL ROPEWAY.

No. 466,279. CHARLES M. NORTH, MONTCLAIR, N. J. *Patented Dec. 29, 1891.* In this ropeway the main cable is stationary, and is inclined about 10°, so that the trolley will run one way by gravity. The trolley is hauled back by the fall rope f, and it is locked in any position by gripping the cable. This is done by a hand line 4 which extends from tower to tower over the main cable. When the line is slack as in Fig. 2, the arm s^1 lays down, but when it is tightened as in Fig. 3, the arm is raised. The shaft v has an eccentric inside the box 3, as shown in Fig. 1, and as it is turned it moves the block r downward and grips the cable between r and s. When the line is slackened the weight of the arm opens the grip. The block i is locked to the trolley by raising it nearly to the top of its lift, so that the pin t^1 shoves the curved end r^2 of the hook r aside and passes above it. The hook drops back by gravity and catches the pin as the fall rope is eased off. By hauling in or paying out the fall rope the trolley may be moved along the cable, as desired. To unhook the block the trolley is gripped to the cable, and the fall rope hauled in. As the block rises the pin t^1 strikes the body of the hook and crowds it back so far that the catch w catches the notch on its lower end and holds it out of the way of the pin. As the block lowers the pin t^1 trips the catch w, as shown in Fig. 3, and lets the hook drop back into place for future operations.



PNEUMATIC TOOL.

No. 461,706. FRANK H. MARSH, NEWARK, N. J. *Patented Oct. 20, 1891.* This tool is designed to strike with great rapidity on the head of a rod R to which a chisel or other tool is attached. The blows are comparatively light, but their great number per minute make them very effective. The piston D is propelled by compressed air which enters by the duct 2, and escapes by the duct 3. The necessary ports are formed by grooves in the outside of the cylinder A, which are covered by the sleeve B. This sleeve is forced on tightly and pinned in place. A small piston valve J moves crossways of the piston D in a seat drilled through the piston, and admits air alternately to the top and lower ends of the cylinder, and also exhausts the spent air into duct 3. The top end of the cylinder is made conical as shown, and is covered by a cap or throttle T. This is provided with several holes 4, of varying size. By turning this cap the duct 3 can be throttled to any desired extent to regulate the rapidity of the strokes, or closed, to stop. The lower head of the cylinder E has a projecting collar 5 which enters the cupped end of the piston D and cushions the blow on the entrapped air, when for any reason the rod R does not come up far enough to receive the blow, the striking head D^1 is renewable. Fig. 2 is a a cross section at the line x, and Fig. 3 is a cross section on the line y, showing the graduated exhaust openings 4, and the spring pin used to hold the cap in place when adjusted.



HYDRAULIC VARIABLE SPEED GEAR.

No. 466,661. LOUIS DUNCAN, BALTIMORE, MD. *Patented January 5, 1892.* In this device a rotary pump is driven by any suitable power, and the liquid discharged by it, preferably oil, is driven through a rotary motor or pump which is attached to the shaft to be driven. To vary the speed of this shaft, the motor is so constructed that the eccentricity of the hub, or of the casing, can be varied at will, thus varying the effective radius of the paddles, and the quantity of liquid used. In Fig. 2, the pump is shown mounted on a loose sleeve B on the driven shaft C^1, and is driven by power applied to the wheel A. D is the casing and G G are the paddles. The motor is of similar general construction, having a fixed casing F, paddles G^1, and a central hub H^1 having a center hole much larger than the shaft. The central hub has a tubular neck H^2 which is encircled by a collar N. A screw L^1 is operated by a crank or wheel on its top end, and serves to move the collar and the center H^1 from the position shown in Fig. 3, to that shown in Fig. 4, thus giving the paddles on the top side of the shaft greater leverage than those on the lower side, and requiring more liquid to fill the spaces between them. As the supply forced in by the pump is steady, the motor runs slower, but with proportionally greater force, thus adapting itself to the heavy strains of stopping and starting cars and other machinery. The ports P, P^1 of the motor are directly connected to the ports of the pump, forming a closed liquid circuit. The pump may be situated anywhere, at any distance from the motor, and the ports may be connected by suitable pipes. A yielding connection is made between the hub H^1 and the shaft C^1, by four springs k, as shown, which allows H^1 to be shifted without losing its hold on the shaft.

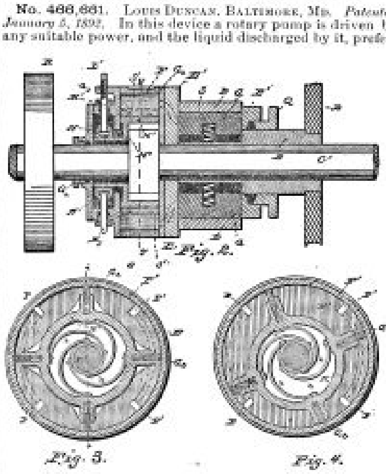


Fig. 3. Fig. 4.

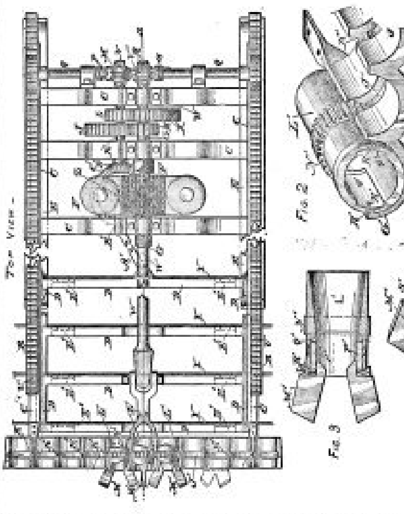
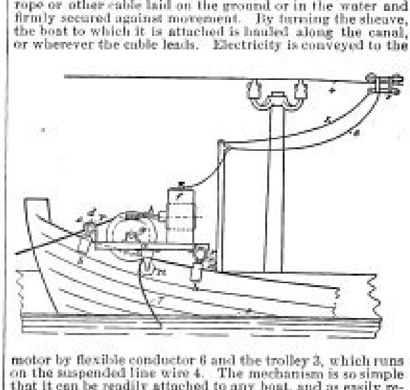
MINING MACHINE.

No. 465,197. JAMES PASSMORE AND PETER A. ARP, PHILIPSBURG, PENNA. *Patented Dec. 15, 1891.* The cutter blades M^1 are each provided with a shank P^8 shaped to fit in a socket Q^8 in the front end of the sleeve L^2. A series of these cutter sleeves are supported in a long cross-head at the front of the machine. The cross head is made in halves, and clamped together the top half being readily removable. Each sleeve has a thrust collar on its front end, and a cog wheel N^1 in the middle. The sleeves lay so close together that the cog wheels mesh and turn each other. The middle sleeve is turned by the shaft W which is below the motor shown, and is connected to it by gears X and L. The cross-head is attached to two racks U which slide in ways on the main frame and serve as guides. The cutters are fed up to their work by pinions on the shaft Q at the rear of the machine. This shaft is driven by clutches P and S, which are moved by a hand lever (not shown), and which engage the worm wheels N and R which turn loosely on the shaft. These worm wheels are driven in opposite directions by worms M and V on the shafts K and W. Four scrapers Y are employed to remove the chips. They are flat plates hinged at E^1 to a sliding frame D, in such a way that they can swing upward to pass over the dirt in moving forward, but stand vertically while moving backward. The frame D is reciprocated by a pitman A^1 and crank B^1 on the lower end of the vertical shaft Z, which is rotated by the bevel gears C^1 D^1 as shown.



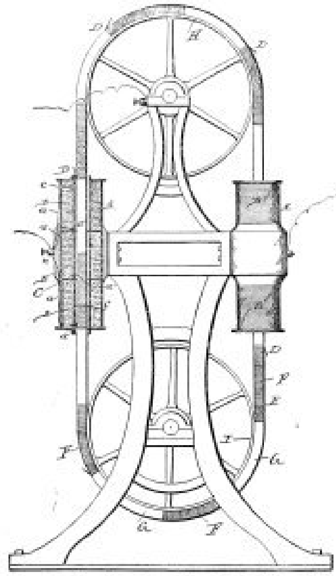
TOWING BOATS BY ELECTRICITY.

No. 464,955. OTTO BUSSE, ODERBERG, GERMANY. *Patented Dec. 15, 1891.* An electric motor f, drives a worm wheel g, and a sheave wheel h. This sheave engages a wire rope or other cable laid on the ground or in the water and firmly secured against movement. By turning the sheave, the boat to which it is attached is hauled along the canal, or wherever the cable leads. Electricity is conveyed to the motor by flexible conductor 6 and the trolley 3, which runs on the suspended line wire 4. The mechanism is so simple that it can be readily attached to any boat, and as easily removed therefrom. A similar apparatus could be fixed to a common dirt car or even a road wagon, and be used for haulage on common roads, for quarries and similar uses, with great advantage.



ELECTRIC MOTOR.

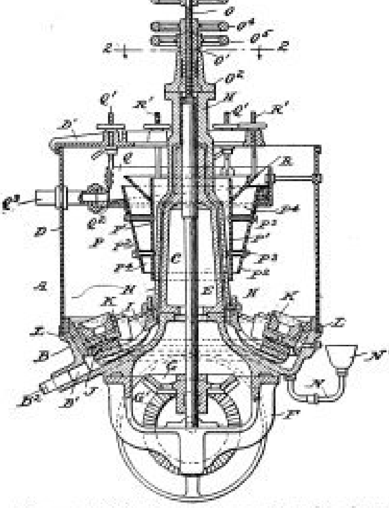
No. 464,063. MARTIN H. COLLOM, DENVER, COLORADO. *Patented December 1, 1891.* This motor consists of a pair of solenoids or open coils A fixed to the sides of the frame shown, and an endless core composed of alternate magnetic and non-magnetic portions. The endless core runs over sheaves I and H. Sheave H is electrically connected to one pole of the battery or dynamo, and the other is connected to the driving solenoids A. The magnetic sections F are electrically connected together by conductors in the non-magnetic sections G. Brushes D project from



the front end of each section F, which rub against contact strips *a* on the inside of the solenoids, and complete the circuit. As a magnetic section F touches the end of the solenoid and establishes a current in it, a powerful attraction is instantly exerted by the solenoid to draw F to the center of the coil. Before it arrives at that point the current is interrupted, and the opposite solenoid is excited and continues the motion of the core until another magnetic section arrives at the first solenoid and excites it. Any number of solenoids may be employed to increase the power of the motor.

GRINDING AND AMALGAMATING MILL.

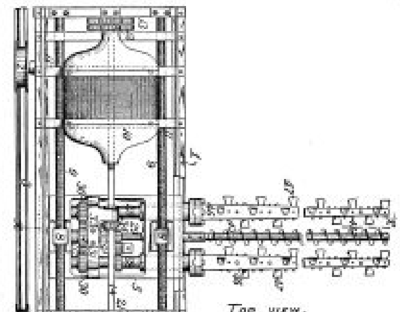
No. 461,162. GEORGE FRASER, AUCKLAND, NEW ZEALAND. *Patented December 29, 1891.* The pan B is stationary, and is provided with a ring die L. The muller H is turned by the shaft E, and carries a spider I at its lower end, which supports a ring J. A series of conical rollers K lay on top of the ring J, with their peripheries against the ring die L. When the spider revolves, the rollers are crowded by centrifugal force against the die L, and they rub against each other, thus thoroughly grinding the crushed ore in the tub D to pulp. Mercury is introduced by the pipe N and cup N^1, which is set above the bottom of the pan. The amalgam is drawn off by the outlet B^1 and the plug B^2. The tailings pass up between the circular shells P^1 and P^2



which are attached to the overflow pan P^4, and to the top by suitable bolts. The inner shell is straight and is fitted with a movable collar R which can be adjusted by the hand wheels R^1 to control the outflow of water and tailings which pass away by the spout Q^1. These two shells serve to protect the tailings at the point of overflow from the whirling water and commotion in the tub, thus giving them a chance to separate by gravity. A muller of five feet diameter grinds from 500 to 800 lbs. per hour, at about 70 revolutions per minute, of stuff passing a half-inch sieve. The machine dispenses with the use of gratings or screens, copper-plate tables, riffles, blanks, and berdans. The machine further reduces the loss of quicksilver to a minimum, and also permits of reducing low-grade ore at a profit.

MINING MACHINE.

No. 465,150. JOHN C. WERNER, BALDWIN, PENNA. *Patented Dec. 15, 1891.* Two cutter bars 46, are employed in this machine, with a worm or conveyor 43 between them to carry away the chips. The cutter bars are bolted by flanged joints to the ends of the shafts 28, each of which has a pinion 30 meshing with wheel 32. This wheel is driven by the pinion 31 above it and the bevel gears 33 and 34. Motion is given to 34 by a square shaft 14 which is driven by gearing at the motor end of the machine from the motor 10, as shown. The cutter spindles 28 and their attachments are



TOP VIEW.

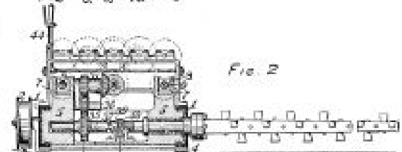


FIG. 2

mounted on a carriage 5, which slides on ways on the main frame 1. The carriage is fed either way by the screws 9 and nuts 8. The screws are turned by the gearing shown at the right hand end of the machine in the top view and by dotted lines in Fig. 2. Friction clutches 16 and 18 are employed to change the speed of the screws. 16 is attached to small pinion 22, and 18 carries a larger pinion 21. Another clutch 37, Fig. 2, is employed to disconnect the driving gears on the carriage from the cutter spindles. The front side of the machine slides on a shoe bar 4, and the rear is supported by truck wheels 2, designed to run on a rail 3.

HOISTING DRUM.

No. 466,158. WILLIAM C. DAVIS, DENVER, COLO. *Patented Dec. 29, 1891.* The friction disc 4 is driven by the bevel gearing shown in Fig. 1. The drum carries a ring X, having a V-edge adapted to the groove in the friction disc. The drum is pressed endways against the friction disc by a screw 2, which is turned by the arm O, which is attached by the link Z to the hand lever y. The brake employed is the well known "differential" brake, consisting of the strap F which is fastened at one end to the long arm A of a lever, and at the other end to the short end C, of the same lever. As the lever moves one end of the strap is slacked off and the other end is drawn up, and the strap is tightened by an amount equal to the difference between the movement of the pins at A and C. When the drum moves with the arrow K for

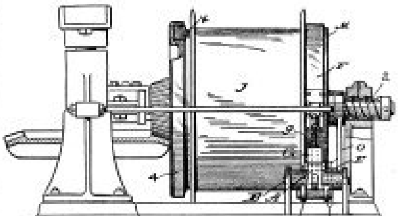

FIG. 1

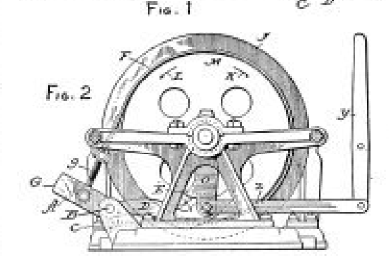
FIG. 2



hoisting the brake lets go automatically, because the arm A slacks off the strap faster than arm C takes it up. When the drum moves with the arrow L, for lowering, the brake tightens itself. To prevent the closing of the brake when not desired, the bent arm D is added to the brake lever A C. When the lever O is moved to the left the drum is forced against the friction disc for hoisting, and the brake is free to slacken itself, and when O is in middle position, as shown in the end view, the drum is released and the brake is free to catch it and hold the load. But when it is moved to the right it depresses the arm D of the brake lever, and slacks the brake suitably for lowering.

TRAVELING GRATE.

No. 465,295. ROBERT J. SHOEMAKER, PHILADELPHIA, PA. *Patented Dec. 15, 1891.* This grate is composed of a series of grate bars 9, of any ordinary construction, which are provided at each end with jaws 12, Fig. 2, on one side, and lugs 13 on the other, which are adapted to pass between the jaws 12 of the next bar. Bolts 14 are used to connect the sections together. The ends of each bar are shaped as at 10, to suit the teeth of the sprocket wheels 7, one of which is located at each end of the fire-box. The fire-box is constructed with flanges or ribs A which project

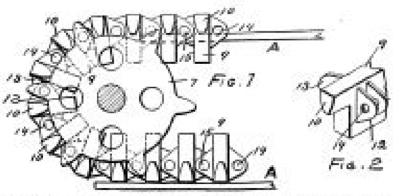


FIG. 1 FIG. 2

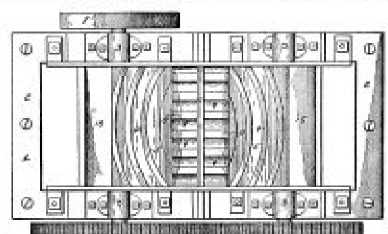
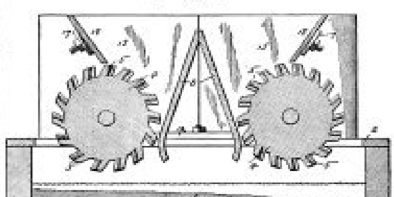
under the ends of the grate bars and support them when moving. the grate may be inclined to any desired angle, and the bars may be designed to suit any variety of fuel. The sprocket-wheels may be driven by power for continuous firing, or they may be moved by hand for occasional removal of the ashes.

COAL BREAKER.

No. 466,185. PHILIP RICHARDS, PLYMOUTH, PENNA. *Patented Dec. 29, 1891.* The novelties in this breaker, are the inclined crushing plates 8 between the rolls, and the curved ribs or teeth 5 on the body of the rolls. The plates 8 are made with deep V grooves 9 running vertically on their faces, and the ribs on the rolls are curved in such a manner



TOP VIEW.



CROSS SECTION

that the coal is crowded toward the middle of the rolls and away from the side housings. The groves 9 serve to guide the coal past the rolls. Thus each roll is independent of its mate and crushes the coal against the plate 8, instead of the teeth of the opposite roll, as in the common type of breaker.

The Weather at Girardville, Schuylkill Co., Pa.

From the records of Mr. E. C. Wagner, of Girardville, Pa., Superintendent of the Girard Water Co., and voluntary observer United States Signal Service, it appears that the chief features of the climate at that point, in 1891, was as follows:

Highest reading of Barometer, December 31st	30·531 inches.
Lowest reading of Barometer, January 23d	29·429 inches.
Highest reading of Thermometer, June 15th and 16th	92°.
Lowest reading of Thermometer, March 2d	7°.
Range of Thermometer during the year	85°.
Total snow fall for the year	42·75 inches.
Total precipitation for the year	62·44 inches.
Average monthly precipitation	5·203 inches.
Greatest monthly precipitation, July	9·64 inches.
Least monthly precipitation, May	1·80 inches.
Greatest daily rainfall August 23d	3·50 inches.
Precipitation 1887	48·73 inches.
Precipitation 1888	62·62 inches.
Precipitation 1889	70·27 inches.
Precipitation 1890	64·65 inches.
Precipitation 1891	62·44 inches.

PERSONALS

MR. JOHN FULTON has resigned from the arduous duties of General Manager of the Cambria Iron Co., and has been succeeded by Mr Chas. S. Price. Mr. Fulton has been reappointed to his former position of General Mining Engineer of the company. In his resumption of his old position he will be relieved of a great many duties that have been particularly arduous, since the great flood of May, 1889. He went through all the horrors of the disaster and keenly felt the loss of townsmen, acquaintances, and intimate friends, and in addition witnessed the destruction wrought in the magnificent plant of which he was the directing head. He has ably filled the position in which he was placed, and under his direction the restored plant of the Cambria Iron Co. has been made more perfect than ever, and he no doubt will enjoy the relief that will come to him in resuming his old and less laborious office.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 9. SCRANTON, PA., APRIL, 1892. WITH WHICH IS COMBINED THE MINING HERALD

THE ECONOMIC GEOLOGY OF ZINC.

The Mineralogy, Mode of Occurrence, and Production of Zinc.

BY H. A. WHEELER, E. M., OF ST. LOUIS.

The number of minerals that contain zinc is not large, and there are only three which are found in sufficient quantities as to be of importance as ores, except at a peculiar local occurrence in Northern New Jersey. These three common ores of zinc are the sulphide, carbonate, and hydrous silicate, and the two latter are due to the alteration by the atmospheric agencies of the sulphide, and hence change into it as depth or the permanent water-level is attained. They have the following characteristics:

Sphalerite, or *Zinc Blende*, is a sulphide of zinc containing about 67% of zinc when pure, and has a non-metallic luster, a yellow to brownish streak, is rather soft, and only moderately heavy (specific gravity is 4·0). It varies in color from white to yellow, red, brown, and black, and is known by the miners under the names of "rosin-jack," "ruby-jack," and "black-jack," according to the color. It is the principal ore of zinc from which by far the larger portion of the world's production of "spelter" is obtained, the latter name being the one under which zinc is sold in the metal market.

Smithsonite, or "dry bone," or "white-jack," is a carbonate of zinc containing about 52% of zinc, when pure; it has a non-metallic luster, usually a yellow to brown color, is quite hard and rather heavy (specific gravity is 4·2). It is generally earthy or massive, usually lacks any decided individuality, and is nearly always stained yellow or brown by iron, though white or colorless when pure.

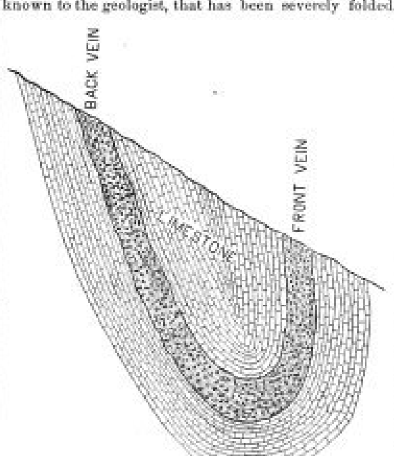
Calamine, or "silicate," is a hydrous silicate of zinc that contains about 54%, when pure; it has a vitreous or glass-like luster, is usually white or brown-colored, rather hard, and moderately heavy (specific gravity is 3·5). It nearly always occurs in crystalline, radiating masses or as small thin-bladed crystals.

In Sussex County, in Northern New Jersey, there occurs, in the vicinity of Franklin Furnace, a peculiar group of zinc minerals that have never been found elsewhere in workable quantities. They occur intimately associated together, are remarkable for their purity, and have thus far proved to be very persistent and reliable in their occurrence. These zinc ores are:

Zincite, or oxide of zinc, containing 80% of zinc, when pure; it has a red color, an orange colored streak, is quite hard, heavy (specific gravity 5·0), and has a non-metallic luster.

Willemite is an anhydrous silicate of zinc containing 58% of the metal; it has a brown to greenish color, a non-metallic luster, is hard, quite heavy (specific gravity 4·0), and generally occurs in granules.

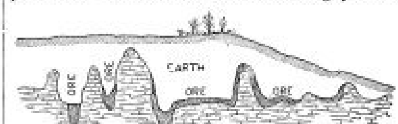
Franklinite is a black mineral with a metallic luster that is very hard, heavy (specific gravity 5·0), and usually occurs in granular masses. It consists of a variable mixture of oxides of iron, manganese, and zinc, and contains from 8 to 20% of metallic zinc. It is too low grade to be used by itself for making spelter, but is quite largely used for making oxide of zinc or "zinc white" that is so extensively used as a paint. These last three zinc minerals are not only unique in their composition and association, but their mode of occurrence is equally as interesting. They are found more or less intermixed in a highly disturbed belt of white crystalline or metamorphosed limestone that is of Archæn age, or amongst the very oldest rocks known to the geologist, that has been severely folded.



SKETCH A.—CROSS-SECTION OF THE STIRLING-HILL VEIN.

This folding has been so sharp as to cause the vein that carries the zinc minerals to double on itself and to again crop out close to and nearly parallel with the original outcrop. This doubling of the vein on itself was not at first suspected by the miners, though predicted by Dr. Cook, the geologist, and they were worked as two independent veins, known respectively as the "front" and "back" veins, each having a different pitch and somewhat different strike; when the workings were extended deeper, the two veins were found to be approaching each other, until finally at the South end of Stirling Hill, they united as one simple folded vein, as shown in sketch A. The vein conforms in strike and pitch with the enclosing crystalline limestone, and has been traced for a distance of four miles, though a large gap occurs in the central portion where the vein *seems* to be absent. The vein varies from five to forty feet in width, and while the general tendency is for these three valuable zinc minerals to occur intermixed, there is frequently and at times a quite persistent segregation of the zincite and franklinite into separate distinct sheets or "veins." Prolonged and costly litigation has largely curtailed the working of the several mines located along the vein, so that the deepest is less than 400 feet; but now that the titles have at last been cleared, the output from this small but important district ranges from 50,000 to 60,000 tons of ore a year, which goes to Newark, and Jersey City, New Jersey, and Bethlehem, Pa., to be smelted.

In the Saucon Valley, near the town of Friedensville, Pa. (four miles from Bethlehem), occur deposits of zinc that have become famous on account of the purity of the spelter made therefrom. The zinc occurs as very irregular deposits in a hard, compact, bluish limestone that vary from mere seams to bodies forty feet in thickness, which is now blende, since the water-level has been reached, while in the upper workings the ore was oxidized to the silicate and carbonate. The blende has a very unusual compact structure with a dark-gray to bluish color, and so closely resembles the limestone in which it occurs as to be distinguished from it with difficulty. No other minerals occur with the blende, except iron pyrites, so that an exceptionally pure grade of spelter is obtained on smelting this odd ore. Some of the mines were so wet as to necessitate their partial abandonment, on account of the excessive quantity of water that had to be pumped, and at one of them is located the famous pumping engine "President," long known as the largest pumping engine in this country. This engine was designed to operate three pairs of 30-inch pumps, and one pair of 22-inch pumps, all of ten feet stroke, by means of a steam cylinder 110 inches diameter by 10 feet stroke, making six to seven strokes per minute. This district has not been a large producer



SKETCH B.—SECTION OF THE BERTHA ZINC MINE, VA.

for some time, on account of the trouble with water, and all the ore now goes to Bergenport, N. J., to be smelted.

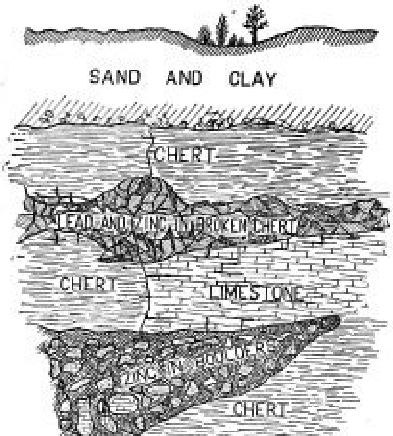
A very interesting deposit of zinc occurs at Bertha, Wythe County, Va., where under a cover of earth that varies from 10 to 100 feet in thickness, an irregular residual deposit of the carbonate and silicate of zinc is found resting on limestone, or flanking pinnacles of limestone that rise well up into the overlying earth, or filling up pockets at the base of the pinnacles and hummocks of the limestone, as shown in sketch B, after McDowell. The ore sheet, or rather accumulation of ore, is usually from one to three feet in thickness, though some of the pockets carry quite large bodies of ore, while in other places the limestone is quite bare of ore. The ore is very free from lead, yielding a high quality of spelter, and it is mined by stripping off the heavy over-burden of earth.

The Bertha mines belong to a series of deposits of zinc and lead-bearing limestones that are said to extend for over 100 miles West of Roanoke in South-Western Virginia, which are oxidized ores or either the carbonate or silicate, as far as they have been worked, but which in depth will undoubtedly run into the sulphide or blende. While this series of deposits have not thus far been extensively worked, except at Bertha and Roanoke, they seem to be quite promising, and probably will become important producers in the future.

The Upper Mississippi Valley lead district contains more or less zinc in association with the lead, and while the zinc was thrown away in the early history of this region by the miners in their search for lead, the zinc has caused the re-opening of old abandoned mines, and infused new life into mines that formerly marketed only the "mineral," as the miners term the galena or lead ore. As this district was described in the article on lead in THE COLLIERY ENGINEER of December, 1891, a description of it will not be repeated here, though it was the joint proximity of coal, and the quite large production of zinc ore by this region that caused the erection of the zinc smelters at Peru, and La Salle, Illinois, of which the latter is by far the largest zinc smelter in this country.

The Central Missouri lead region has also produced some zinc in connection with its lead ores, but no large amounts of zinc have been found, and it has been regarded as a by-product in mining the lead ore. The South-East Missouri lead region, where the galena occurs disseminated in the limestone, does not carry any zinc.

The South-West Missouri lead region was originally opened and formerly exclusively worked for lead, and what zinc (either as "white-jack" or as "rosin-jack") was obtained with the lead, was thrown away on the dump. To-day this same region has become the heaviest zinc-producer in the United States, while the lead is now saved as a by-product in working the mines for the zinc. For, since we have begun to smelt our own zinc-ores and cease to depend on the foreign producers, the price of zinc ore has so risen that it is now more profitable to work them than to seek after the associated galena



SKETCH C.—SECTION OF A JOPLIN ZINC DEPOSIT.

This region may be said to have its center at Joplin, in Jasper County, which is one of the oldest mining camps of the district, and to extend as far West as Cherokee County, Kansas.

The ore is almost exclusively blende, which is usually yellow colored, and is most appropriately called "rosin-jack" by the miners, as it strongly resembles common rosin. Some carbonate (or smithsonite) and silicate (or calamine) has been found near the surface, but except at Granby, in Newton County, Mo., the amount obtained of these oxidized ores has never been large. Variable amounts of galena or sulphide of lead occurs with the zinc, which at times is quite important, especially in the upper part of the ore-bearing stratum, but in most cases the amount is rather too small to be of great commercial importance, though there is always enough to injure the quality of the spelter obtained therefrom, so that it rates as a second quality when compared with the purer ores of the Franklin District, New Jersey, or the Friedensville Mines, of Pennsylvania.

The ore occurs in irregular bodies and caves in a cherty limestone formation of sub-carboniferous age, or just below the coal measures. In the ore-bearing limestone occur "bars" or strata of chert that are usually highly shattered and broken, and the ore is found filling the numerous cracks and fissures in the chert as shown in sketch C. The ore-bearing horizon has not been worked to a greater depth than 200 feet, and most of the mines are very shallow, or less than 100 feet deep. More or less tough yellow to brown residual or "tallow" clay occurs with the zinc, besides iron-pyrites, calc or lime spar, dolomite, and galena. A local custom largely prevails in this district of leasing out the mineral-bearing lands in small lots that are usually 200 feet square, on a royalty of 10% to 25%. A so-called land company will sink a central shaft by which the adjacent territory is drained, and will then lease out the adjoining lots to any miner or prospector who is capable of sinking a small working shaft and can carry on the crudest kind of mining and ore-dressing. The outlay involved on the part of the miner in equipping his lot with a kit of hand-mining tools and a hand-windlass or horse-whip or whim for raising the ore, is so small, that almost no one is debarred from lack of capital, with the result that most of the ore is produced by a large army of small independent leasers. The ore requires concentration before it is salable, as it will only run from 10 to 30% as mined, so that a hand-jigging outfit is the usual accompaniment of the lot leasers, though a few large power or steam concentration mills have been erected by some of the larger companies. The dressed or cleaned ore will run from 50 to 62% in zinc, which is sold on the ground to traveling buyers that are kept constantly in the field by the numerous smelters in Missouri, Kansas, and Illinois, that depend on this district for their ore supply. The price of the dressed ore fluctuates considerably, dependent on the quality and usual market conditions, and first-class ore is liable to fluctuate from $20 to $28 a ton. Recently some sales have been made to English smelters, who in spite of the heavy charges that the ore will have to bear in being shipped to Swansea, still regard it as more profitable to buy than their own lower grade home ores.

Associated with the argentiferous lead-ores of Leadville and Central City, Colorado, are quite large quantities of zinc-blende which generally contain so much iron as to be black or dark-brown in color. The blende does not usually contain sufficient silver to permit being profitably worked as a silver-ore (or from 5 to 15 ounces per ton), while it is too intimately associated with the lead and iron ores to permit the zinc to be profitably extracted in the attempts that have thus far been made to work them. Large quantities of this impure blende is being stocked as tailings by some of the concentrating mills of Leadville, which in time will probably be profitably worked when the local market has enlarged and the cost of working will have been cheapened. Many other of the Rocky Mountain silver-lead mining camps produce similar argentiferous blende, which is too low grade to work for its silver contents by the present processes, and is too far away from cheap facilities for smelting and marketing the zinc to be of value for spelter. Recently a mine having a large body of zinc ore near Socorro, New Mexico, has been able to profitably ship its ore to the La Salle smelter, at La Salle, Ill., and in time this will undoubtedly be followed by others of the numerous scattered zinc producing mines of the Far West when the conditions improve as regards cheaper labor and more reasonable railroad freights.

Some of the silver veins in Maine carry considerable blende which is too low grade in silver to pay as a silver ore, and which is too impure with lead and occurs in insufficient quantity to permit being profitably worked as mere zinc mines, and this same remark can be extended to similar deposits that occur in the Southern States, especially in the Carolinas. Small amounts of zinc ore have been mined and shipped to the New York Bay smelters from Tennessee, but the quantity has thus far been small and the shipments are quite irregular.

Arkansas contains some zinc in the form of blende in association with the sulphides of lead, iron, and copper, in the central part of the state in fissure veins, but the veins have not thus far proved profitable. Close to the Missouri border, in Marion County, occur a very different class of zinc deposits in limestone and chert that are likely to become quite productive when the district enjoys favorable railroad facilities from which it is now debarred. The ore, as blende and carbonate, occurs in flats or sheets so intermixed with the chert as to require concentration, before it can be shipped during the high water season by flat-boats down the White River to the Iron Mountain R. R., and thence to St. Louis for a market. The region is so inaccessible that most of the land is free, and the claims are located according to the U. S. mineral statutes, or in parallelograms 1,500 by 600 feet.

The production of spelter (or metallic zinc) in the United States for the year 1891 is estimated by the *Engineering and Mining Journal* at 76,500 short tons (2,000 lbs.) Of this amount, the Eastern Zinc Works, located at Bertha and Roanoke, Virginia; at Lehigh, Pa.; at Bergenport, Newark, and Jersey City, N. J., furnished about 12,000 tons. The balance came mostly from the South Western Missouri district, which sent its ores to five works adjacent to this region in Kansas that produced about 20,000 tons; to four works in Missouri that produced about 16,000 tons; and to three works in Illinois that are credited with a production of over 28,000 tons, the larger portion of which came from the huge establishment of Mathieson & Hegeler, at La Salle.

In the world's production of zinc the United States is decidedly eclipsed by the enormous output of the mines in Belgium and the adjacent Rhine provinces, which, as a group, stand conspicuously in the lead. Silesia ranks second, and before we were able to supply our own markets, this was one of the most important of the foreign brands in our market, on account of its purity. Our production ranks third, as may be seen from the following figures of the world's production for the year 1890, in gross-tons (of 2,240 lbs.)

WORLD'S PRODUCTION OF ZINC IN 1890, IN GROSS TONS.

	Tons.		Percentage.
Belgium and Rhineland	137,630	or	40%
Silesia	87,175	or	25%
United States	60,020	or	17%
Great Britain	29,145	or	9%
France and Spain	18,240	or	6%
Austria	7,835	or	2%
Poland	5,030	or	1%
Total	343,265	tons, or	100%

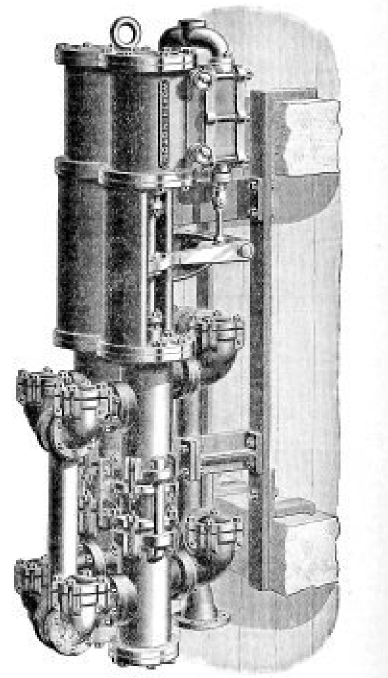
The Worthington Sinking Pump.

Of all the situations in which steam pumps are required to work, none are, in all probability, so exacting as where they are used in sinking mine shafts and recovering flooded mines.

The work is rough, severe, and continuous, calling for great care in the selection of the materials of its construction and a design combining great strength with simplicity and compactness, and what is also very important, employing the least possible amount of shaft space.

The necessity for an efficient steam pump embodying the above requirements which should be positive in operation and quiet in its action, has long been felt, and the sinking pump shown has been designed in order to meet all the conditions mentioned, and possesses some additional features which are new and cannot fail to be appreciated by mine men and others who use pumping machinery of this class.

In the first place, the pump is duplex, and being fitted with the well known Worthington Valve Motion, its operation is positive, therefore, it is always ready to start and when running there is an entire absence of the concussive action which results from the use of



single sinking pumps and often causes serious trouble and annoyance by bursting the column pipe. Being self-contained and working with perfect smoothness, the strain on supports and hanging irons is naturally reduced to a minimum.

The use of the Worthington valve motion obviates any possibility of the pump refusing to start from the action of condensation water in the steam pipe, or from the formation of ice, where compressed air is used. The steam cylinders are fitted with dash relief valves, for regulating the stroke; the two water plungers are double acting, working through exterior stuffing boxes and adjustable packing. Experience having proven that the outside packed plunger is much superior to any other form for sinking work. The water valves are enclosed in heavy pots and are made accessible for examination or repairs by means of swing bolt covers to the valve pots.

The suction opening is at the lower end of the pump, the most convenient place for attaching the suction hose. The discharge connection to the column pipe is on the side; the discharge steam and exhaust pipes are placed inside next the shaft; the valve motion, which is very simple, is also inside next the shaft and is protected by the heavy cradles as shown.

Means are provided for either suspending the machine at the link at the ends of the steam cylinders or of hanging it on suitable timbers on the side of the shaft, by means of hanging irons.

These machines are made in several sizes and are manufactured by Henry R. Worthington, No. 86 and 88 Liberty Street, New York City, and No. 607 Arch Street, Philadelphia, who will be pleased to furnish further particulars on application.

METHOD OF WORKING THE PITTSBURGH SEAM.

A Plan of Working to Economically and Safely Remove all the Coal.

BY JOS. W. BLOWER, COLUMBUS, OHIO.

It will be generally admitted by those financially and officially interested in working the Pittsburgh seam, that a larger percentage of the coal in the seam should be taken out, and that, owing to the limited supply of timber and its great cost, other means must soon be adopted to secure the roof.

The present systems of mining are, (1) As shown on the accompanying plan on No. 1 entry, with 21 ft. rooms and 12 to 13 ft. pillars, and (2) As shown on No. 3 entry with 27 ft. rooms and 6 to 7 ft. pillars, which are left permanently.

The method shown on No. 1 entry is favorable only when the cover is light so that the falls can be controlled easily when the ribs or pillars are drawn. The coal, when worked by this plan, should have well defined facing and end joints, so that no powder is used in its extraction. Under such conditions, from 90 to 95 per cent. of the coal has frequently been taken out. Such conditions, however, are the exception now and not the rule. Conditions quite the reverse are found after No. 2 Pool on the Monongahela River is passed. Then the system shown on No. 3 entry is almost universally adopted, because greater losses of coal were experienced when the other method was tried. The 12 ft. pillars being crushed to slack by falls and squeezes, and frequently lost altogether. The squeeze extending over a large area when it had once set in and occasionally closed the entry also. The method shown on No. 3 entry is therefore preferable under the existing conditions.

The rooms in both systems are laid off to run only 75 yds. and break-throughs are made every 35 yds., or less if necessary, and about $1.00 per 1000 bushels of coal mined is required for timber. (Posts, caps, etc). Break-throughs cost 50 cts. per yard and are very unsatisfactory for ventilating purposes. In nine cases out of ten they are the direct cause of the rooms closing and burying large quantities of coal, even when the system as shown on No. 1 entry is worked fairly successfully. Break-throughs are not usually paid for when the rib or pillar is only six feet thick, for, when the room has advanced nearly far enough to need a break-through, the miner commences "gripping" out in order to thin the rib, and finally a hole is put through, which the gob partly fills up again. These break-throughs are generally made in a straight line, parallel with the entry. Sometimes 20 or 30 rooms are working together, with a few at the beginning of the entry finished which begin to "cave." This "cave" having free access by way of the break-throughs to the other rooms, often affects a number of them also. As some of these have only been worked two-thirds of their intended length when this occurs, the officials say "we can get this coal from the other entry." But the same conditions are met there and the coal is often irretrievably lost. Of course the owner does not know this, generally for two reasons: First, because he does not often personally go in the mine, and second, because, owing to a false idea of economy, the entries only are surveyed, the rooms being placed on the map approximately. The excuse given is "the business is not profitable enough to give the surveyor any more work than what is actually necessary to comply with the letter of the law and to prevent working in land outside of the lease or mine property." Acres of coal are thus lost, the room pillars alone representing about 20% of the coal in the seam, and frequently the entry pillars are also left in.

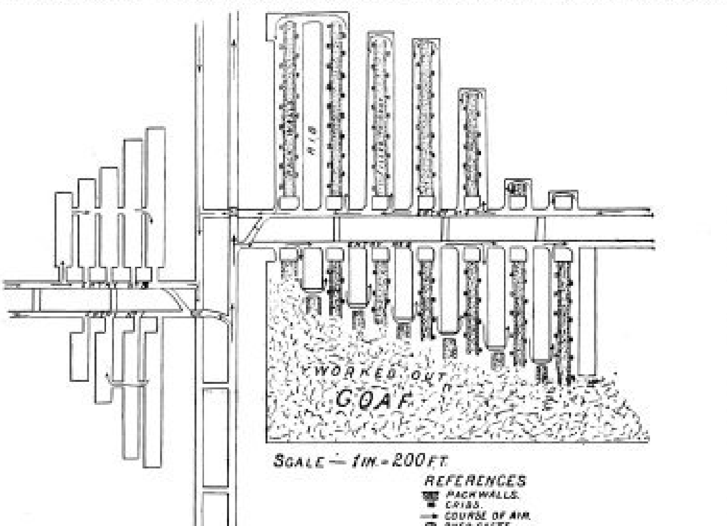
The disadvantages of the present methods, will, I think, be very generally admitted, and they may be summed up as follows:

(1.) Only 70 to 75 per cent. of the coal is extracted, while the expense necessary to extract the whole has been incurred.

(2.) The cost of timber is too great, and owing to its limited supply new methods must eventually be adopted.

(3.) Break-throughs are expensive (when paid for), and inefficient sources of ventilation, and they are the direct cause of rooms caving prematurely.

To remedy these, the plan of working, as shown on entries 2 and 4 is suggested. I think it will be found very satisfactory for the Pittsburgh seam, and especially for it as found on the Third Pool of the Monongahela, and in fact at any place where it is possible to post the roof, providing there is sufficient *debris* to build the necessary pack-walls. No change is made in the entries or in the laying off of the rooms. Two rooms are connected, leaving the same amount of entry stump as under the old methods. The track is run alongside each rib making the room 39 ft. wide, and a pillar 27 to 29 ft. wide, with a track on each side of it. The refuse, which amounts to one third of the seam, will be packed to the roof between the tracks, filling up about 20 ft. of the width of the room forming an artificial brattice, by which the air can be circulated around the face of the rooms, and which also forms the support for the roof. If not sufficient *debris* is found in the rooms, the slate from entries and rooms being turned can be taken in and gobbed. It will be seen that the ribs will be left intact, and posts are not used, except temporarily for slate; cribs take their place. These cribs are placed every ten yards apart, beginning at 5 yds. from the entry stump on the side of the room whose rib will be drawn first. The cribs on the other side beginning ten yards from the entry stump. The advantage of this arrangement is apparent on inspection of the plan. If the pack-walls are built properly, these cribs will not be necessary until the rib is drawn back, but the best plan is to set them as the room is being driven. They may be built of old posts, ties, wooden rails, etc., with a foundation of say 9 to 12 inches of slack, and wedged up tight to the roof. The necessity for the slack will be best shown on their removal, as they can then be undermined easily. It also allows them to give a little as the weight upon them is increased.



It is generally known that these rooms will not "cave" when 39 ft. wide, but the roof coal will "sag" sufficiently to make the packed gob air-tight.

In bringing back the rib, small cribs made from wooden rails about 2½ ft. long, set on a base of slack, can be used. A few posts may also be necessary.

Another pack-wall may be brought down with the rib, as shown on plan, which will prevent any fall taking place, and a gradual subsidence will only occur, and no large reservoir for the accumulation of gas, will be formed.

Ribs brought back in this way will be "Longwall retreating" on a small scale, and in case it is found that a roadway can be carried along the face of these ribs, every two alternate rooms could be left, and the coal worked back in this way, making a face length of 94 feet, more or less, as circumstances may allow. Or the room may be made wider, and the car taken along the face of the room. The tracks would be safe, having one solid rib side, and pack-walls and cribs on the other. Conditions existing would soon prove what modifications of the general plan could be made. It will be seen that rooms can be driven an indefinite distance without fear of caving, and it will pay to drive them a minimum distance of 100 yds. or longer, if it will pay to haul one car further. Besides five pairs of entries will only be needed where six pairs are required by present methods.

The proposed system will be found applicable where "soot seams" affect the roof and coal.

I have found by experience, that double rooms were safer and required less timber in proportion to width than narrow rooms, and that while entries and narrow rooms would cave until the roof had arched itself, the wide rooms allowed sufficient sag to relieve the pent-up gas, or they may be allowed to break in the center.

For machine mining, the plan suggested, has a longer face length to work upon with no unnecessary moving of the machine. The machine can be set down on one side of the room and work its way across. The truck in the meantime being changed to the other side, ready to transfer the machine elsewhere.

Another advantage will be that the miners will work double, and in this way reduce the length of time the room will be in operation. Fewer tight shots will be needed, some of the labor of bearing in will be reduced, and better coal will be secured.

In my opinion many accidents occur when miners work singly, which would not occur if the men worked together. Men are often hurt and unable to report the accident, which becomes more serious on account of lack of timely assistance.

It will, no doubt, be said that the system proposed is impracticable, and that the rooms will cave, but this will not be found true if, the pack-walls are properly built, and anyone acquainted with Longwall work, will substantiate me.

But, suppose the rooms did cave. The ribs or pillars are large enough to allow a skip, say 12 or 15 ft. wide, to be taken, and thus the face of the room can be reached and finished, or the remaining portion of the rib may be brought back and no coal will be lost.

The advantages claimed for this system, are:

(1.) The extraction of all the coal.

(2.) A reduction in cost of timber.

(3.) The ventilation of the working faces without incurring the cost of the ruinous and inefficient break-throughs.

(4.) It requires fewer entries, and as a consequence less rubbing surface, thereby producing better ventilation with the same expenditure of power.

(5.) Large accumulations of fire-damp will be avoided, if the *debris* is properly utilized.

(5.) The miners will have a wider room, better ventilation, and will use less powder.

(7.) The system is better adapted for machine mining.

(8.) The mine foreman or his assistants, when making the required visits to working places will have only half as great a distance to travel.

I hope those interested will give the subject a careful investigation, and if in their opinion the system is practicable, try it in one entry at least. I do not claim the idea is perfect in detail. Some modifications due to local conditions, may be necessary, but these will soon suggest themselves to the practical official.

Can the Pittsburgh seam be worked by Longwall? is a question often asked. If this system is tried the answer will come, and it will not entail the risks of Longwall advancing. It certainly can be worked by Longwall retreating, but no one is prepared to go to the first expense.

Safety Signals for Mine Shafts.

A mining contemporary gives an account of an electrical apparatus designed for the prevention of accidents to miners while riding on the cages in the shaft, and which will also, it is said, tend to lessen the number of accidents occasioned by cages coming in contact with the chairs. The invention has been in successful operation during the past two years at the Drum Lummon Mine, Montana, and it was devised by an ingenious employe of the company owning the mine. The arrangement consists of an electrical connection between the cage and the chairs on the different levels of the mine, and also between the cage and the engine room. An ordinary battery is placed in the bottom of the cage, and wire attached to it run through a contact piece to the side of the shaft, something on the same principle as the trolley on an electric street car. An ordinary push-button is placed in such a position on the cage that the station tender can readily reach it. Wires running down the shaft connect with the trolley on the cage, and at the other end are attached to a dial in the engine-room. Another wire connects with the chair in the mine, and as the dial is in full view of the engineer, he can tell at a glance whether the chairs are set or not. Should an accident happen to anyone on the cage between two levels, by pressing the push-button, the cage can be brought to a stop in a moment. In the ordinary way, with a bell-rope attachment, if the cage is going at even a slow speed it is dangerous to attempt to grasp the bell line, on account of the liability of getting an arm caught between the sets.

The Western Pennsylvania Mining Institute.

At the February meeting of the Western Pennsylvania Mining Institute, held at Monongahela City, Pa., Mr. W. J. McMasters, of Munhall, presided in the absence of the President. Mr. Wm. Seddon read a paper on the objects of the Institute, which was discussed by a number of the members. That portion relating to gases was particularly discussed, and as some of the members present stated that they had encountered a strange inflammable gas, the Secretary was instructed to procure samples of it, and have it analyzed by some capable chemist, and report at the next meeting. Mr. W. J. McMasters exhibited a model of a self-closing door to be used in main entries, or any other part of the mine where doors are necessary. Its advantages and disadvantages were fully discussed, and several suggestions as a means of further improvement in the invention were offered. Mr. McMasters also exhibited an improved Chirry lamp, which met with general commendation on account of its economical features.

As the next meeting (July 9th) will be the fifth anniversary of the formation of the Institute, Messrs. Henry Louttit, Adam Kyle, and Robert C. Campbell were appointed a committee to arrange a programme, and they were directed to report to the Secretary not later than April 1st.

THE PROGRESS IN MINING.

Reviews of Important Papers Relating to Mining in the Proceedings of the Mining and Scientific Societies, and in the Mining Journals of Europe, United States and Canada.

The Gas Enclosed in Coal and Coal Dust. A paper on this subject was recently read before the members of The North of England Institute of Mining and Mechanical Engineers. This paper was the result of experiments made by Messrs. Bedson and McConnell with Bituminous coal taken from the Hutton seam at Ryhope Colliery. A known weight of coal in small lumps was heated for several hours at 212° Fahrenheit *in vacuo*. The gases produced were drawn off, measured and analyzed. The analysis showed a mixture of carbonic acid gas, oxygen, nitrogen and marsh gas ($C H_4$). After the coal had ceased giving off gas it was pounded into a fine powder and this dust was again heated *in vacuo* for several hours at the same temperature (212° Fahrenheit). The result was to obtain another volume of gas from this dust. This gas was similar in composition to that given off by the coal while in lumps except that instead of marsh gas there was a quantity of heavier hydro-carbon. These experiments are interesting as a proof that all the gas in coal will not escape, even when the coal is reduced to a dust, unless subjected to heat. The natural conclusion therefore is that Bituminous coal dust holds a certain volume of combustible gas ready to escape when heated.

Safety Explosives. In further reference to the paper recently read before The Colliery Managers' Association of Great Britain, by Mr. Foggin, and which was reproduced in THE COLLIERY ENGINEER for February last, we are indebted to *The Colliery Manager*, of London, for the following letter written by Mr. H. Bigg-Wither, General Manager of the Roburite Explosive Co., Ltd., of Wigan, England.

Mr. Bigg-Wither says: "I wish to point out that in discussing a subject of this kind writers should carefully discriminate as to the particular words they use. For instance, there is an absolute difference in the meaning of the words "percussion" and "concussion;" and the term "explosion" can be very easily misapplied unintentionally, inasmuch as it may have several distinct meanings when applied to explosives. Thus, the explosion of gunpowder is the result of combustion; that of high explosives generally is the result of detonation, while in the case of some high explosives it is the result of detonation and combustion combined.

"With this preface I will now call attention to the results of percussion tests detailed by Mr. Foggin. We have a percussion apparatus at our works similar to the one described. The falling weight is 50 lbs., and we can get a fall of 40 feet. This year we have made a great number of tests with explosives of various classes, and we have found that with explosives of the Sprengel type, consisting of a dual mixture of nitrate of ammonia and a hydro carbon, a blow of sufficient weight simply produces decomposition of the portion struck, and that the surrounding mass of explosive is not affected by this so-called explosion, the result being merely a sharp crack or report. Moreover, we have obtained this same result with substances which are not classed or used as explosives.

"Mr. Foggin's statement that this so-called explosion was not produced by "ammonite" at different heights from 5 to 25 feet is quite unaccountable, except on the supposition that there was some accidental mechanical difference in the carrying out of the various experiments, for, out of seven experiments made on one day with ammonite, we got the following results: Two experiments at 5 feet drop, one sharp report; two experiments at 4 feet drop, both gave sharp reports; three experiments at 3 feet drop, one gave sharp report. I may say that on the same day we got a more resonant report from dynamite, carbonite, and tonite with a drop of only 6 inches at the first experiment with each.

"Having previously remarked the difference in the report produced by "roburite" and "dynamite" under percussion, we thought that it would be interesting to study this difference, and see whether other experiments would not assist us in demonstrating that the report produced by the Sprengel class of explosives was no true explosion, inasmuch as no detonating wave was set up, but that, on the other hand, the report from dynamite, for instance, was a true explosion, and that a detonating wave was set up. We have made a series of elaborate experiments in this direction which have thoroughly convinced us that our theory is absolutely correct."

How Anthracite was Formed. *The Colliery Guardian*, of England, publishes in a recent issue, a paper by a Canadian correspondent on the coal fields of Nova Scotia. We give the following summary of the paper as likely to be of interest to our readers: It is interesting to inquire whether the Mammoth seam of Pennsylvania is co-existent with the coal measures of Canada.

There is a 40 ft. seam of Bituminous coal in Pictou County, Nova Scotia, which enters one of the basins from the southwest, and therein trends north several degrees east. This Bituminous seam which is heavily charged with hydro-carbons and sulphurous gases although now being worked has stood in abeyance for many years. It is stated that this seam is a continuation of the Anthracite Mammoth seam of Pennsylvania and the alteration in its nature from Anthracite to Bituminous has caused much conjecture. The writer of the article goes on to submit the following theory:

He first briefly refers to petroleum and natural gas and states that springing from one source these two owe their existence to the conditions under which coal was formed, namely, the decomposition of animal and vegetable life.

Pennsylvania petroleum is a mixture of hydro-carbons (which may be classed under the marsh gas series) with paraffins and olefines. Pittsburgh natural gas contains 67% of marsh gas, 22% of hydrogen, 3% of nitrogen, 5% of the heavy hydrocarbons and the remainder of oxygen and the carbon-oxides.

The writer goes on to say that assuming these two bodies possessed an origin identical with coal and noting their present order of deposit in the earth, their ingredients must have been originally removed from the great Pennsylvania Anthracite measures, thus assigning to these measures their unique nature.

Any Bituminous coal subjected to distillation in a closed vessel would precipitate (1) watery liquor, (2) aetherial or volatile oil, (3) volatile alkali, (4) thick greasy oil. The closed vessel in this case is nature's distillation in the crust of the earth. Internal heat, which has torn the country of the Eastern Alleghanies into such great contortions, acting on carboniferous deposits would gradually distil these liquids above mentioned and the whole would be driven through the cracks in the earth's crust out of the country of the Eastern Alleghanies into the region they are now found.

Good Surveying. We are indebted to the proceedings of The Mining Institute of Scotland for a short description of "Shaft Surveying at the Przibram Mines," taken from a recent volume of the Transactions of the Institution of Civil Engineers, England. Two shafts—the Adalbert and Maria—had been sunk in 1879 to the thirtieth level at a depth of 3200 feet and it was proposed to deepen the Kaiser Franz Josef shaft from the seventeenth level to the level of the other two, a depth of 1864 feet. To hasten the work the sinking of the shaft was begun simultaneously at four different points. While one set of sinkers was sinking from the seventeenth level another set were rising from the twenty-third level to meet them. Another starting down from the twenty-third was being met by a rising set from the twenty fifth. Similar operations were being conducted between the twenty-fifth and twenty-eighth, and between the twenty-eighth and thirtieth.

It will thus be seen that eight points of work were in full force at one time. The relative positions of the three shafts were first determined by a survey at the twelfth level with a mining theodolite with two verniers reading to one minute. The total length of the survey was 3673 feet with forty-four stations, and the traverse gave the sides and angles of the triangle formed by the three shafts at

Side of Triangle.	Distance in Metres.	Angles Opposite.
a. Maria—Adelbert	= 564·091	A at Franz 90° 34' 58"
b. Maria—Franz	= 546·091	B at Adelbert 37° 18' 28"
c. Adelbert—Franz	= 442·828	C at Maria 52° 6' 34"

The survey was repeated after a connection had been effected in each of the sections, the total distance surveyed being eleven miles with 684 stations. The operation was completely successful, as the shaft was formed full size (19$\frac{1}{2}$ feet $\times$ 6$\frac{1}{2}$ feet) and no alteration was found necessary in timbering or masonry in any section when a holing was made.

The Capell Fan in Westphalia. From the Transactions of The Mining Institute of Scotland we give the following extract regarding some tests made at the Prosper I mine at Berge Borbeck. There was originally a Guibal fan at the colliery, 39 ft. diameter, with a maximum capacity of 76,000 cubic feet per minute with a 3·2 inch water gauge. As this was inadequate a Capell fan 12·3 feet diameter and 6·9 feet broad was substituted. This fan after a few months' working shows what are quite justly described as "astonishing results." The fan engines are coupled, and the cylinders are 20$\frac{1}{2}$ in. diameter with 31$\frac{1}{2}$ in. stroke. The fan is driven by a camel hair belt 23·6 inches broad and makes four revolutions to one of the engines. Special trials were made with the fan running at 228 revolutions per minute. With a water gauge of 7·3 inches 105,000 cubic feet per minute were obtained. This was an efficiency of 52·039 per cent. or 5 per cent. greater than the best of the fans reported on by the recent Prussian Fire-damp Commission. At a speed of 350 revolutions of the fan per minute the effective work was calculated at 53 per cent. Lubrication of the fan axles is effected by kidney fat broken up into small lumps in the oil boxes with a continuous stream of water falling on it. With this lubricant no heating of the journals was observable, whereas experiences with oil and tallow were not nearly so satisfactory.

The use of Roburite and Tonite in Mines. A series of experiments to test whether the fumes from these explosives are more dangerous to the health of the miner than gunpowder smoke was recently carried out by a committee of The North of England Institute of Mining and Mechanical Engineers. The decision arrived at is that the products of combustion are not more deleterious with one explosive than with another. As both roburite and tonite are safer and more powerful than gunpowder, their use should be extended now that the main objection to their adoption has been groundless. The committee are very emphatic in their declaration on this point, they say: "It has been ascertained in the examinations made by Professor Bedson that the amount of carbon monoxide resulting from the explosion of roburite or tonite is not practically, and on an average, greater than that produced by gunpowder. Moreover, it has been shown that, after a very short interval, this and other gases are entirely carried out of the place by the air current. We are, therefore, unable to assign the ailments complained of by the men to any poisonous or specially hurtful influence of the explosives."

Coal Dust Explosion. In an article on "Explosions of Coal Dust in Artificial Fuel Factories" (*Dingl. Poly.*), two accidents due to the explosion of coal dust are described in the *Jahresbericht d. K. preuss. Gewerberathe für* 1888. At the Reichenwald works an explosion of coal dust took place in the dried coal store-room whilst the operations were in full progress, with the result that the front of the drying-house was violently blown out and a considerable conflagration occurred in the factory. At Furstenberg on the Oder, where the works are entirely built of stone and iron, a similar explosion occasioned no damage, either to the workmen or to the buildings. The ignition of the coal dust appears to have commenced in the lowest feeding screw belonging to the drying room elevator, and to have spread forwards to the store-room and backwards to the two drying-houses. Five explosions followed in quick succession in different parts of the works, the detonation being strongest in the store-room, and in a few minutes all the chambers containing dry coal dust were on fire. These accidents show that coal dust is itself a dangerous explosive, the presence of which must be guarded against in factories, mines, &c., by thorough ventilation and other protective measures.

The Value of Bore-Hole Records. When a mining company puts down a bore-hole they do so with the main object of proving the existence of some particular seam or vein. Sometimes the bore is successful in its search, sometimes it is not. In the latter event no value is placed upon the records of the boring and they are often allowed to disappear or are at least carelessly kept. In some instances where the mineral looked for is expected to be found at a shallow depth from the surface no written records are kept at all and bore-holes are put down with as little system of geological knowledge as if the cost of each was little more than of shoving a walking cane into the ground. Little thought is taken of the fact that the usefulness of these bore holes does not end with the attainment of the present object or that perhaps in a few years their records may save a lot of money in proving the existence of say a valuable clay where previously the search was perhaps only for a good house coal.

The State Geologist of Missouri, in his preliminary report on the Coal Deposits of that State appreciates the value of all these local records as a means of assisting him in formulating a reliable State Geological map and we cannot do better than present his own words on this point. He says:

Of especial value in this report are the records of the various deep shafts and drill holes which are included. These were furnished by many different individuals, and, in each case where the results are quoted, recognition of this assistance is expressed. With a few exceptions, the individuals and corporations of the State have generously contributed such results in a free, public-spirited manner. The importance of furnishing such records to the survey, where they may be kept on file for ready reference, cannot be too strongly emphasized. Hundreds of such holes have been put down in the State for various purposes, and from comparatively few of such are reliable results now available. Such holes are generally sunk for a definite purpose and when that end is reached it occurs to few that the results may still be valuable for other purposes. But this is almost always the case. Whether a thick coal bed be encountered or not a good record establishes a series of facts concerning the geology of the locality and is, hence, valuable. For instance, the record though *apparently* barren of results of economic value, may show that the drilling stopped in a certain limestone, which, by comparison with a record obtained elsewhere, we know is 20 or 50 feet, as the case may be, above a certain valuable coal bed. Hence from the study and comparison of these two records we are able to predict the probable existence of workable coal within a short distance of the bottom of the hole. Again, the hole may have penetrated rocks which we recognize as below any coal in the State; in this case the result is of general value in preventing further exploration below this depth. Only from the results of such deep drilling can the area of available coal in the State be exactly determined and the limits of the individual beds be defined, especially in those parts of the State where the coal beds are deep beneath the surface.

The reason why records of value are not always attainable is, however, not only because of negligence on the part of those immediately interested to preserve them, nor yet because of refusal to contribute them. It is unfortunately the case that many holes have been put down by incompetent men, or by men who know merely how to handle a drill without having sufficient knowledge of lithology or geology to be able to accurately describe and record the descriptions of the rocks they encounter, nor to interpret the meaning of all they pass through. In cases it is even worse than this, and the history of many a deep and expensive drill hole in the State shows evidence of trickery and bad faith on the part of the driller towards those in whose service he was supposed to be working. The uncertainty attending such work has thus brought disfavor in many localities upon deep drilling as a public enterprise; many having acquired the impression that only indefinite results of small practical value could be reached. This impression is wrong and unfortunate, for such work can and should be prosecuted by every progressive community in the coal regions which is anxious to determine the existence of coal beds and to have them developed. In view of these facts the survey suggests a possible plan of co-operation which if adopted, would ensure a well conducted drill hole, a reliable record and an official report on the same, and would, at the same time, secure for the State complete results of the drilling in such condition that they can be unhesitatingly used and will be entirely comparable. To any private individual or community desiring to have a *deep* drill hole sunk, the survey could arrange to recommend reliable men whom the individual or community can employ to do the work of drilling; second, it could supervise this work, and last, it could furnish an official statement of the results of this drilling. In return for this service, it would be required that the survey be allowed full and free use of the results for the benefit of the State. That this would be, in every way, a liberal offer, cannot be disputed. In addition to securing reliable results, the individual would, by this means, be put in possession of a report, which would be, as it were, negotiable. Being of an official nature, from an impartial source, others will place faith in it and will invest money on its authority, for purposes of actual development, where they would not do so, were the report of a private nature, emanating from an interested source. If such a plan of co-operation were generally adopted, the State would soon have accumulated an invaluable mass of material from which it would be possible to outline, with a high degree of accuracy, the general limits of each and every coal bed in the State. From this the prospects of finding coal at any one point could be predicted, as well as its probable depth and thickness when found. Surely the attainment of such a condition of exact knowledge is worthy of our serious efforts.

Draining in Mines.

We are indebted to the *Iron and Coal Trades' Review*, of London, Eng., for the following extract from a paper on the above subject recently read by Mr. Henry Davey, M. I. C. E., before the Cleveland Institute, of Engineers.

The author dealt with some of the leading general principles involved in methods of draining mines under the most important conditions of both coal and metalliferous mining. In treating of draining during sinking operations, he said the conditions vary greatly in sinking for coal or for ore. In the former case the shaft or pit is usually completed before the coal is worked; in the latter the shaft is generally deepened during the working of the mine, and is, therefore, never in a permanent condition. Temporary steam pumps might be used to advantage for small quantities of water from moderate depths, but for any important work a surface engine with bucket pumps having proper lower appliances should be adopted. Pumping water was not a costly operation if proper and sufficient pumping plant was employed for the work, but if this plant is insufficient, the loss often is very serious. Even with proper plant sinking through water-bearing strata is slow and costly, because of the delay occasioned by the sinkers having to work in water. Heavy pumping under such conditions could be expedited by the use of jet pumps and other auxiliary appliances, by means of which it was unnecessary to lower the main pumps so frequently. Hydraulic pumps might be used to great advantage. Many special appliances of this nature might be employed if they could be procured when wanted, but no one kept special appliances. Makeshift plant was procured, and the sinking in consequence became very slow and costly. The author said that for many years he had been convinced that a sound investment would be found in the establishment of a depot where the best sinking appliances might be obtained on hire or purchase. In sinking shafts and wells through water bearing strata, great cost was usually incurred and much time taken up. The subject was of considerable local importance because of its bearing on the sinking of mining shafts. The problem was simply that of keeping down the water in water bearing-strata in advance of the sinking operations, so that the excavation of the shaft should be done in dry ground. The ordinary method was to sling a pump or pumps in the shaft and to lower the pumps from time to time as the sinking progressed; obviously the excavation had to be performed in water, and if the quantity of water was great, a large portion of the work had to be done by the men working in 2 or 3 feet of water. To facilitate the work, and reduce the water in which the men had to work, a sump was made under the suction pipe of the pump, and it was the keeping this sump excavated in advance of the other work which was most difficult and tedious.

In the plan proposed by the author the pump would be placed in a borehole made before the commencement of the sinking of the shaft. It was necessary that *debris* should not go down the borehole in quantity sufficient to choke it up. That is provided against by means of a heavy taper shield of cast steel surrounding the pump, and resting on the edge of the borehole. This shield is perforated with holes inclined upwards towards the pump to allow water to get into the borehole, but to exclude *debris*. The shield is made very heavy, and by its own weight follows the excavation around the pump, and also protects it from injury through the blasting of the rock. The pump is made without a foot valve, the rod of the bucket working through the seating of the valve which rests on the top of the working barrel. By this arrangement the drawing of the bucket also draws the valve, and should the bottom of the borehole be filled up with sand, it can be removed by lowering a sand pump. The boreholes should be made to a greater depth than that required for the pump to provide space for sand and *debris*. The application of this pump would be varied to suit the local circumstances and the geological formation of the strata to be passed through. In some situations the shaft might be drained by means of boreholes outside the diameter of the shaft altogether. It was usual and necessary to have duplicate pumping engines, and where two engines were made to pump from the same well, the well must be very large to accommodate two sets of pumps. Such wells were usually from 12 to 14 feet in diameter. A simple borehole could be made cheaply and expeditiously. Four 30-inch boreholes could be put down in a small fraction of the time required to sink a 12-foot well in the ordinary way. Instead of making a large well, the author puts down four boreholes to accommodate the pumps for duplicate pumping engines. The boreholes being completed, the pumps are lowered into them, and coupled up to the permanent engines. The author held that it was true economy to have a pumping engine large enough to do the work at half or even one-third its full speed, or what might be called two or three times too big. He was at present putting down large pumping plant at great cost to recover a colliery drowned because it was formerly drained by means of underground steam pumps. The practice had been to put down a new pump for every new feeder, but one day a big feeder broke in, and the pumps were soon under water and the colliery also.

Underground pumping engines had been largely employed of late years, but the author thought it a mistake to take steam underground. It was not possible to get dry steam to underground engines through pipes carried down the shaft, and with wet steam the engine would give a low duty. He had found the engines on the surface could be made to work with one-half the steam required by the best underground engines for the same work. In some places underground pumping engines were more suitable than surface engines, but in most of such cases the pumping was better and more economically done by means of hydraulic pumps from an engine on the surface. He instanced the installation of Messrs. John Denton & Co., at the Grimesthorpe Colliery, Sheffield. The work was previously done by means of steam pumps, but the steam was such a nuisance underground, the mine was made so hot, and the steam pipes and plant gave so much trouble, that Messrs. Denton resolved to try another plan. The shaft is an inclined one. There are three hydraulic pumps placed in different parts of the mine. The first lifts 150 gallons per minute 300 feet high; the second 137 gallons 300 feet high; and the third 30 gallons 300 feet high. The power is supplied from the surface through pressure pipes 4 inches, 3 inches, and 2½ inches in diameter at 700 lbs. per square inch. The pumping plant cost $7,425 and the pipes $2,481.

The author stated that he had devoted considerable attention to the system of applying hydraulic power to underground machinery, and he gave particulars of the hauling and pumping engines at Altham Colliery, the New Russia Company's Collieries, and the Quebrada Copper Mines. He expressed his conviction that for vertical shafts, where considerable quantities of water had to be dealt with, the pumping could be more safely and economically performed by means of surface engines and pump rods than by any other means. Where, however, their use is inadmissible, the system of hydraulic transmission is the most economical, convenient and practicable, not only for pumping, but also in many cases for hauling purposes. Conveying steam underground for pumping purposes was to be avoided, if possible, except under very special circumstances. The author mentioned that several installations had been put down for pumping by electrical power. He also cited a colliery near Marseilles where three hydraulic pumps were placed in different parts of the mine, which is 1,100 feet deep.

Dimension Stone Quarrying.

Mr. W. L. Saunders, M. Am. Soc. C. E., recently read an interesting paper on this subject before the American Society of Civil Engineers. We append the following excerpt of the paper:

With beds of solid and valuable building stone it is a point of importance to secure as large a percentage of marketable rock as possible. One of the oldest methods of obtaining this is to drill deep holes. Quarrymen have often observed that holes drilled by hand are never really round, but are somewhat triangular in shape and when a blast is fired in one of these holes the rock usually breaks in three directions radiating from the points of the triangle. This is very extravagant on the rock as the pieces are irregular in shape and a large percentage of stock is wasted in trimming off the stone into a cubical shape.

One of the first devices for overcoming this waste was to insert the charge into the hole encased in a canister of peculiar shape. The hole was drilled from 10 to 12 inches in diameter. The drill used was shaped like a broad axe and was worked by being raised up a certain height and then dropped; the weight of the drill in falling being the force which struck the blow. The canister containing the charge was made of two curved pieces of sheet tin with soldered edges. When this canister was placed in position in the hole, there was a space on each side shaped like a crescent moon. This space was filled in with sand or earth and as the canister was placed so that its section lay lengthways in the desired direction of fracture, the effect was the same as if the hole had been drilled in the shape of the canister. If it had been possible to drill the hole exactly in the shape of the canister a good deal of work would have been saved.

Another system was what is termed Lewising. A Lewis hole is made by drilling two or three small holes close together and parallel with each other. The partitions between the holes was then broken down leaving one hole of a long narrow shape of section. This form of hole is used in granite. Sometimes a series of Lewis holes are drilled in a straight line and at equal distances apart (sometimes 10 to 25 feet) and fired simultaneously by electricity.

Mr. Saunders describes the following new system developed by Mr. Knox which possesses advantages over the two aforementioned. A round hole is first put down, preferably by machine to secure a perfectly round section. After this has been done a V-shaped groove is cut out on each side of the walls of the hole in the direction of the desired line of cleavage. These grooves are cut with a "reamer" by hand, and the greatest care must be taken to preserve a uniform direction with the V-shaped grooves or in other words the "reamer" must not be allowed to twist, or otherwise a bad fracture will result.

If a bed of rock in a quarry has to be moved and a natural seam divides the bed at each end of the walls of the quarry then there will only be one face, the back to set free.

Knox holes are put in at equal distances apart along the line of desired cleavage and these are fired electrically.

The explosive recommended is one of a low grade. Dynamite is not suitable, and black powder, or Judson powder, or other explosives which act slowly are preferable. No definite rule can be laid down as to the amount of powder to be used to secure equal results in every case. A hard, fine-grained stone requires less powder than soft stone. As a matter of fact very little powder is required for most rocks. If too much powder is put in each hole, the rock, especially if it be soft like sandstone, is shattered. It is preferable, therefore, to put a smaller charge in and to place the holes closer together. In this improved form of hole the tamping should not be put down directly on the powder. An air space should be left between the powder and the tamping. The tamping can be sustained at the top of the hole by first inserting a wad of hay, grass, oakum, or other material. When a series of these holes have been blasted it is found that a clear fracture along the line of holes is obtained and a solid cubical mass of rock is thereby set loose. The theory of this action in these V-shaped holes is that the gases formed by the explosion finding no sharp angle as a starting point for a fracture at any point in the circumference of the hole until they come to the Vs, they rush to these two points and concentrate all their energies on them acting like two wedges driven from the center by a force equally prompt and energetic.

Similar holes to cut in two directions, one at right angles to the other, are made by cutting one additional pair of V shaped grooves on the opposite sides of the hole.

Mr. Saunders in his paper also deals with the merits of the Knox system adapted to the details of rock cutting.

An Electric Safety-Lamp.

The members of The Mining Institute of Scotland recently had an opportunity to inspect Bristol's Patent Electric Safety-Lamp. The following is a short description of it: The battery consists of 3 cells of accumulators. Its action is that if a current is sent through it for a certain period it will afterwards when switched on a lamp give off a corresponding current for a corresponding time.

The lamp can be charged to give a light for 10 hours.

The cost of these lamps in England is $8.40 and for an installation of 500 lamps at a colliery including a two-horsepower dynamo and all connections the first cost will be $4,500. The first cost for a similar outfit of Evan Thomas, Marsaut, or similar good-class oil safety-lamps will probably be $2250 including a Howat's Patent Lamp locking and cleaning machine or just half the cost of the electrical plant and lamps.

The cost of running and keeping 500 Bristol Electric Safety-Lamps to burn 8 hours a day will be 8 cents per lamp per week.

Taking attendants' wages, deterioration of plant and 5% on capital outlay, into account the anual cost will be $2,760 or $5.52 per lamp per annum.

Electricity applied to Mining.

Mr. D. S. Bigge discussed "Theory" and "Practice" in the application of electricity to mining in a paper read before The North of England Institute of Mining and Mechanical Engineers, at Newcastle, Feb. 13th, of which the following is an abstract:

The question of power transmission by means of electricity is by no means a new or untried one, and though, perhaps, little is known of the details as yet by the mining world in general, results have been obtained in actual practice which merit serious attention. Electricity has now been applied, and with great success, in mining work for haulage, pumping, drilling, coal-cutting, and other minor uses, and as in the cases of electric lighting, electric power may now fairly be said to have passed out of its experimental stage, and to have become an accomplished fact. It is chiefly as a means for transmitting power to great distances with small loss along the line that electricity will be found to predominate over any other known form of power transmission, and as distance is usually a most important factor in mining operations underground, electricity in a large number of cases will be found to adapt itself admirably to the work required to be done.

The advantages claimed may be tabulated as follows: 1. A very large increase in working efficiency over any other known form of power transmission. 2. Considerable reduction in capital expenditure, when compared with other systems, a reduction which becomes more and more apparent as the distance for the power to be transmitted increases. 3. Increased facility in running the cables when compared with the laying of air or hydraulic mains. 4. Very small loss in the cables through resistance or leakage to earth when compared with the waste on a compressed air system. 5. Smallness in size of the machinery, thus proving itself to be of a portable nature and easily manipulated. 6. Absence of heat from the machinery underground. 7. Great simplicity in working. 8. Small cost of maintenance. 9. Finally, the ease and speed with which the whole plant can be erected and set to work.

The principal objections raised against the employment of electric power are the following, viz.: 1. Danger arising from sparking at the motor brushes and main switch underground. 2. The idea that electrical machinery is of too delicate a nature for use in mines. 3. Risk of fire from breaking of the main cables by falls of stone, derailed tubs, or other causes. Having dealt with the three objections raised the author proceeded to consider the general question of power by electricity. When one power is transmitted from one place to another by means of steam, air, or water, through pipes, the difficulty of pre-determining the exact loss of power from friction in these pipes is very great; in fact it varies so much under different circumstances that the author believed that exact determination may be said to be impossible. So also the loss of power in the motors driven by fluids is equally undeterminable with any degree of accuracy, on account of the variations in efficiency caused by slight alterations in load or speed, or by leakage through the valves or packings. These difficulties in calculation do not present themselves with electrical transmission of power. The loss of power in the cables depends solely on the electrical resistance, which is a practically constant quantity, and the current passing through the cables, which can be estimated with great accuracy. Nor is the loss of power in the motors more difficult to estimate; first, with a given motor the losses can be calculated with almost any degree of accuracy, from its known resistance and electrical or magnetic qualities; and secondly, since the experimental determination of the efficiency of dynamos and motors is so readily carried out, a very great number of actual efficiency tests have been taken from which the efficiency of a given size of machine of any particular type or construction can be easily foretold. The calculation therefore of the power wasted in transmitting power by means of electricity is extremely simple, and the efficiencies of a plant can be readily foretold, and the results to be obtained guaranteed with perfect confidence.

Where there are two or more collieries under the same management within a comparatively short distance of one another, at which power is required, one central station should be established where plants should be installed of sufficient power to serve the several collieries. The advantages of this plan are clear. (*a*) Inasmuch as all the machinery will not be working to its full capacity at each of the collieries simultaneously, the actual power at the one central station will be less than the sum of the powers which would have to be installed at each separate position, and in addition to this the plant would be cheaper, because the price of machinery does not vary directly as its output. (*b*) The cost of maintenance of a few large dynamos and engines will be less than that of a greater number of small ones. (*c*) Greater efficiency is obtained by running the machinery more nearly at its full load, the percentage variations of power required being smaller, when a large number of motors are taking power from the one plant. (*d*) The cost of attendance on the generating plant will be enormously reduced, the same number of men being able to attend the one central station as would attend to each of the separate plants. The great saving in all these directions had been fully proved by actual practice in the large central stations supplying light and power in London and other large towns.

COAL IN WEST VIRGINIA.

Reports of the Inspectors of Mines for the Year ending June 30, 1891.

Annual reports of the State Mine Inspectors of West Virginia have just been made to the Governor and contain valuable information and interesting statistics. The reports show that during the year ending June 30, 1891, the total coal production in the State was 7,281,430 tons of 2,240 pounds each, and the coke production in the same time was 1,238,418 tons. In 1880 the coal production of the State was 1,568,000 short tons. In 1889 the production of coal was 4,726,047 long tons, and of coke 665,193 long tons. The reports for the last year also show that there were 179 mines in operation in which there were employed 14,178 men. There were 4,117 coke ovens in operation and 777 more building.

Inspector Harr, of the First District, reports 14 fatal and 24 non-fatal accidents during the year. He says: "Upon making careful inquiry into the cause of these accidents, I find that a majority of them resulted from the carelessness of the workmen themselves. A careless miner is the worst enemy to his fellow-workmen. I can not see how best to remedy this evil, but would suggest that the mine boss in charge, exercise more strenuously his authority in this matter. In no case should he allow men to work in danger, no matter what their experience may be. There has been but one explosion of gas during the year, from which four men lost their lives. This happened May 7, 1891, in Harrison County, at the Ocean mine."

There were six mines opened in the First District during the year and eight are now being opened. There are 1207 coke ovens in blast and 235 are being erected.

Inspector Spruce, of the Second District, reports 25 fatalities. He says: "The fatalities in the counties of Mason, Putnam, Kanawha and Fayette are one in 748 miners employed, while in the counties of Mercer, and McDowell they are one in 180 miners. According to these figures about four times as many men get killed in the mines of Mercer and McDowell as in the other counties just named, in proportion to the number employed. This is due, he expiains, more to the fact that inexperienced men are employed there than that the mines are dangerous; and also that the miners are not required by the companies to set posts in their own rooms or working places. He recommends that the miners be paid for setting their own posts instead of its being done by men employed for that purpose."

There were 35 new mines opened during the year and a large number of coke ovens built.

NUMBER OF MONTHS WORKED AND AVERAGE EARNINGS OF THE MINERS OF THE SECOND DISTRICT OF WEST VIRGINIA, FOR THE YEAR ENDING JUNE 30, 1891.

County.	Number months worked.	Average earnings of miners per month.

A FOREMAN FOR EACH MINE.

The Pennsylvania Bituminous Mine Law Defined to Mean That Operators Must Employ a Certificated Foreman for Each Important Opening.

We are indebted to the *Scottdale Herald* for the follow important decision of Judge Doty, of Westmoreland Co., Pa.:

By the Court: On 30th June, 1885, the Legislature of this Commonwealth passed an Act entitled, "An Act relating to Bituminous coal mines and providing for the lives, health, safety, and welfare of persons employed therein." It was intended to be a complete system. Everything is required that was thought to be for the welfare of the miners, and everything prohibited that was likely to prove detrimental to the lives, health, or safety of those employed in such mines.

Among other provisions, the Act provides for the appointment of Inspectors, and prescribes minutely the duties to be performed by such inspectors. It is one of the duties of an inspector "to examine the mines in his district as often as possible, which shall be not less than once in three months, to see that the provisions of this Act are observed and strictly carried out."

In pursuance of his duty, William Jenkins, an Inspector of the Second District, on the 30th of April, 1890, gave notice to John P. Brennen, Superintendent of the McClure Coke Co., that but one mine boss was employed for two mines, known as Bessemer and Rising Sun, contrary to the provision of the fifth section of the said Act of Assembly, and requested an additional mine boss to be employed by said company. From this decision of the Inspector an appeal was taken to the Court of Quarter Sessions, under the fourteenth section of the Act. Again, it was decided by the Inspector that the McClure Company was violating the fifth section in employing only one mining boss for the mines known as Donnelly No. 1, Donnelly No. 2, and Mayfield; and also in employing one mining boss for Hazlett Shaft, and Hazlett Slope.

From the latter decision appeals were also taken.

On the 4th October, 1890, the Court appointed three practical, reputable, competent, and disinterested persons to forthwith examine such mines, and report, under oath, the facts as they exist, together with their opinions. For some unexplained reason such report was not filed in Court until 22d September, 1891. There is a difference in opinion among the viewers, but an agreement as to the facts as they exist.

The fifth section of the Act provides as follows: "In order to better secure the proper ventilation of every coal mine, and promote the health and safety of the persons employed therein, the owner or agent shall employ a competent and practical inside overseer, to be called mining boss * * * ." We think there is no difficulty in arriving at the meaning of this section. From the language of the section the expressed purpose of the Act and the many and exacting duties imposed on the inside overseer, it seems plain that the section requires a mining boss to be employed for every coal mine. The plain requirement is that to secure the proper ventilation of every coal mine a proper mining boss shall be employed.

What then is a coal mine in the sense in which it is employed in this statute?

A coal mine is defined as, "a mine or pit containing mineral coal;" and a mine is, "a pit or excavation in the earth from which ores are taken by digging." The number of men employed is immaterial, as it is provided in a subsequent section that the Act shall apply to every mine employing more than ten men. The extent of the mine does not seem to be a consideration in the mind of the Legislature, nor the amount of territory embraced in one mine. It seems equally clear that it is not the intention to require a mining boss for each separate working drift in the same mine. Nor is it necessary to inquire as to the quantity of coal mined, or whether the output from a mine goes to one or different places. It is not intended that but one mining boss should be employed by each coal company, or the Legislature would have so said in unmistakable terms. A single company may, and frequently does, control many mines extending over a great extent of territory.

Underground communication is an element not to be lost sight of, but these ramifications under ground may connect many different coal mines. "Every coal mine," then, evidently means every separate and distinct mining operation; mine disconnected with any other mine; an excavation from which coal is taken by digging, having a system and operation distinct and disconnected from any other mine. We have seen the definition of Webster, and, as commonly understood, a coal mine is also a pit where coals are taken out by digging in a distinct and separate operation. Every coal mine has its machinery and equipment for taking out the coal; its shaft, or slope, and system of ventilation; its mules and tracks and the men who work especially in that mine. And in and of itself contains every element of the definition, and so far as its operations are concerned, is independent of and disconnected from any other mine.

Now, what are the facts in these cases? The Hazlett mines are known as the Hazlett Shaft and Hazlett Slope. The two are connected by an entry for the purpose of drainage, but the entry is not sufficient for the purpose of travel. Each mine has its tipple and its system of ventilation, and apparently all the appliance for mining. Seventy-three men are employed in the one and thirty-one men in the other. The only other things in common are, that they are operated by the same company, have substantially the same name, and one mining boss has supervision over both. In other respects, so far as we are advised of the facts, each is independent of each other. We have no doubt that one mining boss could supervise both these mines. The territory is not large and not many men are employed: but we are also persuaded that each is a distinct coal mine, and under the Act it will be necessary to employ another certificated mining boss, one for Hazlett Shaft and one for Hazlett Slope. It might be a more reasonable requirement to give a mining boss supervision of a certain amount of territory, or over a certain number of men, but if such change is desirable it is for the Legislature and not for the court.

When we look at Bessemer and Rising Sun Mines the situation is somewhat different. These are connected by underground traveling ways. Both are of small area and confined within a limited space and only about eighty-four miners are employed in the two mines. Each mine has its own tipple and its own system of ventilation, and one mining boss has supervision of the two. Each seems to be complete in itself and independent of any other. Bessemer has all the machinery and equipment necessary for mining coal, and the operations there would go on if the other had no existence. What is true of Bessemer is also true of Rising Sun. The two mines are not one. The two have underground connection. One mining boss, in our opinion, could easily superintend both mines. But we have no discretion in the matter, and our duty is simply to construe the law, and, as we understand it, the law requires a mining boss for every coal mine.

It is very evident that East Donnelly, West Donnelly, and Mayfield are three distinct mines. Each has its own tipple. Each its system of ventilaton, and all the machinery and equipment necessary for mining coal. One mining boss has supervision over East Donnelly, and West Donnelly and one mining boss over Mayfield. Between East and West Donnelly there seems to be no connection underground. And yet in these three mines only 103 miners are employed. It seems an unnecessary burden to impose upon the company the duty of employing three mine bosses, but under the facts found, such seems to be the law. The concluding paragraph of the minority opinion is as follows:

I am also of the opinion that one mine boss can properly attend to two or three or more small mines, where the outlets are convenient of access to each other, and within close proximity to each other, where the number of men aggregate within reason, say 200 men. There are many mines in the Bituminous region, having one mine boss, where there are employed from 250 to 500 men, and the area of such mines being of far greater extent than is the area of any of these mines in dispute, namely, "The Hazlett," "Bessemer," and "Rising Sun," and "Donnellys 1, 2," and "Mayfield."

And now, January 30, 1892, it is therefore ordered and directed that one certificated mining boss be employed for each of the following mines: Hazlett Shaft, Hazlett Slope, East Donnelly, West Donnelly, Rising Sun, Mayfield, and Bessemer. And it is further ordered that the appellant pay the costs of this proceeding, including a reasonable compensation to the viewers, which compensation shall be agreed upon by the counsel for the parties, or, on failure to agree, hereafter to be fixed by the court.

The Origin of the Name "Tram" Road.

Webster's Dictionary tells us that the origin of the word tram is *probably* Scandinavian. This is an instance in which the Dictionary is mistaken. Before the days of the railroad, the canal was, in England, as elsewhere the most convenient means of transit for heavy loads and the owners of these many water-ways stood much in the position of the railroad kings of to-day.

Among the most successful canals in England was the one stretching from Derby to Birmingham and Staffordshire. One end of it extended to the north of Derby about four miles to a place called Little Eaton and its terminus there formed a convenient connection with the extensive house-coal, iron and pottery fields of the Alfreton and Ripley districts. The land from Little Eaton to Alfreton has a considerable rise and it was thought unremunerative to build so many locks as would be required if the canal were extended to the latter town. A road was laid therefore through a tract of land purchased for the occasion by the Canal Co., and this road is in active operation in connection with the canal to the present day. The designer of the road was James Outram, of Little Eaton. It consisted of flat cast-iron flanged plates each 3 feet long with a gauge about equal to an ordinary cart. The rails were laid at each end on stone blocks and fastened to them by spikes driven into a lead plug run in a hole in the stone. The road was called, after its inventor an Outram road afterwards contracted into 'tram road.

The cars run on the road are made with removable bodies that can be hoisted bodily with their loads of two tons each into the canal boats. When these boats arrive at their ultimate destination the car bodies are then hoisted out and laid with their load on cart frames and the soft high class coal of the Kilburn Valley is thus transported direct from the coal pit to the very cellars of the consumers without being once transshipped.

This explanation of the origin of the word tram is given in Dr. Smile's Life of George Stephenson.

Removal.

Mr. H. A. Kingsbury, dealer in mine, mill, and railway supplies and manufacturers' agent, 435 Spruce St., this city, announces his removal on April 1st, to Temple Court Building, 313 Spruce St. The well known high standing of the manufacturers he represents and his close connection with them, together with the undisputed superiority of their goods enables him to offer the best material at the lowest prices. His reputation as an honorable business man insures perfect satisfaction to his customers. He has demonstrated the fact that careful attention to his business, truthful representations as to his goods and honorable treatment of his competitors, are a means of success. In his new quarters he will be prepared to estimate on machinery and supplies for any part of the continent. We wish him continued success in his new and better location

THE USE OF THE UPPER TELESCOPE.

A Practical Example Illustrating its Use and the Calculations Required to Obtain the Correct Vertical Angle.

BY H. W. ALTHOUSE,

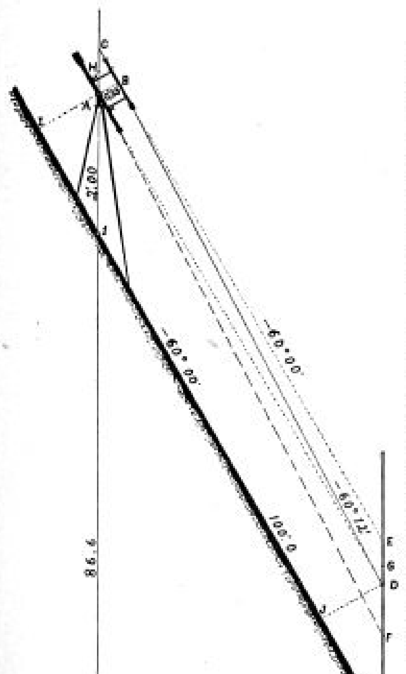
Assistant Engineer Consolidated Coal Company, of St. Louis.

This necessary adjunct to the mining transit is designed especially for use on heavy pitches where the lower telescope proves of no effect, either as to taking the course or for obtaining the vertical angle.

Perhaps to no other part of the transit is given such little attention as this same telescope, which, being a separate article, seldom receives the care to which it is entitled, and at times it is looked upon as rather an evil. However, its employment is necessary in that portion of the Anthracite coal fields where heavy dips are of frequent occurrence.

The upper telescope should be in adjustment with that of the lower, for level, plus the height between the center of each, which by construction in most transits is 0·35 ft., and under no circumstances is it advisable to remove the telescope until after having completed the heavy angles, as the adjustment would likely change. A good policy always is to test it before using.

Other devices for taking vertical angles on steep inclines are in use, but ineffective where most needed;



such as in lining slopes and repeating the vertical angles, which should always be done, and the angles averaged, care being taken that the rear and fore rods are vertical and that the heights to the lower telescope on both correspond.

For determining the vertical heights by means of the upper telescope many different methods, though at variance with each other, and also incorrect, are commonly employed. Thus, as in annexed sketch, the pitch of slope being 60° 00′, the height of transit (1 H), two feet and the rod 2 G the same. Now in sighting, the angle B to G is thus made less than it should be and the height changing from 1 H to nearly 1 B, it does not follow that by simply deducting the distance (A B), 0·35 ft. from the apparent vertical height that the latter is correctly attained.

Another method used to considerable extent, is to take the angles to G and 2, and give the heights of instruments 1 B and whatever other it will make by sighting to 2. This may not appear incorrect, but a glance at the sketch will show its inaccuracy.

Still another plan, and as with the rest, above mentioned, at fault, is occasionally used. By placing the height A C to the vertical height obtained by sighting B D. This mode on heavier pitches requires plumbing, etc., in order to find the point of intersection at C which can not be done without assistance, and is dangerous, in fact, almost an impossibility.

If anything the engineer desires to complete his work quickly, as on a slope there is no time and it is no place to be reaching unnecessarily about on pitches of 60° to 80°, and even as great as 83°, an instance of which I know, nor is it pleasant to be grasping a rope or rail on such dips in winter, the mercury near zero and ice continually falling, making the work dangerous and difficult.

After thoroughly considering the foregoing methods I evolved a plan to obtain the true vertical angle which worked successfully requiring less labor at the instrument, and also being simple and accurate. An explanation of which is as follows:

Noting the sketch D on the rod marks the "elevation" or height 1 A of the transit, invariably to be taken to the lower telescope because most easily accomplished. Then as the distance 1 2 is 100·0 ft. which I J also equals, and the line B D found to read minus 60° 12′, giving the right angle triangle, A B D with the angle B 90° 00′, perpendicular (A B) 0·35 and the base B D, 100·0 ft. to find the angle at D.

$$\frac{A\ B}{B\ D} = \text{Tang. angle D.}$$

$$A\ B = 9{\cdot}544068$$
$$B\ D = 2{\cdot}000000$$

Tang. angle Corres. 7.544068 = 0° 12′ angle D.

The line B D being—60° 12′ and since this line D is found to be 0° 12′ in excess, of B E the true vertical angle would read—60° 00′, which for 100·0 ft. on the pitch gives the vertical and horizontal distances as 86·6 ft. and 50·0 ft. respectively.

In the other methods of using the "top" telescope, the distance on the same pitch decreases and the angle increasing, the error becomes greater, and on very heavy dips, is considerable.

Therefore, in determining elevations with the upper telescope, great care should be taken, and the plan I have given will be found convenient and accurate.

The Pennsylvania as a Disburser.

The speech of President Roberts at the annual meeting of the Pennsylvania Railroad was interesting in giving a novel and striking idea of the importance to the business interests of the community of a great corporation. The public, except that portion of it employed by the railroads, is apt to regard them as a tremendous concern which simply moves freight and carries passengers and as a great absorber of money. They do not know, or they forget, that the railroad company pays back to the community in cash promptly the larger portion of its earnings in wages, and that it is, besides, a large purchaser of manufactures and a patron of every department of trade. A purchasing agent in this city recently bought for his company some sewing needles and an anchor on the same day. It would be difficult to mention any article of commerce in which a railroad company in its capacity as a consumer does not deal.

In his speech, Mr. Roberts pointed out the extent of the Pennsylvania Railroad's operations as a purchasing and consuming portion of the community. He showed that during the last decade that corporation had absorbed the productions of Philadelphia alone to the extent of \$15,800,000, or at the rate of \$1,500,000 per year. The man or corporation which adds \$5000 per day to the business of his city, and does it for ten years, ought to be cultivated. This sum, it is understood, includes only the money spent in actual improvements—in terminals, wharves, warehouses, shops in the city, &c., which indirectly tend to make further increases in commerce and trade in many directions.

The total expenditures of the Pennsylvania Railroad are, of course, much larger, and, after showing what the road had done for the city, President Roberts took up those figures. In the single year of 1891 the Pennsylvania Railroad expended in this Commonwealth the enormous sum of \$52,000,000, or at the rate of \$1,000,000 per week. There are not three railroads in the United States whose gross earnings are equal to this sum, a fact which, after all, gives but a small idea of the immensity of the Pennsylvania's disbursing capacity, as we believe forty other millions were spent on portions of the line outside the State. The figures do not need elaboration. They demonstrate at once how much and how important a part of the community the Pennsylvania Railroad is, and point out its intimate relations to all matters pertaining to business in a most striking way.

The ultimate effects of these large, constant, and timely expenditures cannot be contemporaneously known or pointed out. We of this generation can only see that they have added largely to the convenience of the public, that they have made the city more accessible to freight shippers, that they have increased our coastwise and foreign trade, that they have added to our manufacturers, and in a hundred ways built up and promoted the stability of the city and Commonwealth. President Roberts and his able lieutenants are to be congratulated on having done so much towards the development of commerce and the promotion of all that tends to a broader and more beneficent civilization.—*Editorial in Philadelphia Press March 10, 1892.*

To Pump Users.

Imitation, it has been well said, is the sincerest flattery, and the makers of the Pulsometer Steam Pump, now known the world over, have therefore much upon which to congratulate themselves. Imitations of the Pulsometer have, within the past half-dozen years, been turned out in growing numbers, but, without exception, they have failed to secure that degree of economy, convenience, and general adaptability to a wide variety of uses for which the genuine Pulsometer has become so justly famed.

Years of practical work with the Pulsometer, under all kinds of conditions and for the most varied uses, have demonstrated the merits claimed for it in the most striking manner, and leave little more to be said in its favor. Carefully conducted expert tests, moreover, made within the past year at Stevens Institute of Technology, one of the foremost engineering schools, have given figures for economy of performance of the Pulsometer which firmly establish it in its high rank of excellence among that class of water raising machinery with which it was designed to compete, and have entirely wiped out the erroneous impression, held by some, that it is an uneconomical machine in point of steam consumption.

The test figures show that the performance of the Pulsometer ranges considerably above the performances of the average of the direct-acting steam pump, and its efficiency further is maintained steadily and uninterruptedly, and will not, after a comparatively short period of use, come down to a low notch, as is the case with most direct-acting pumps.

There is nothing to wear out in the Pulsometer that cannot in a few minutes, at an insignificant cost, and without removing the pump from its postion, be replaced; no leakage of valves, plungers, pistons, staffing boxes, and the like—and hence its unique position in point of excellence of performance and durability.

As regards cost, the Pulsometer defies the competition of other pumps of the same rated capacities. Its cheapness and freedom from complicated mechanism at once commend themselves, even to the most inexperienced, and to those desiring simple pumping machinery capable of handling large quantities of water or other liquid, with the least trouble and expense.

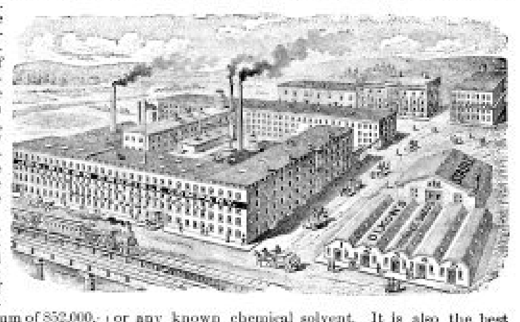
The Graphite Industry.

The graphite industry is fittingly represented by the company whose founder first gave it birth.

The Joseph Dixon Crucible Co., Jersey City, N. J., was founded by Joseph Dixon in 1827, who, at that time began the manufacture of black lead crucibles and completely revolutionized the crucible business. All crucibles used at the present day for melting brass, steel, copper, gold, silver, nickel, etc., are made of blacklead (the common name for graphite), and by the Dixon process.

The Dixon company have not only been progressive, but they have been aggressive, and have pushed their goods into all parts of the civilized world. During the past year they made extensive changes in their factories, and we take pleasure in showing by the illustration below the main works and offices located in Jersey City. Their graphite mines are at Ticonderoga, N. Y., and their cedar mills are at Crystal River, Fla.

The nature of graphite, sometimes called plumbago, or blacklead, is not generally understood; and therefore its great value in the mechanical arts has not been fully appreciated. Graphite is one of the forms of carbon. It is not affected by heat, cold, acids, alkalies



or any known chemical solvent. It is also the best solid lubricant known to science, a remarkable conductor of heat and electricity. The peculiar qualities of graphite have given it a wide range of usefulness. It is used in the manufacture of lubricants for all purposes, crucibles, stove polish, lead pencils, foundry facings, electrotyping, graphite, graphite paint, etc.

The Dixon Co. are miners as well as importers of graphite in all its forms, and use no graphite that they do not mine or prepare. Their mines are located in Ticonderoga, N. Y., and they have every facility in the way of chemists and expensive machinery, etc., necessary for completely freeing the graphite from the silica, sulphur, and other impurities which it contains when it comes from the mines.

The company's illustrated catalogue of graphite productions is an interesting pamphlet and well worth reading. It is sent free on application.

Rope Haulage and Rope Transfer.

It may be interesting to know what the Trenton Iron Company are doing in the wire rope tramway business, in addition to the line which they have just so successfully built for the Holy Moses Mine in the New Creede district. They have received the following contracts: One line for the Amethyst Mining Company in the Creede Camp, having a length of 8,250 feet, and a capacity of 200 tons per day; another line of 5,150 feet for the Smuggler Union Mining Company in Ouray, Colo., with a capacity of 200 tons per day, and another line for one of the Haggin Mines in Guanacevi, Mexico, having a capacity of 100 tons per day, and a length of 5,900 feet. They are also under contract for one of their large cable hoists for the Avondale Stone Company, of Pennsylvania, and have just completed a duplicate one for the Passaic Quarry Company, of Paterson. They are about to duplicate the big cable transfer over the Susquehanna at Williamsport; and are now constructing an additional 800 tons per day tramway for the Pennsylvania and West Virginia Coal Company, in West Virginia, and another for the transportation of colm for the St. Bernard Coal Company, of Kentucky, and also a large haulage plant for the Croton Falls Magnetic Iron Ore Company, near Brewsters, N. Y.

Correspondence

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.*

Mensuration.

Editor Colliery Engineer:

SIR:—Will some of your readers kindly answer the following question:

One evening I chanced with a tinman to sit,
Whose tongue ran a great deal too fast for his wit;
He talked of his art with abundance of mettle,
So I asked him to make me a flat-bottomed kettle;
Let the top and the bottom diameters be,
In just such proportion as five is to three;
Twelve inches the depth I propose and no more,
And to hold in ale-gallons* seven less than a score.
He promised to do it and straight to work went,
But when he had done it he found it too scant;
He altered it then but too big he now made it,
For though it held right the diameters failed it;
Thus making it often too big and too little,
The tinman at last quite spoiled his kettle;
But he vows he will bring his said promise to pass,
Or he'll utterly spoil every ounce of his brass.
Now, to save him from ruin, I pray find him out
The diameter's length, for he'll never do it, I doubt.

*Ale-gallon = 282 cubic inches.

Yours, etc.,
L. P. H.

Avoca, Pa., Feb. 11th.

The Siphon.

Editor Colliery Engineer:

SIR:—In answer to "S. U. P.," in the January issue, I would say that the quantity of water delivered per minute is about 30 gallons (U. S.). See THE COLLIERY ENGINEER Pocket-Book for table; for 2″ pipe look on page 110, in upper right hand column. Then

$$30 \times 60 \times 4 = 7200 \text{ gallons in four hours;}$$

this being 75% of the total quantity we have 7,200 + 2,300 = 9,500 U. S. gallons made in 24 hours.

If "S. U. P." wishes to make the calculation, I know of no better formula than Hawsley's, viz.:

$$\text{Imperial Galls.} = \sqrt{\frac{(15\ d)^5 \times H}{L}}$$

Where
d = diameter in inches.
H = head of water in feet.
L = length of pipe in yards.
Galls. = gallons per hour.

This only leaves 100 U. S. gallons in the 24 hours difference between the two formulæ.

Yours, etc.,
J. V.

Punxsutawney, Pa., Feb. 15th.

Speed of Fans.

Editor Colliery Engineer:

SIR:—The barometer reads 29·5° where a fan is making 40 revolutions per minute, if the barometer suddenly falls to 28·5° would the fan travel faster (owing to diminished density) or otherwise, the power remaining the same?

Would some of your able correspondents kindly answer the above question?

Yours, etc.,
C. A.

Broadford, Pa., Feb. 3d.

Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following in reply to "Carbon," of Lemont Furnace, Pa., in the January issue:

The quantity will be in proportion to area, thus—

$$6{,}250 : 22{,}500 :: 25 : x, \text{ or } 58 \text{ sq. ft. area.}$$

Yours, etc.,
T. K.

Mt. Olive, Ill., Feb. 10th.

Gas in Siphon Pipe.

Editor Colliery Engineer:

SIR:—Will you please publish the following, that some of your able correspondents may express their views:

A siphon is laid in a mine, and it is found that after running several hours it "cuts off." There is little or no leak in the pipe, which on being uncoupled at or near the summit, and a lamp held near the pipe to see if there is any obstruction, a gas is fired, and the pump being on the inner or feed end is started. The gas burns at end of pipe until water forces the gas all out. Now, what kind of gas is it, and how can the difficulty be avoided; or, in other words how can the gas be removed from pipe while still running so as to prevent stoppage of siphon?

It has been claimed by some that an air chamber at summit and two valves, one below chamber and one above, so as to have a space above pipe for the gas and air to accumulate in, and then, by closing the lower valve and opening the upper one it would escape. Would this be effective? State reasons *pro* and *con.*

Yours, etc.,
S. U. P.

Lawsonham, Pa., Feb. 16th.

Mechanics.

Editor Colliery Engineer:

SIR:—I submit the following in answer to Thomas M. Brown, of Pinckneyville, Ill., in your last issue:

Let,
A = area of cylinder in sq. inches.
D = diameter of piston in inches.
P = average pressure of steam in lbs. per sq. in. in cylinder.
S = length of stroke in feet.
R = number of revolutions per minute.

Then, we have the following formula:

$$\frac{2\,A\,P\,R\,S}{33{,}000}, \text{ or } \frac{A\,P\,S\,2\,R}{33{,}000} = \text{H. P.}$$

Substituting values, we have

$$\frac{2 \times 20^2 \times {}^{\cdot}7854 \times 44 \times 6' \times 20}{33{,}000} = \frac{3{,}317{,}529{\cdot}6}{33{,}000} =$$

100·5, the horse power of the engine.

Yours, etc.,
L. P. H.

Avoca, Pa., Feb. 11th.

Mathematics.

Editor Colliery Engineer:

SIR:—Please publish the following in reply to question by "F. W.," of Duncan P. O., Pa., in your last issue:

A shaft 12′ in diameter was measured by a rod the exact depth of the shaft, and on leaning it over against the other side, thereby forming the hypothenuse of a right-angled triangle, it lacked one inch of reaching the top, what is the depth of the shaft? Please explain fully.

Let x = the depth of the shaft in feet, it will also equal the hypothenuse of the right-angled triangle formed; $(x - \frac{1}{12})$ will equal the perpendicular of the triangle, and as the square of the hypothenuse equals the sum of the squares of the other two sides, we have

$$x^2 = (x - \tfrac{1}{12})^2 + 12^2, \text{ or}$$

$$x^2 = x^2 - \tfrac{1}{6}\,x + \tfrac{1}{144} + 12^2,$$

transposing

$$x^2 - x^2 + \frac{x}{6} = 144 + \tfrac{1}{144},$$

collecting and solving

$$x = 6\,(144 + \tfrac{1}{144}) = 864'\ 5'',$$

depth of shaft.

Yours, etc.,
W. J.

South Fork, Pa., Feb. 16th.

Ventilation.

Editor Colliery Engineer:

SIR:—In THE COLLIERY ENGINEER of June, 1891, there is published the following question: "A fan running at 40 revolutions per minute, produces 60,000 cu. ft. of air per minute, what will the quantity be if the revolutions be increased to 60?" The formula used in solving was:

$$40 : 60 :: 60{,}000 : 90{,}000 \text{ cu. ft.}$$

In January, 1892, this question was given, "A fan making 80 revolutions per minute produces 40,000 cu. ft. of air, how much more would it produce if the revolutions were doubled?" It is worked out by the use of this formula:

$$\sqrt{80} : \sqrt{160} :: 40{,}000 : x, \text{ or } 56{,}445\tfrac{1}{2} \text{ cu. ft.}$$

Now, as the questions are similar, I would like to know which of the two formulæ is the right one to use for such examples? Please explain fully.

Yours, etc.
J. E. J.

Duryea, Pa., Feb. 15th.

Mensuration.

Editor Colliery Engineer:

SIR:—I submit the following in answer to second part of "Trackman's" question, which appeared in the October issue; the first part having been answered by others: A tree 80′ long, 6′ diameter at butt end, tapers to 1′ diameter, how long a rope will it take to coil around it, the coils to be close together, also how long will the rope have to be, allowing 12″ between coils?

We may liken the circumference of the tree to a series of right-angled triangles, with bases decreasing from 18·8496′ to 3·1416′ with an altitude of 1′. The length of rope required to go around one section will be the hypothenuse of the triangle, and for the tree it will be the sum of the hypothenuse of the 80 sections.

From the end diameters the mean diameter is found to be 3½′. Then,

$$3\tfrac{1}{2}' \times 3{\cdot}1416' = 10{\cdot}9956, \text{ the mean circumference;}$$

and by using the following formula we find the required length:

$$\sqrt{10{\cdot}9956^2 + 1^2} \times 80 = 833{\cdot}27832'.$$

Yours, etc.,
J. E. M.

Duncan, Pa., Feb. 15th.

A Suggestion.

Editor Colliery Engineer:

SIR:—I notice in the Inspectors' report for 1890, that Ex-Inspector Austin King has not corrected the error he made in 1889, but assumes that some parties holding first grade certificates are not qualified according to law. This is, no doubt, correct; yet, there are others whom he failed to mention who have labored for years in gaseous mines. I would suggest that Mr. King publish the names of all the first and second class certificated men, and let the public see who the impostors are. The Board appointed by the proper authorities granted the certificates. If there are men who obtained first grade certificates under false pretenses the law will deal with them. If Mr. King has not the names Mr. D. H. Thomas, his successor, can furnish them.

Yours, etc.,
FAIR PLAY.

Rimersburg, Pa., Feb. 9th.

Siphon.

Editor Colliery Engineer:

SIR:—Please insert the following in reply to "S. U. P.," of Lawsonham, Pa., whose question appeared in the February number:

"A siphon 550′ long and 2″ in diameter has a lift of 8′ from sump to summit, and 25′ fall from summit to discharge. What will be the volume of water discharged per minute? The water is allowed to accumulate 14 hours, and the siphon will run off this head, in addition to the water made while running, in 4 hours. Now, what is total amount of water conveyed in 18 hours. This being 75% of water made, what will be the total amount for 24 hours?"

Now, using Eytelwene's formula,

$$W = \sqrt{\frac{D^5 \times H}{L}} \times 4{\cdot}71.$$

When
D = diameter of pipe in inches.
H = head of water in feet.
L = length of pipe in feet.
W = cubic feet of water discharged per minute.

To those who do not understand what is meant by "head of water," as used in this formula, I would say it is the vertical difference between the lift and discharge. Now, in this question, we have a lift from sump to summit of 8′, and from summit to discharge a fall of 25′.

Then

$$25' - 8' = 17' = \text{H}.$$

$$W = \sqrt{\frac{2^5 \times 17}{550}} \times 4{\cdot}71 = \sqrt{\frac{32 \times 17}{550}} \times 4{\cdot}71 =$$

$$32 \times 17 = 544,\ 544 \div 550 = {}^{\cdot}9890909090.$$

$$\sqrt{{}^{\cdot}9890909090} = {}^{\cdot}99448.$$

$\cdot99448 \times 4{\cdot}71 = 4{\cdot}684 +$ = the number of cubic feet of water discharged per minute, and

$4{\cdot}684 \times 60 = 281{\cdot}04$ cubic feet of water discharged per hour.

Judging from the nature of the question, the siphon runs 4 hours out of every 18. In one hour it discharges 281·04 cubic feet of water, in 4 hours it will discharge 281·04 × 4 = 1124·16 cubic feet, being the amount of water conveyed in 18 hours, this being 75% of water made in 18 hours, to find total amount made we will solve it thus: 75% : 100% :: 1124·16 : 1498·88. This is the total amount of water made in 18 hours. To find the total amount made in 24 hours, we use the same rule.

$$18 : 24 :: 1498{\cdot}88 : 1998{\cdot}5.$$

Yours, etc.,
J. N. K.

Mansfield Valley, Pa., Feb. 14th.

Ventilation.

Editor Colliery Engineer:

SIR:—Please publish the following in answer to "S. U. P.," of Lawsonham, Pa.:

It is not the raise and dip of a mine that will make so large a difference in the ventilation as friction resistances. The velocity of the large mine is 4·08 times that of the small mine, and the frictional resistance increases as the square of the velocity.

For the first mine, we have 6′ × 9′ = 54 sq. ft., area at inlet; area of furnace = 8 × 6 × ·7854 ÷ 2 = 18·84 sq. ft.; and 10,000 + 15,000 ÷ 2 = 12,500 cu. ft., the average amount of air passing through the large mine. Then, $q \div a = v$, or 231·4′ at inlet, leaving a velocity of 663·4′ per minute at furnace.

The area of inlet of second mine = 5′ × 7′ = 35 sq. ft., and 2,500 + 4,000 ÷ 2 = 3,250 cu. ft. of air, the average amount of air passing through small mine. Then $q \div a = v$, or 92·8′ at inlet, with a velocity of 162·5′ per minute at furnace. Now, $v \div v = D$, or 663·4 ÷ 162·5 = 4·08 times greater velocity at large furnace than at small one; also, $v \div v = D$, or 231·4 ÷ 92·8 = 2·5 times greater velocity at inlet at large mine than at small one.

Yours, etc.,
RICHARD LEWIS.

Gosford, Armstrong Co., Pa., Feb. 15th.

Thin-Coal Mining in Missouri and Kansas.

Editor Colliery Engineer:

SIR:—With reference to Messrs. Winslow & Gluck's very interesting paper on the above subject, in March COLLIERY ENGINEER, I should like, with your permission, to ask the authors for a little further information on one or two points that bear directly upon the practical mining of these thin coal seams:

FIRST. It would be useful to know the *details of the sections of the seams*, together with a description of the *cleat* or "*face and butt*", if any; and what effect this cleat has upon the digging of the coal: the all-round or "circle system" of working indicating, as I consider it does, that there is no well-defined system of joints in these coals.

SECOND. Fig. 3 shows that all the coal has been removed from around the foot of the hoisting shaft—that no shaft-pillar has been left. The air shaft-also, is upon the gob. Will the authors please inform us what the practical effect was upon the shafts owing to no pillars being left; *i. e.*, how much did they subside; were they pulled out of plumb; how long did it take for them to become quite settled after coal was mined out around them; were the gobs packed or filled up solid from the start; was the coal got out around them from them outwards, or towards them from a short distance away?

THIRD. To what scale is plan Fig. 2 drawn?

FOURTH. Does the $5.00 a running yard said to be paid for removing coal in entrywork in pillars, mean for *coal only*, the floor-lifting being extra?

FIFTH. What is about the *average thickness of brushing* in the "short room ways"?

SIXTH. Please give the *dimensions of screens* used at Leavenworth Mines.

SEVENTH. A description of the "sled-like buggies" used where roofs are weak, would be of interest; and are they run upon the bare floor of the working-place, or upon boards, or what?

EIGHTH. Should like to be informed as to *nature and extent of surface settlement* due to mining these thin seams, to which authors make reference.

Yours, etc.,
W. S. GRESLEY.

Erie, Pa., March 23d.

Mensuration.

Editor Colliery Engineer:

SIR:—In answer to "Beginner," of Riverton, Ill., would say I think answer given by me in December issue is correct.

I stated the formula precisely as given by Haswell, but in order to make it plainer for "Beginner," I herewith give answer and process of finding same:

$1 + 6 = 7 + 2 = 3·5 \times 3·1416 = 10·9946 \times 80 = 879·57$, and

$879·57 \times 879·57 = 773643·3849 + (80 \times 80)$, or $6400 = 773707·3849$ and $\sqrt{773707·3849} = 879·65$ feet.

The following formula, perhaps, would be plainer than one given in December:

$$\sqrt{(6 + 1 + 2 \times 3·1416 \times 80)^2 + 80^2} = 879·65'.$$

James Payne, of Adger, Ala., solves the question in January issue, giving same answer.

Yours, etc.,
H. L. D. W.

Cincinnati, Ohio, February 16th.

The Siphon.

Editor Colliery Engineer:

SIR:—Will you please insert the following reply to the question regarding the siphon, in your February issue, by "S. U. P.":

The flow of water disregarding friction is due to the difference of level between the ends of siphon which in this case is 17 ft., and now according to the laws of falling bodies—square root of twice the product of the gravity and space fallen through is equal to the velocity in feet per second;

$\sqrt{2 \times 32 \times 17} = 32·241$ ft. per second, and the amount of water flowing is equal to the area of the pipe times the velocity per second

$2^2 \times ·7854 = 3·1416$ area of pipe.

Then, $3·1416 \times 32·241 \times 12 = 1215·196$ cu. in. per second—which converted to gallons of water per hour equals

$$\frac{1215·196 \times 60 \times 60}{276} = 15850·382 \text{ gallons per hour.}$$

And as the siphon ran off all the water made in 18 hours in 4 hours, the total amount of water made in 18 hours $= 15850·382 \times 4 = 63200·152$ galls. of water ran off in 4 hours and made in 18 hours. This being 75% of what was made in 24 hours, therefore, $63200·152 \div ·75 = 84266·869$ gallons made every 24 hours. The above is theoretically, the quantity made and ran off by siphon. But taking friction the quantity is considerably reduced. Considering friction we have the following formula to compute the flow of water through pipes:

$$48\sqrt{\frac{D \times H}{L + 54\ D}}$$

Let D = diameter, H = head, and L = length of pipe; placing the value in the above formula we have

$$48\sqrt{\frac{\frac{1}{6} \times 17}{55 + 54 \times \frac{1}{6}}} = 48\sqrt{\frac{\frac{17}{6}}{559}} =$$

$$48\sqrt{\frac{17}{6} \div \frac{559}{1}}, \text{ or } 48\sqrt{\frac{17}{6} \times \frac{1}{559}} =$$

$\frac{197·9088}{57·913} = 3·417 \times 12 = 41·004$ ins. = velocity per second.

As stated in the first solution the quantity of water is equal to the area of the pipes times the velocity of second, which is

$3·1416 \times 41·004 = 128·8181664$ cubic inches per second, and taking 276 cubic inches to the gallon we have

$$\frac{128·8181664 \times 3,600}{276} = 1680·2369 \text{ gallons,}$$

per hour and $1680·2369 \times 4 = 6720·9476$ gallons ran off in four hours, which is the whole water made in 18 hours and 75% of water made in 24 hours which will be

$$\frac{6720·9476}{·75} = 8961·2635$$

gallons made in 24 hours.

Yours, etc.,
M. D. R.

Kingston, Pa., February 20th.

The Utilization of Electricity.

Editor Colliery Engineer:

SIR:—The object of your valuable journal being "the education of your readers in everything relating to mining," and as electricity is likely to become a great power in the near future in mining, as in almost every other branch of industry, information as to generating, accumulating, and storing electricity would be quite "*apropos*."

Being an old miner myself (but not at present employed in the mines), and although but a new subscriber, still I am greatly interested in your journal, and would like to ask through your columns, if some of your numerous and able correspondents, many of whom are, no doubt, *au fait* in the *modus operandi*, would advise me as to the following idea:

I am running a plant here with a Westinghouse compound engine, the main driving belt, 24'' wide, has a velocity of nearly 5,000' per minute, generating in the immediate vicinity of the pulleys, a great amount of electricity. My idea (Quixotic perhaps) is that this electricity could be utilized in illuminating the engine and boiler rooms, if it were possible to accumulate and store it. As I have no knowledge, theoretical or practical, of the application of electricity to practical purposes, I would be glad if some of your readers would inform me, if, in their opinion, there is sufficient electricity developed, under the above conditions, to run one or more lights, arc or incandescent, and if so, how it could be accumulated and stored and what appliances I would require.

Yours, etc.,
EDWARD HALPIN.

Allegheny City, Pa., February 18th.

Mechanics.

Editor Colliery Engineer:

SIR:—I submit the following answer to the question asked by "F. W.," in your February issue: "A shaft 12' in diameter was measured by a rod the exact depth of the shaft, and on leaning it over against the other side, thereby forming the hypothenuse of a right angle triangle, it lacked one inch of reaching the top, what is the depth of shaft?"

Let x represent the depth of shaft from the point where the rod came in contact with the other side.

Now $x^2 + 144^2$ is equal to $(x + 1)^2$,

Or $x^2 + 144^2 = x^2 + 2x + 1$.

Or by cancelling the x^2 on both sides we find

$144^2 = 2x + 1$.

Transposing we have $144^2 - 1 = 2x$,

Then

$$x = \frac{144^2 - 1}{2},$$

or 10367·5 inches = perpendicular.

To prove the above solution we will find the depth of the shaft from the above data, the base of the shaft is given as 144 inches, and we have found that the perpendicular or the side of shaft from the point where the rod came in contact with it, to be 10367·5 inches.

Now,

$\sqrt{10367·5^2 + 144^2} = 10368·5$ inches equal to length of rod and depth of shaft. Trusting that it is fully explained, I remain

Yours, etc.,
M. D. R.

Kingston, Pa., Feb. 20th.

Mensuration.

Editor Colliery Engineer:

SIR:—Would some of your able correspondents kindly inform me how to change the rise per yard measured on pitch to degrees and *vice versa*. For instance.

(1.) An incline pitches 8°, what is the rise per yard of incline?

(2.) An incline is 33 yards long, and rises 9'' to the yard, what is the degree of divergence?

Please give rule without having to use tables of sines, etc.

Yours, etc.,
J. V.

Punxsutawney, Pa., February 21st.

Ventilation.

Editor Colliery Engineer:

SIR:—In "L. P. H.'s" answer to "Carbon's" question, in the January issue, I beg to state that he makes the area too small, it should be about 124 sq. ft. "L. P. H." is all right as far as he goes, but he should also take the rubbing surface of the 90' area, and the rubbing surface of the 25' area and proportion them thus:

$$\sqrt{20} : \sqrt{38} :: 90 : 124.$$

If "L. P. H." will work out the formula

$$\frac{k\,s\,v^2}{a}\ g = u,$$

he will find u to be larger for the 90' area than for the 25' area, but for 124' area, supposing them all square, he will find that for the quantities mentioned, that u is about the same. Taking the length as 1,000', u = nearly 6,800.

Yours, etc.,
J. V.

Punxsutawney, Pa., February 21st.

Mathematics.

Editor Colliery Engineer:

SIR:—In answer to "F. W.," of Duncan P. O., Pa., would say that if the rod on measuring the shaft, was placed close to the side, then leaned over to the other side, as described, the shaft would be $864\frac{1}{24}'$ deep.

The 12' diameter would equal the semi chord, the inch short on the rod would equal the rise, and the depth of shaft the radius. The rule for working out such a problem is to square the semi-chord, divide by the rise, to quotient add the rise, and, then, dividing by 2 gives the radius. (See The Colliery Engineer Pocket Book, page 9, and 9th rule on page.)

Then,

$12^2 = 144$, and $144 \div \frac{1}{12} = 1728' + 1'' = 1728\frac{1}{12}'$ and $1728\frac{1}{12}' \div 2 = 864\frac{1}{24}'$ = depth of shaft.

Yours, etc.,
J. V.

Punxsutawney, Pa., February 21st.

The Siphon.

Editor Colliery Engineer:

SIR:—I offer the following solution to question by "S. U. P.," in the February issue:

A siphon 550' long and 2'' in diameter has a lift of 8' from sump to summit, and 25' fall from summit to discharge, what will be the volume of water discharged per minute?

Using Eytelwein's formula:

D = diameter of pipe in inches.
H = head of water in feet.
L = length of pipe in feet.
W = cubic feet of water discharged per minute.

$$4·71 \times \sqrt{\frac{D^5 \times H}{L}},\quad \sqrt{\frac{32 \times 17}{560}} \times 4·71 = 4·71$$

cu. ft. discharged per minute, and

$$\frac{4·71 \times 7·48}{231} = 35·23$$

gallons per minute.

The water is allowed to accumulate 14 hours and the siphon will run off this head in addition to the water made while running in 4 hours, thus making 18 hours water run off in 4 hours, what is total amount of water conveyed in eighteen hours?

If the siphon discharges 35·23 gallons of water per minute, it will discharge $35·23 \times 60 \times 4 = 8455·2$ gallons in four hours which is the amount of water conveyed to sump in 18 hours?

This being 75% of water made what will be the total amount for 24 hours.

$$\frac{8455·2 \times 100}{75} = 11274 \text{ gallons nearly,}$$

$$\text{and } \frac{24}{18} \times 11274 = 15028·24 \text{ gallons in 24 hours.}$$

Yours, etc.
A. B.

Oakwood, Vermillion Co., Ill., March 5th.

Ventilation.

Editor Colliery Engineer:

SIR:—I submit the following in reply to "Alberto," Wall, All'y Co., Pa.,—question No. 2: He wants to know, if the pressure at entrance of air-way 4000' long with 4000' return is indicated by W. G. to be 0·5, what it will be if taken 2000' farther in, he also wants a rule to find the pressure at any given distance. In the first place the difference indicated by W. G. is caused by the air rubbing against the surface exposed in its travel from the time it enters the mine until its exit, and the pressure is increased or decreased in proportion to the surface exposed, the velocity remaining the same. We therefore have in this case an example in the following proportion, $4000' \times 2 - 2000' = 6000'$. Therefore as $8 : 6 :: 0·5 : x$, or $0·375$ = pressure 2000' farther in. For rule explaining fully the friction of air in mines, I would refer Alberto to THE COLLIERY ENGINEER pocket book, page 74.

Yours, etc.,
T. K.

Mt. Olive, Ill., March 16th.

Specific Gravity of Gases.

Editor Colliery Engineer:

SIR:—Will some of your readers kindly give rule for finding the specific gravity of the different gases? Please explain fully.

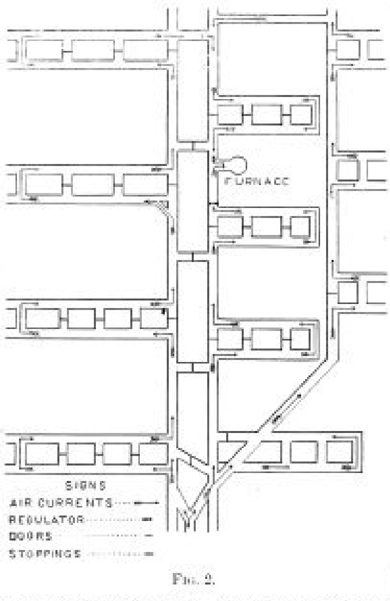

FIG. 2.

any suggestions whereby the system of ventilation can be bettered, and point out any faults?

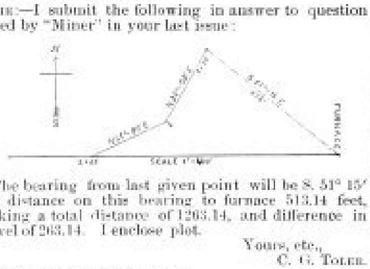
Yours, etc.,
C. D. R.

Hope Church, All'y. Co., Pa., March 5th.

Surveying.

Editor Colliery Engineer:

SIR:—I submit the following in answer to question asked by "Miner" in your last issue:



The bearing from last given point will be S. 51° 15′ E.; distance on this bearing to furnace 513.14 feet, making a total distance of 1263.14, and difference in travel of 263.14. I enclose plot.

Yours, etc.,
C. G. TOLER.

Coalburg, Ala., March 18th.

Miscellaneous Questions.

Editor Colliery Engineer:

SIR:—It will interest me very much to read answers to the following questions:

1. How would you timber a drift through quicksand?
2. Where would you leave the strongest pillars in synclinals or on anticlinals?
3. What size would you dig a mine drain to convey 300 gallons per minute with a fall of 2″ to 100′?
4. When a miner asks you for work at the mines, by what are you guided in deciding upon his qualifications for the position applied for?
5. In opening up a new coal field, by what are you guided in locating the shaft, slope, or drift?
6. Make the necessary calculations on the following mine survey:

1. Main Heading.
   1. N. 16° 9′ E. 203′ to 1st Right. 2. N. 25° 3′ E. 300′ to 2d Right. 3. N. 18° 13′ E. 275′ to 3d Right. 4. N. 20° 38′ E. 300′ to 4th Right.
2. First Right Entry.
   1. S. 80° 10′ E. 604′. 2. S. 84° 25′ E. 900′.
3. Second Right Entry.
   1. S. 84′ E. 700′. 2. S. 80° 1′ E. 750′.
4. Third Right Entry.
   1. S. 75° 10′ E. 1100′ S. 81° 52′ E. 400′.
5. Fourth Right Entry.
   1. S. 85° 55′ E. 1300′.

It is desired to drive a heading from a point which is 1400′ due east from the pit mouth or starting point of the survey to a point which is 10′ back from end of 4th Right, thus crossing the intervening entries. Give points in each and direction by angle both ways, that workmen may work both ways in each entry and have the work all in a straight line.

Yours, etc.,
WILLIAM HIBBS.

Scio, Ohio, Feb. 29th.

Ventilation.

Editor Colliery Engineer:

SIR:—In your March issue Peter Jeffrey is right in regard to his criticism of the comparative amount of air we obtain when we double the speed of the fan. This question was answered in January issue as follows:

$$\sqrt{80} : \sqrt{160} :: 40{,}000 : x, \text{ or } 56{,}445\tfrac{1}{2}$$

or if we double the number of revolutions of the fan we would only obtain an increase of air from 40,000 to 56,445½ cu. ft. This is worked out from the equation

$$Q = \sqrt{\frac{a^3 p}{k s}},$$

showing the quantity to vary as the pressure. But the question is not, if we double the pressure, but, "If we double the speed of the fan."

Now if we refer to the equation of a straight paddle fan we find the pressure varies as

$$n^2 \times \sqrt[3]{n^2};$$

and also the quantity supplied by such a fan varies as the expression

$$n \times \sqrt[3]{n}.$$

Hence we see if we double n we would obtain

$$2\sqrt[3]{2} \text{ or } 2.52$$

times the quantity of air; and

$$4\sqrt[3]{4} \text{ or } 6.348$$

times the pressure. But this formula has yet to be corrected for the increase of resistance in the fan due to increase of speed which will bring the quantity down to about double, for double the speed. But it cannot reduce it down to the mere fractional increase shown in the January issue.

Yours, etc.,
J. T. BEARD.

Ottumwa, Ia., March 15th.

Ventilation.

Editor Colliery Engineer:

SIR:—In the February issue of THE COLLIERY ENGINEER there appears an answer to a question of "A. B.'s," of Hanna City, Ill., by "N. S.," of Dagus Mines, Pa. The question being, an air-way 8′ × 8′ × 1,000′ is passing 40,000 cu. ft. of air, what diameter should a circular air-way 1,200′ long be to pass one-half the quantity, the pressure remaining the same?

"N. S." works this question by finding the relative lengths of an equivalent air-way which are found to be 8195′ and 2430′ respectively, and concludes by saying, "Therefore, a = 37·5 and o = 21·7 for the circular air-way, the diameter of which is 6′ 11″." I would like to have "N. S." show more plainly where he gets the 37·5′ area and the 21·7′ perimeter as it is not clear enough for myself and a number of your readers.

I feel much gratified for the several answers to this question that have appeared in your paper by your correspondents, as I was inclined to think there was not sufficient data given by which to work it, and now find it can be worked by several methods.

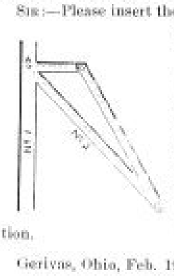
Yours, etc.,
T. S. CUMMING.

Gardner, Ill., March 5.

Mensuration.

Editor Colliery Engineer:

SIR:—Please insert the following in your journal that some of your correspondents may answer:



In the sketch, No. 1, represents the main gangway of a mine, a breast A B is opened off from it at right angles and is 25 yards long. From B it runs to C a distance of 75 yards and at an angle of 60°. At C it intersects gangway No. 2, now what is the length of No. 2, or from A to C, and what is the angle? Please give a plain and simple solution.

Yours, etc.,
JOHN CATAR.

Gerivas, Ohio, Feb. 19th.

Fans in Mining.

Editor Colliery Engineer:

SIR:—Will "T. S. C.," of Gardner, Ills., who answers so ably the questions of "E. R.," of Hopwood, Pa., relative to the above subject in the February issue of THE COLLIERY ENGINEER tell us farther what water-gauge he will have in the mine in question into which he furnishes 40,000 cu. ft. of air per min. by a fan 11·13 ft. diameter.

And also, assuming the area of the entry or air-way to be 50 sq. ft. or its size 6′ × 8⅓′ giving a perimeter of 28⅔ ft., what would the length of the air-way be, allowing for the purpose of discussion that the shaft offers no resistance to the current?

And, also why does he mention no breadth of blades or temperature, or barometric pressure, all of which play a certain part or enter as factors into the problem.

This is not asked as a catch question, but to lead to a legitimate discussion of the use of the "Equivalent Orifice" as a basis of comparison of different Mines. We believe it is wholly dependent upon a variable quantity and is therefore unreliable as a base of comparison unless the temperature and barometric pressure are mentioned.

Yours, etc.,
J. T. BEARD.

Ottumwa, Ia., March 15th.

A Problem in the Development of Coal Lands.

Editor Colliery Engineer:

SIR:—I would be pleased to have some of your able correspondents consider the following questions: There are two bodies of soft coal, each containing 500 acres of the same coal seam. The first body of coal is 500 feet vertical above railroad grade, and can be developed for working by drift, with incline 1500 feet long which would cost $1500.00 to grade. The second body of coal at the point for opening, is 60 feet below the surface or "water level," and 70 feet below railroad grade, and would have to be developed by shaft or slope through overlying strata. This 60 feet covering is half ordinary sandstone and half hard shale or slate. The coal seam in each case is 5 feet thick, and dips 3 feet in 100 feet towards the point of opening. It is desired to select one of these bodies of coal for developing to ship 600 tons per day by rail. Assuming all other conditions to be equal, and that the cost of labor and material is the same as is usual in the coal regions of Pennsylvania, which of these bodies of coal is preferable for the purpose?

(2). What would you estimate (roughly) to be the probable difference in the cost of developing and equipping for shipping coal?

(3). Would you develop the second body of coal by shaft or slope? State your reasons for your preference please.

(4). Assuming that both of these bodies of coal were developed and properly equipped, and that the drift mine made 25,000 gallons of water per day, while the other mines would make four times that quantity, all of which could be drained to the opening, but in the latter case would have to be lifted by pump to the surface, 60 feet; what would you estimate would be the difference in the cost of operating said mines per day?

Yours, etc.,
H. J.

Charleston, W. Va., March 19th.

The McAlester Explosion.

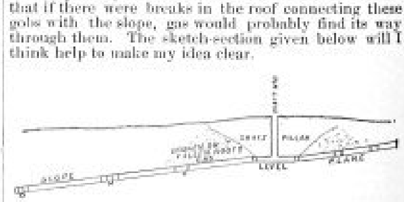
Editor Colliery Engineer:

SIR:—It seems to me, after reading Mr. Farnham's description or account of this terrible disaster and after looking at his plan of Mines No. 7 and 11 accompanying same, that we have not nearly all the evidence before us here to enable any very reliable opinion being given as to how the men, collected in the vicinity of the downcast or hoisting shaft at the moment of the explosion, came by their deaths, *i. e., what it was that exploded in this particular portion of the pit.*

We are not told the nature of the burns on the poor men's bodies; whether coked dust was or was not found adhering to the timbers or about the head of the slope or between that point and the foot of shaft; or whether the entry, "upper O", here signs of having been filled with flame after the firing of the shots therein at 5.04 P. M.; neither does the report say anything about how clean or how imperfectly the coal was worked out in this—the slope—section of the pit, especially in the neighborhood of the "knuckle". No gas having been found that day is no proof that the mine contained none, by the *mine* I mean the old workings or fallen-in places towards the upper parts of the lifts I and K or immediately to the dip of "main west" gangway.

Now, Sir, it seems to me a not altogether unlikely or improbable thing that the concussion produced by the firing of shots in "upper O" brought out fire-damp from the gobs of old workings near the top of the slope, which exploded at the men's lamps in the main intake within a hundred yards of the shaft.

I don't of course know how the coal was worked in the rooms off I and K entries, but merely beg to suggest that gas possibly lurked in the broken roof of some of these places, which, being the (?) highest point in the slope-district of the mine would not be unlikely to have collected there and ready to be driven or sucked out from any heavy concussion in the air-current. I think that if there were breaks in the roof connecting these gobs with the slope, gas would probably find its way through them. The sketch-section given below will I think help to make my idea clear.



I venture to think that if gas did exist about the point marked "GAS", it was this that blew up and killed the men, rather than any *dust* on the roads, because dampness, wet and mud seem to have been the prevailing condition in the part of the pit affected.

If this letter draw forth any comment or bring out any new facts of this case, the space I hope you will give it in your April issue will not have been occupied to no good purpose.

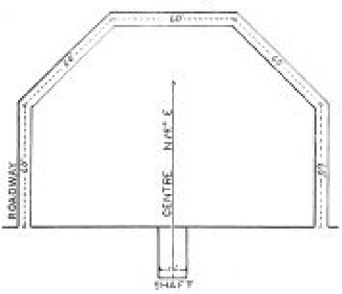
Yours, etc.,
W. S. GRESLEY.

Erie, Pa., March 14.

Surveying.

Editor Colliery Engineer:

SIR:—I desire to drive a roadway from one side to the other of a shaft, in five sections in the form and dimensions of the following diagram:



The shaft is 14′ wide, and each section of roadway is 60′ long and 12′ wide, what would be the distance from center of shaft to center of roadway, and what would be the bearing of each section? The center of shaft is N. 19° East. The roadway to be on North side of shaft.

Yours, etc.,
D.

Wilkes-Barre, Pa., March 2d.

Mathematics.

Editor Colliery Engineer:

SIR:—Please insert the following solution to question by "F. W.," in the February issue:

We have given in the question the chord of an arc of a circle and the height of arc of segment to find radius of the circle.

Then, we can ascertain the depth of shaft thus, the diameter 12′, is half the chord, and the inch equals the height of arc of segment, therefore

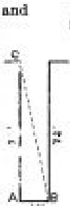
$$12^2 + 1'' = 144 + \tfrac{1}{12} = 1728''$$

and

$$1728'' + 1'' = 1729 \div 2 = 864{\cdot}5'',$$

and

$$864{\cdot}5'' \div 12'' = 72\tfrac{1}{24}', \text{ depth of shaft.}$$



To prove the correctness of the above, I enclose a sketch to represent the shaft. To get rid of decimals we will omit the fraction and call the depth 72′. Then by trigonometry

$\sqrt{AC^2 + AB^2} = BC = 73'$ nearly, and $AB \div BC =$ sine of $C = {\cdot}1642$, or an angle of $9°\ 27'$. Then,

$$90° - 9°\ 27' = 80°\ 33', B;$$

the sine of B is ·9864, and as sine A or 90° : C B :: sine B : C A, or 1 : 73′ :: ·9864 : 72′ depth of shaft.

Yours, etc.,
JOSEPH QUIGLEY.

Westville, N. S., Feb. 16th.

PERSONALS

MR. A. N. HUMPHREYS, of Irwin, Pa., formerly of Wilkes-Barre, Pa., has been appointed General Superintendent of the Westmoreland Coal Company's collieries, shops, etc. Mr. Humphreys was, a good many years ago, a mining engineer in Schuylkill County, and later in Luzerne. For some years past he has been the Westmoreland Company's Chief Engineer.

He has had a great deal of experience in mining and mechanical engineering work, and has erected some fine colliery structures, and designed a great deal of excellent machinery. We do not hesitate in saying that in his present position Mr. Humphreys will manage affairs with much ability as well as profit to the Company.

The Westmoreland is the largest gas coal mining company in this country, shipping coal all along the Atlantic sea board from Maine to Florida, also to Cuba and South America, and exporting it to Europe. The Company owns and has in regular service several thousands of the largest and best railroad cars, and uses besides cars belonging to many railroad companies. The coal is taken off the laterals at the collieries by the Pennsylvania Railroad Company's locomotives and distributed to all other railroads, and it may often be seen passing northward through this city.

The directory of this Company is a most able one, and the executive is very progressive and advanced in ideas and business methods.

MR. THOS. LYNCH, the General Manager of the H. C. Frick Coke Co., (the largest coke company in the world) is a comparatively young man, being considerably on the sunny side of fifty. In stature he is about medium height, squarely built, and has bright blue eyes that flash intelligence and kindliness combined into the faces of those with whom he converses. His hair is dark brown mixed with gray, as is also his full beard which he wears closely trimmed. He resides in a pleasant home in the beautiful town of Greensburgh, at the junction of the Penna. R. R. main line, and the Southwest division.

DR. JOHN C. BRANNER, for several years in charge of the Geological Survey of Arkansas is now connected with Stanford University, Menlo Park, Cal. Dr. Branner is a geologist and engineer of more than usual ability, and withal is a pleasant, cultured gentleman. His contributions to scientific literature, both as an official of the Pennsylvania and Arkansas geological surveys, and as a private writer, rank very high.

MR. ARIO PARDEE, one of the pioneer coal operators of the Lehigh region, died at Rock Ledge, Florida, on Saturday morning March 26th. Mr. Pardee was almost eighty-two years of age and was blessed with remarkable good health throughout his long life. The funeral took place at Hazleton on Wednesday afternoon of the 30th ult., and was largely attended by coal operators from all parts of the state. A sketch of his life will appear in our May issue.

Lunkenheimer's Regrinding Globe Valve.

We present with this a sectional view of a valve that possesses some features of special merit. Instead of the hub being threaded direct to the body of the valve, it is merely fitted into it plain, and rests upon a flange which fits upon the upper edge of the opening, as shown. The hub is then secured by a nut which fits over the flange, and is threaded to the outside of the body of the valve, as shown.

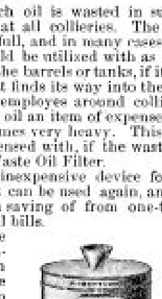
REGRINDING GLOBE VALVE.

The result of this arrangement is that the valve can be reground at any time with the greatest facility, because all that is necessary is to loosen the nut, remove the hub, place a little sand and soap under the disk, and then replace the hub, leaving the nut loose, so that the hub is free to turn with the stem during the grinding. A piece of wire is passed through a hole provided for that purpose in the lower end of the stem and disk, so that the disk will turn with the stem during the grinding, which, of course, it does not necessarily do when in use. The hub being in place when the grinding is done, effectually centers the stem and holds it in proper place, so that the regrinding is done correctly. The valve can thus be readily ground while in position, and in many cases does away with the necessity for breaking connections. The disk is also, of course easily replaced when required. The valves, as a proof of their superiority, are extensively used on locomotives, steamers, and in the United States Navy on cruisers where the requirements are very severe. These valves are made only by The Lunkenheimer Brass Mfg. Co., Cincinnati, O.

Save Your Oil.

It is astonishing how much oil is wasted in supply houses and engine rooms at all collieries. The drip pans are almost constantly full, and in many cases they overflow with oil that could be utilized with as good results as that drawn from the barrels or tanks, if it was not for the dirt and grit that finds its way into the drip pans. The carelessness of employes around collieries makes the loss from wasted oil an item of expense that in the course of a year becomes very heavy. This loss, can be almost entirely dispensed with, if the waste oil is filtered in a Robertson Waste Oil Filter.

This is an ingenious and inexpensive device for reclaiming waste oil so that it can be used again, and its employment will result in a saving of from one-third to one-half in lubricating oil bills.



While exceedingly simple it is very effective. It consists of a galvanized iron tank in which are three movable trays. The top one being of finely woven brass wire gauze, and the two under ones of suitable filtering cloths. The oil being poured in at the top, a spreader on the under side of the lid scatters the oil over the first tray (separating all large refuse), and the oil then passes on down through the filtering cloths into the bottom chamber, thoroughly cleaned of all foreign matter and in a condition to use again. This process can be repeated indefinitely, and the original oil used many times. A siphon is arranged in the filter to automatically carry off water poured in with waste oil, which if not needed can be closed with a plug. The trays being loose, the entire filter can be cleaned in a few minutes. Suitable gauge glass and valves with cock to draw off the oil are arranged in proper portions. Very strongly made it will last many years, and being handsomely japanned and striped is an ornament. It is manufactured and is for sale by Messrs. Hine & Robertson, of 45 Cortlandt Street, New York, who will be pleased to furnish inquirers with testimonials as to its efficiency and economy.

Messrs. Thos. Carlins' Sons, of Allegheny, have just moved their foundry and boiler shop into their new buildings on River Avenue, and have now increased facilities for turning out first class work at reasonable prices. The foundry is 60 ft. × 110 ft., and the boiler shop is 42 ft. × 110 ft. Both built almost entirely of iron, and so arranged with improved traveling and swinging cranes, trolleys, etc., as to ensure most convenient handling of materials. The largest being a 40 ton traveling crane in the foundry. The boiler shop is thoroughly equipped with steam riveter, bending rolls, and numerous punches and shears. The new machine shop is in course of construction, and will be ready for occupancy in the course of a few weeks. The old machine shop, 66 ft. × 88 ft., will be used for warehouse purposes in addition to the present warehouse, which is 24 ft. × 100 ft. This will enable the firm to have such a stock on hand as to ensure immediate delivery. Their railroad facilities are excellent for shipping to all parts of the continent—either by Pennsylvania or Baltimore and Ohio systems.

COLLIERY IMPROVEMENTS.

Colliery Owners, Superintendents, Mining Engineers, Contractors, and others are respectfully requested to inform us as early as possible of all improvements contemplated at their mines. We desire to make this department as complete as possible.—*Editor.*

*** The Sterrick Creek Coal Company, of Peckville, Lackawanna County, Pa., has awarded the contract for sinking the No. 1 or "Old Shaft," from its present depth, 100 ft. deeper to the Clark seam, to Ward & Griffith, of Scranton, Pa. They are also enlarging the area of the old shaft from 22 ft. x 10 ft. to 28 ft. x 12 ft.

They have also started on extensive repairs in the breaker; having torn down the narrow part and the inclined trestle, which will be replaced by a wider screen room and a tower. They are also strengthening the screen room, and altering the jackets on the screens.

In addition to the old machinery, the remodelled breaker will contain a new breaker engine, a new pair of main rolls, two new mud screens, one new center screen, two new main screens, and two new buckwheat screens.

This company was formerly known as The Grassy Island Coal Company. A charter was recently taken out in the name of The Sterrick Creek Coal Company. Mr. James Archbald, Jr., is the superintendent.

*** The Springside Coal Company, of Pana, Ill., contemplates substituting either Rope Haulage, Electric Haulage, or Compressed Air Locomotive for mule haulage in the course of a few months.

*** The Tennessee Coal, Iron and Railroad Company, of Pratt Mines, Ala., has recently contracted the operation of a certain field of coal, situated within a mile of Pratt Mines, to Mr. Charles A. Nolan, which will be known as Slope No. 6. Mr. Nolan is now putting up the necessary machinery, buildings, etc. This slope is really a part of shaft No. 1 and was driven from that place a distance of 6,000 ft. to the outcrop in order to furnish another opening to that part of the mine known as Rock Slope. This is the first instance in the State of Alabama where the entire length of slope has been driven before any side headings were driven off. The drainage from this place will flow through to shaft No. 1 and will be pumped to the surface at the drainage shaft two miles distant.

The company has also contracted the operation of a field of coal near the Blossburgh Mines of The Sloss Iron and Steel Company on the Georgia Pacific Railroad, some 20 miles west of Birmingham, Ala., to Mr. James C. Patterson, who was formerly mine boss of its slope No. 4. The coal can be worked by drift. He is at present opening two drifts, building tenement houses, tipples, etc. The railroad connections are being put in.

A tunnel driven at Slope No. 2 to a drainage shaft, which, when completed, will cause all the water in the mine to flow to the shaft where it will be pumped direct to the surface. At present the drainage of the mine is accomplished by means of 7 pumps operated by compressed air and scattered over the mine. The above arrangement will dispense with all these air pumps.

These improvements are under the supervision of Erskine Ramsay, Esq., Mining Engineer for the T. C. I. & R. Co.

*** The Centralia Mining and Manufacturing Co., of Centralia, Ill., having completed its new shaft 886 feet in depth is about to erect a new headgear and Litchfield engines 24" x 36" with 10 foot drum and sheaves. Plans are also being prepared for the ventilation and haulage plants. Mr. P. Forsythe is Superintendent of this company.

*** The Southern Land Improvement Co., of Pineville, Ky., Mr. J. D. Blake, Gen. Manager, is mining a 36 inch vein of fine gas and coking coal. They are at present considering the installation of an electrical plant for lighting, hauling, and mining. The erection of a disintegrator for crushing and disintegrating the coal before coking is also under contemplation.

*** The Rock Springs Coal Co., of Rock Springs, Wyo., Mr. F. J. Quealy, Manager, contemplates improvements which will double their output at No. 2 Mine, Rock Springs, These include a new hoisting engine and fan, also a re-screener and elevator with storage bins. Another chute will be added to the dump. These improvements will raise the output to 800 tons of lump per day. This mine is especially arranged for the production of commercial coal, and is one of the most completely equipped of the district.

*** The Redstone Oil, Coal, and Coke Co., of Grindstone, Pa., is about to erect a small haulage arrangement for manipulating the mine cars on the surface. The machinery and plant are on the ground and the work is being pushed forward under the supervision of Mr. I. F. Cook, the Superintendent of the company.

*** The H. C. Frick Coke Co. is to the front with a new steel headgear at the Leisenring No. 2 shaft. This is a valuable addition to the plant and is the first girder derrick erected in this district. It was designed by I. H. Paddock, Esq., chief engineer to the Company, and was erected by the Keystone Bridge Co. The shaft is fitted with the Ramsay shifting truck and steam rams for pushing loaded and empty wagons on and off the cages. No. 2 Mine is one of best equipped mines in the neighborhood and is fitted with an underground haulage which although working under the great disadvantage of crooked roads, is still giving excellent results. Two haulage engines are erected at top of the air shaft one in each side, and if anything should happen to either of the engines the other is capable of maintaining the output. One of the haulages is very crooked for over 1700 feet, and gave a great amount of trouble at first but, as is invariably the case where the management is determined and intelligent, these difficulties have now been overcome.

*** The Bell, Lewis & Yates Co., of Buffalo, N. Y., is putting in operation one of the largest mines in the country at Big Soldier Run, near Reynoldsville, Pa. The vein is over six feet thick and the mine is already a large producer. The company are preparing to put in a rope haulage plant and arrangements have been made for a new iron tipple. When these arrangements are completed, which will be within a year, they will be able to turn out six thousand tons of coal per day, making the largest output of any one mine in the country, if not in the world.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED 1881. INCORPORATED 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER, RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
ALEX. DICK, MINING ENGINEER, ASSISTANT EDITOR.
THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send upon payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed

THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Scranton, Pa.

Cable Address—"Retsof, Scranton."

THE CO-EFFICIENT OF FRICTION.

If we draw a piece of cotton-waste across a smooth table it seems to travel pretty easily. If we draw the same piece of cotton-waste across an unplaned plank it does not go so easily. It requires a certain power to overcome the resistance or the friction of the rough plank. The extra power thus required is called the co-efficient, or the equivalent of the frictional resistance.

If it requires ¼ of a pound of pressure to pass this cotton-waste over a square foot of plank, it will require ½ a pound of pressure to overcome the resistance of two square feet.

This is the principle which governs the friction of air in mines. *As the extent of the rubbing surface increases or decreases, so does the pressure required to overcome it increase or decrease.*

Every mining student knows the formula evolved by Atkinson, the pioneer of the theory of mine ventilation—$p = \frac{k \quad s \quad v^2}{a}$—but just what is, or ought to be, the exact value of k nobody seems to be able to say.

Atkinson suggests that k = ·0217 lbs., the pressure required to overcome the resistance of one square foot of rubbing surface at a velocity of 1,000 feet per minute. Other writers have differed from this so much, and presented so many varied co-efficients, that

"By their own perplexities involved
They ravel more."

The following is a table of the co-efficients proposed by the various authorities:

TABLE OF VARIOUS CO-EFFICIENTS OF FRICTION OF AIR IN MINES.

	Pressure per sq. ft. in decimals of a lb. for each foot of rubbing surface and a velocity of 1,000 feet per minute.
Atkinson's Treatise	·0217
A. Devillez, in *Ventilation des Mines.*	
Forchies	·008211
Crachet-Picquery	·008928
Grand Buisson	·008611
Average of 2, 3, and 4	·008585
Used in *Ventilation des Mines*	·008511
Arched Tunnels	·002113
Along a working face of coal	·001266
G. G. Andre, *Atmosphere of Coal Mines*	·022424
Peclet, *Chemineé* (Devillez, p. 112)	·008697
D. K. Clark	·002272
According to Goupilliere's *Cours d'Exploitation des Mines*, vol. ii., p. 389.	
D'Aubuisson	·000955
Narier	·001872
W. Fairley	·010000
J. Stanley James	·000290

Here are fifteen various co-efficients used by various authors. The highest but one is that used by Atkinson and the lowest is that of D'Aubuisson.

The question naturally rises to one's mind; "What difference would these two extremes make in the total power required for the ventilation of a colliery.

If by Atkinson a force of 79 horse power is required to ventilate a certain colliery, then by D'Aubuisson the energy required would be only 7·1 horse power; a ratio of 11 to 1! Here is a diversity of opinion. If Atkinson is right then D'Aubuisson must be incompetent, while if D'Aubuisson is correct Atkinson is most extravagant. Fairley, in his "Theory and Practice of Ventilating Coal Mines," suggests ·01 as being a sufficient value for k. This figure he arrives at by striking a medium between Atkinson and Clark, but his figure is only an assumption.

Such diversity as is here shown tends to make a student wary in estimating the value of the co efficient of friction, and, as it is better to have too much power at a colliery than too little, the result has been to cause most people to cling to Atkinson's figures.

We do not intend here to formulate a new co-efficient, their name is legion already, and it will require a thorough and exhaustive series of experiments to find out a reliable figure. We think that until this is done something like Atkinson's co-efficient should be used As it stands, however, his figure entails considerable calculation and to avoid this we would suggest that the co-efficient ·02 be used instead of ·0217. The difference would be exceedingly small and the labor of calculation reduced to a minimum. According to the case previously cited the energy required would be 73 horse power, as against 79 horse power with Atkinson's figure.

The importance of the general use of some figure as a co-efficient cannot be over-estimated.

Text-books on mine ventilation are now becoming numerous. Several authors formulate their own co-efficient, and every book has its own advocates. If any one of these authors gave definite proof of the correctness of his co-efficient the matter could be easily settled, but each one founds his figures upon experiments which have been too restricted.

This being so, a mining student entering an examination for a mine foreman's or mining manager's certificate is probably at a loss to know which co-efficient finds most favor with the examiners in his district and he runs a risk of being thrown out.

This difficulty arose before us in preparing the Instruction Papers in connection with The Colliery Engineer School of Mines. After careful deliberation we found we were coerced into using Atkinson's figure because it is the one in common use, at present, at examinations in this country. Nevertheless, we are still inclined to advocate the advisability of such a compromise as is offered by the use of ·02.

DANGEROUS OCCUPATIONS.

Whenever one of those large colliery disasters, which from time to time send a thrill of horror through the community takes place, the daily press, as a rule, speaks of the occupation of the miner as being more dangerous than any other.

We have just received an advance copy of the third annual report of the Inter-state Commerce Commission containing the Statistics of Railways of the United States for the year ending June 30, 1890.

From certain tables contained in this report we find that there are proportionately many more fatal and non-fatal accidents amongst railway employes than amongst miners.

We have selected a few figures from these tables and present them in a tabulated form alongside similar statistics relating to the mining industry of Pennsylvania.

	Number of Persons Employed.	Number of Fatal Accidents.	Deaths per 1,000 Employes.	Number of Non-Fatal Accidents.	No. of Accidents per 1,000 Employes.
Railways of United States,	530,999	2,451	4·615	22,396	42·177
Anthracite and Bituminous Mines of Pennsylvania,	183,604	524	2·854	1,388	7·559

These figures speak very strongly. They tell us that a man employed about a railroad has twice as much chance of being killed as a man about a Pennsylvania colliery, and the collieries of Pennsylvania are as fiery as any in the world. They also show that if a man is liable to be injured in a mine once a year, his brother working on the railroad system of America is equally liable to accident once every seventy-five days.

There is no doubt that the mistaken idea which exists regarding the risk incurred by the miner is due in a great measure to sentimentality. There is something peculiarly revolting in the idea of many men being forever immured in the bowels of the earth, without a moment's warning, by a single disaster. There is some meagre consolation to the widow and fatherless to be able to secure a last look at their dead.

It is this touch of excusable sentiment which detracts from the horror of the daylight accident on the railroads, and adds to the already exaggerated notion of the danger of a miner's life.

We do not write this article for the purpose of deprecating the risks of mining. We know what these risks are, and we continue to advocate with all our might for more careful management and better display of judgment on the part of the miner himself to reduce these risks.

We consider, however, that it is our duty to point out this mistaken idea in defence of a large army of officials who are striving to the best of their ability to combat these dangers.

Many bosses are much in the position of the philosopher who said when he was dying that his knowledge was as meagre and his conceit as great as that of the man who picked up the shell on the seashore and thought by studying it he could learn all about the mysteries of the great ocean. What they don't know would fill a big book. But there are hundreds of others, however, who are trying their best to master all the many subjects allied to the theory of their calling and in face of the newly discovered danger of coal-dust (before unsuspected) they have a big job on hand.

We repeat, it is in defense of these officials, as well as of the increased intelligence exhibited by the miners themselves, as shown by the decrease of the number of accidents in mines in recent years, that we present these figures.

MINING INSTITUTES.

We have the authority of the old proverb for believing that "in a multitude of counsellors there is wisdom," and we think it safe to say that there is no business in which this is more true than in mining. There are often several ways of remedying a difficulty, but there is always one which is best suited to the particular circumstances. If a man can hear the opinions and experiences of others who have met similar difficulties, he will be able to piece out his own judgment with their experience, for a wise man often receives valuable ideas from men of much less ability than himself.

There has been, in times past, some feeling that if a man told what he knew to others he was giving away his knowledge and getting no return for it, but now the most intelligent men are not only willing but anxious to exchange experiences with one another, whenever there is a proper opportunity, knowing that both will be benefited.

There are a few organizations in the United States and Canada to enable practical mining men to get together and discuss matters pertaining to their business, and great good comes from them, but there is room for many more. Recently a representative of THE COLLIERY ENGINEER has been traveling through the mining districts of Elk, Jefferson, and Clearfield Counties of this State, and in conversation with some of the leading superintendents and mine bosses, the wish was often expressed to him that an Institute might be organized in that region. Many successful practical men said that they would take great interest in such an organization if formed, but no one seemed to know how to proceed to form it.

We have always taken great interest in all such movements and believe that there is no way in which a man of experience can derive more benefit, than from such discussions as naturally come before these societies. We shall be very glad to give all the assistance possible to those wishing to form such organizations, and if some one in each district of the state will write a letter offering to receive communications from those interested, we will cheerfully publish it, and we think that when in this way an expression of willingness to take the matter up is obtained from a number, it will not be difficult to arrange a time and place for a meeting where a permanent organization can be formed.

It will be well if a number of institutes can be formed so that it will not be necessary to make too long journeys to the place of meeting. In this way it will be possible to have more frequent meetings and the interest will be greater as subjects of direct personal interest to those in attendance can be brought up. Who will make a beginning?

COAL IN ILLINOIS.

THE tenth annual compilation of statistics taken from the Mine Inspector's Report of the State of Illinois which ranks next to Pennsylvania in production of coal, has just been published. The total number of tons of coal mined during the year ending July 1, 1891, is 15,660,698. The average price paid per ton for mining was 71½ cents. The average number of employes for each life lost was 549 as against 461 in the Bituminous region of Pennsylvania. The state is divided into five inspection districts. The following is a table of the number of employes, the tons mined, and the number of fatal and non-fatal accidents in each district:

Districts.	Number of employes.	Number of Tons Mined.	Number of Tons per Employe.	Killed.	Employes per each man killed.	Injured.	Employes per each man injured.	Average thickness of coal seams in feet.
First	9,128	3,082,915	338	15	609	86	106	2 to 6
Second	5,089	1,440,265	283	4	1272	58	88	2 to 7
Third	6,458	2,794,004	432	9	718	41	157	2.2 to 6.6
Fourth	5,881	4,427,622	753	12	490	77	76	2 to 8.3
Fifth	6,395	3,915,402	612	20	320	105	61	1 to 9
Total	32,951	15,660,211	475	60	549	367	89	1 to 9

Several things may be noticed about this table. For instance, the number of tons mined per man in the fourth district is 753, which is much above the average; the fifth district comes next with 612 tons per man, while the second district is lowest with 283 tons. The explanation for this may be obtained by observing the average thickness of the seams in each district. It will be observed that the seams in the fourth district have a somewhat higher range of thickness than those of the first, second, and third districts. The seams of the fifth district have even a higher range than those of the fourth, but they have also a lower range than any of the other districts.

As in other states the greatest number of accidents occurs from falls of roof and sides. The average in Illinois for 1891 is 55 per cent. The average for the preceding year was 67.9 per cent.; so there is an improvement here.

From the report it seems that the value of lump coal at the mines ranges from $1.426 per ton in the second district to 75.7 cents in the fifth. The average value is exactly $1.

For the last ten years, with one exception, the value has declined. From 1882 to 1886 the decline was 41 cents per ton, and from the latter date to 1891, 10 cents per ton. The one exceptional year was 1888, when values showed a slight increase averaging 3.7 cents per ton. Since then the decline has been slight but continuous.

There are 241 mining machines in use in Illinois and these machines produced 2,423,080 tons of lump coal during the year and found occupation for 3,005 men. No particulars are given in the report as to the cost per ton by machine as compared with hand mining, but an idea may be obtained when we say that the machines mined 18.7 per cent. of the entire output with only 9.1 per cent. of the men employed, or in other words each man engaged in machine work sends out rather more than double the tonnage sent out by the hand miners.

The law recently passed by the legislature requiring mine managers to hold certificates has given an impetus to technical education which we ourselves can evidence by the fact that Illinois alone provides over 50 students to the present roll of the Colliery Engineer School of Mines.

Certificates of service are granted to managers at present holding an appointment as such but these certificates are only available for their present situation. As no man cares about being conscious of the fact that when he loses his present situation he is ineligible for another the result is that all the old bosses are dusting the cobwebs off their lesson books and competing for a certificate of competency wherewith to assert their freedom. Such action is creditable to them.

The Anthracite Trade.

The Anthracite coal trade is rather quiet at present, with the outlook encouraging for the future. March proved to be an unusually good month for the retailers. The output is being limited to the actual requirements of the market as far as possible, and in consequence a number of collieries have been shut down completely, and others during certain days of the week. With the output well restricted, the stocks of coal on hand at tidewater points will soon be reduced. The Philadelphia *Public Ledger*, of the 28th inst., in its coal trade report says:

"The outlook for a good year for the Anthracite trade is excellent, and notwithstanding the great production of coal in 1891—the largest of any year on record—it is believed by those who study the situation carefully and keep correct statistics that the production of Anthracite in 1892 will break all previous records. The actual selling price, too, it is expected, will average a better profit to the mining and carrying interests than last year's results. The Eastern coal trade is very quiet, and until after May 1st no more coal than is actually needed for immediate consumption will be shipped in that direction."

It has been agreed to restrict the production for April to 2,500,000 tons, including the output of the Pennsylvania Railroad.

The Bituminous Trade.

The Bituminous coal trade is quiet, although large amounts of coal to fill contracts are being shipped. Outside of this contract coal the business is rather dull. The Pittsburgh and Hocking Valley mine owners have made an agreement, whereby the Pennsylvania operators are to be allowed five cents a ton reduction in tolls, and it will go to the consumer. New York reports a dullness in the market for fuel of all kinds. Prices have been cut to a great extent by certain Bituminous operators, some, however, are making contracts with their regular customers at good figures, as the cut rate people cannot supply the full demand.

The Coke Trade.

The Connellsville coke trade remains in about the same condition as last month. Prices are well maintained as follows: Furnace coke $1.90; foundry coke, $2.30; crushed coke, $2.65; all per ton of 2,000 lbs. f. o. b. at ovens. The Connellsville *Courier*, in its issue of March 25th, says.

Our detailed report of the operation and output of the region for the week ending Saturday, March 19th, shows 13,259 active ovens and 3,965 idle, a change of an even hundred evens from the active to the idle list since the previous week. Production remains practically the same.

OBITUARY.

Henry Morris Luther.

Henry M. Luther, Assistant Engineer in charge of the Mahanoy District, Philadelphia and Reading Coal and Iron Co., died of Bright's disease on the 19th ult., at Atlantic City, N. J., in the thirty-seventh year of his age.

Mr. Luther was the youngest son of the late Peter D. Luther, an old time operator in the Schuylkill region, and a brother of R. C. Luther, Esq., Genl. Supt. of the Phila. & Reading Coal & Iron Co. He was born and raised at Pottsville, Pa., and in 1873 entered the engineering department of the P. & R. C. & I. Co. as a chainman in the same district of which he was engineer in charge at the time of his death. He had recently been elected Secretary of the Peerless Coal Co., of West Virginia, and was also to have been its Superintendent.

As a boy he was exceptionally bright, and his early manhood showed that each year was developing greater talents. His rise from the position of chainman to that of Assistant Engineer was gradual but regular, and at the time of his death he ranked as senior Assistant Engineer.

He began his work as chainman under his brother, who was at that time resident Engineer of the Mahanoy District, but who resigned to accept another position soon afterward. On Mr. R. C. Luther's return to the Phila. and Reading Co., he found his younger brother, the subject of this sketch, had, by his own exertions and careful work, risen to a prominent place among the company's engineers. His official position was not in any way due to favoritism, but was due solely to his own exertions. Early in 1875, the writer, who at that time was employed as a chainman by the same company, was transferred to the Mahanoy District, and first made the acquaintance of Mr. Luther, and this acquaintance developed into a friendship that lasted till it was severed by the sad and early death of Mr. Luther.

His character was one that made all acquaintances friends, and we doubt if there is a man that ever met Harry Luther, that did not express sorrow at his death.

He was a man of strong likes and dislikes, but he was always open to conviction and was easily won as a friend by any person who proved himself at all worthy of his friendship. In business transactions his integrity was unquestioned and socially he was exceedingly popular.

He was married in the early part of 1883 to Miss Ida M. Thirlwell, of Ashland, who with two young sons survive him.

Mr. Luther's health first gave signs of breaking down last fall, and he was compelled to take a rest of several weeks. Shortly before the holidays, and before he returned to work, he spent an evening with the writer, and rejoiced greatly over his recovery and prospects of future good health. But his recovery was not a complete one, and his expectations were not realized. Early last month he again became incapacitated and, with Mrs. Luther, went to Atlantic City on the 10th ult. in hopes that a few weeks rest at the sea shore would restore his health but his disease had progressed too far, and his death occurred at 2.30 a. m. on the morning of the 19th. Less than twenty-four hours before he had written his eldest son a letter in which he stated that he was some better, but not as well as he should be.

Mr. Luther was a consistent member of the Protestant Episcopal church, and was a vestryman and treasurer of St. John's Church at Ashland, Pa.

His funeral took place on the afternoon of the 22d ult., from his late home at Ashland, and was very largely attended.

A Fine Publication.

Some months ago, Mr. W. L. Saunders, of the Ingersoll-Sergeant Drill Company, showed us the illuminated cover and some proof sheets of a catalogue he was getting up, and said "I want to get out a catalogue that for size, value and beauty, will excel any ever issued by any firm or company in our line of business." It has been issued, and Mr. Saunders has accomplished his purpose. It is a handsome volume of 225 pages, printed on toned paper in the most artistic manner. It is replete with fine engravings, and while it acts as a trade catalogue, it is also full of useful information to practical men engaged in mining, tunneling, and quarrying. The illustrations are drawn with the view of showing machinery at work, and the reading matter has been arranged to the end that the whole subject divided under its different departments may be placed clearly before one who seeks this kind of information.

The volume contains so much of interest concerning rock drills, air compressors, blasting apparatus, and rock work generally, that every mining engineer, mine official and contractor should have one in his library, and they can secure one by addressing a request to the Ingersoll-Sergeant Drill Company, No. 10, Park Place, New York.

The Cassier Magazine Company, of New York, publishers of Cassier's Magazine, has issued to its advertisers a convenient and strong receptacle for duplicate advertising contracts. Twenty-eight prominent technical publication's names are alphabetically arranged on the outside of a strong 10″ x 4½″ envelope, and opposite each publication's name are spaces that give at a glance, the space of each advertisement, when it began, number of times it is to appear, and amount to be paid for it. The idea is a good one, and the Cassier Magazine Company is to be congratulated on its success in devising so convenient a holder for duplicate contracts.

ANTHRACITE COAL STATISTICS.

Statement of shipments of Anthracite coal for month of Feb., 1892, compared with the corresponding period last year. Compiled from the returns furnished by the Mine Operators.

	February, 1892.	February, 1891.	Difference.		For Year 1892.	For Year 1891.	Difference.	
From Wyoming Region,	1,625,520'18	1,235,190'11	Inc.	390,330'07	3,146,448'04	2,919,497'16	Inc.	226,950'08
From Lehigh Region,	532,232'19	374,725'18	Inc.	157,507'01	885,579'19	874,147'10	Inc.	11,432'09
From Schuylkill Region,	1,059,218'15	767,285'03	Inc.	291,933'12	1,994,810'19	1,722,517'10	Inc.	272,293'09
Total	3,216,972'12	2,377,201'12	Inc.	839,771'00	6,026,839'02	5,516,162'16	Inc.	510,676'06

The stock of coal on hand at tide-water shipping points, February 29, 1892, was 885,653 tons; on January 31, 1892, 790,932 tons; increase, 94,721 tons.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since our Last Issue.

La Fortuna Mining Co.,	San Antonio, Texas.
The Queen City Iron Co.,	Queen City, Texas.
La Belle Mining Co.,	Dallas, Texas.
Llano Marble & Granite Co.,	Llano, Texas.
Bald Mountain Consolidated Milling Co.,	Deadwood, S. Dak.
Pennsylvania and Ohio Fuel Co.,	Chicago, Ill.
High Point Mining Co.,	Joplin, Mo.
The Sterrick Creek Coal Co.,	Scranton, Pa.
Skagit Valley Mining Co.,	Mt. Vernon, Wash.
The Idaho Aluminum Mining and Mfg. Co.,	Spokane, Wash.
The Kansas and Utah Mining Co.,	Salina, Kan.
Washington Ice Co.,	Duluth, Minn.
Putnam Iron Co.,	Duluth, Minn.
Hale Iron Co.,	Duluth, Minn.
Towanda Iron Co.,	Duluth, Minn.
Swedish American Iron Co.,	Duluth, Minn.
Security Iron Co.,	Duluth, Minn.
Iron Belt Mining Co.,	Duluth, Minn.
New York Iron Co.,	Duluth, Minn.
Twin City Iron Co.,	Duluth, Minn.
Mesaba Chief Iron Co.,	Duluth, Minn.
Boston Iron Co.,	Duluth, Minn.
The American Mining Co.,	Minneapolis, Minn.
Bradley Iron Co.,	Duluth, Minn.
Osceola Iron Mining Co.,	Duluth, Minn.
Virginia Iron Co.,	Duluth, Minn.
The Jeff Davis Mining Co.,	Colorado Springs, Colo.
Golden Gate Mining Co.,	Spartansburg, S. C.
Crescent Oil and Mining Co.,	Trenton, N. J.
The Houtzdale Coal Mining Co.,	Camden, N. J.
Peoples Pebble Phosphate Co.,	Plant City, Fla.
King Mining Co.,	Roanoke, Va.
The Central Land Improvement Co.,	New York, N. Y.
Whitlatch Union and McIntyre Gold Mining Co.,	Helena, Mont.
Eureka Mining and Reduction Co.,	Helena, Mont.
The Champion Mining Co.,	Darlington, Wis.
Athens Iron Co.,	Duluth, Minn.
Duluth Iron Mining Co.,	Duluth, Minn.
Elmira Land & Loan Co.,	Duluth, Minn.
Lackawanna Iron Co.,	Duluth, Minn.
The Star of the West Mining and Milling Co.,	Colorado Springs, Colo.
The Black Eagle Consolidated Mining Co.,	Aspen, Colo.
The Myrtle Mining Co.,	Colorado Springs, Colo.
The Harding Smelting Co.,	Aspen, Colo.
The Midland Mining and Land Investment Co.,	Denver, Colo.
The Boulder County Ore Reduction Co.,	Denver, Colo.
The Black Hawk Reduction Co.,	Denver, Colo.
Northern Land and Mining Co.,	Hancock, Mich.
American Developing and Mining Co.,	Marysville, Mont.
Queen of the Mountain Mining Co.,	Great Falls, Mont.
Jones Lumber Co.,	Parkersburg, W. Va.
The Salsbury Mining Co.,	Butte, Mont.
The Buckeye Stone Co.,	Galion, Ohio.
Keystone Iron Co.,	Duluth, Minn.
Buckeye Iron Co.,	St. Paul, Minn.
Drake Co.,	St. Paul, Minn.
American and Mexican Mining and Milling Co.,	San Francisco, Cal.
The Hurricane Hill Mining Co.,	Port Angeles, Wash.
Arizona Onyx Co.,	Paterson, N. J.
Petit Jean Oil and Mineral Co.,	Magazine, Ark.
The Miner's Dream Mining and Milling Co.,	Ward, Colo.
The Railway Conductors Mining and Milling Co.,	Colorado Springs, Colo.
The Big Pocket Mining and Milling Co.,	Colorado Springs, Colo.
The Denver City Consolidated Mining Co.,	Pueblo, Colo.
The Orphan Bell Mining and Milling Co.,	Colorado Springs, Colo.
The Plute Mining Co.,	Colorado Springs, Colo.
The Maricopa Gold and Silver Extraction Co.,	Denver, Colo.
The Yampai Gold and Silver Mining Co.,	Denver, Colo.
The Manhattan Gold Mining and Milling Co.,	Manhattan, Colo.
The Equitable Mining and Milling Co.,	Colorado Springs, Colo.
The Rocky Mountain Mining and Investment Co.,	Colorado Springs, Colo.
The Creede Gold and Silver Mining Co.,	Denver, Colo.
The Superior Jasper Co.,	Superior, Wis.
Great Western Mining Co.,	Duluth, Minn.
The Pennsylvania Iron and Steel Co.,	Duluth, Minn.
Gray Jockey Mining Co.,	Dewey's P. O., Mont.
The Saline River Point Co.,	Kansas City, Kans.
Providence Mining Co.,	San Francisco, Cal.
The Baltic Consolidated Mining Co.,	Grass Valley, Cal.
Abundancia Mining Co.,	New York, N. Y.
The Forsythe Manufacturing Co.,	Charleston, W. Va.
Marble Hill Quarry Co.,	Pittsburgh, Pa.
The Pennsylvania Hard Vein Slate Co.,	Easton, Pa.
North Star Mining and Milling Co.,	Spokane, Wash.
Crawford, Hannon, and Clayton,	Seattle, Wash.
Eureka Oil Co.,	Eureka, Cal.
Chicago Zinc Co.,	Chicago, Ill.
Clark Iron Co.,	Duluth, Minn.
The Iron Cliff Mining Co.,	Duluth, Minn.
The Martinsburg Oil, Gas, and Mineral Development Co.,	Martinsburg, W. Va.
Greenbrier Coal and Coke Co.,	McDowell, W. Va.
Roseburgh Gas Co.,	Roseburgh, Ind.
The Hollensbe Stone Co.,	Sand Creek, Ind.
The San Juan Mining and Milling Co.,	Chicago, Ill.
The Rock Glen Town and Mining Co.,	Colorado Springs, Colo.
The Cripple Creek Silver Bell Mining Co.,	Pueblo, Colo.
The Colfax Mining Co.,	Colorado City, Colo.
The Golden Reward Mining Co.,	Denver, Colo.
The Washington Mining Co.,	Colorado Springs, Colo.
Thomson Gold Mining Co.,	Spartansburg, S. C.
Shipman Gold Mining and Manufacturing Co.,	Detroit, Mich.
Elkins Gas Coal Co.,	Philadelphia, Pa.
Newell Coal Co.,	Peoria, Ill.
Ridgeville Gas Co., of Ridgeville, Ind.,	Ridgeville, Ind.
Hicks Fork Mining Co.,	Big Timber, Mont.
Florida Phosphate, Mining, Transportation, and Storage Co.,	Bartow, Fla.
Austerlitz Gold Mining Co.,	Norwich, Conn.
Everett Snohomish Mining Exchange Co.,	Everett, Wash.

Shenandoah Lumber and Iron Co.,	Baltimore, Md.
Eureka Mining Co.,	Tacoma, Wash.
The Fort Scott Mining Co.,	Fort Scott, Kans.
Stockton Consolidated Mining Co.,	Stockton, Cal.
Valenzuela Consolidated Mining and Land Co.	San Francisco, Cal.

THE COMPANY STORE.

The Decision of the Supreme Court of the State of Illinois Declaring the "Truck Store Law" Passed by the last Legislature of that State Unconstitutional.

An enactment called "The Truck Store Law" was passed by the last Legislature of the State of Illinois. It contained the following clause:

"It shall be unlawful for any person, company, corporation, or association now engaged, or hereafter to be engaged, in any mining or manufacturing business in this state, to engage in or to be interested, either directly or indirectly, in the keeping of a truck store, or controlling of any store, shop, or scheme for the furnishing of supplies, tools, clothing, provisions or groceries to his, its, or their employes, while so engaged in mining or manufacturing."

A case of violation of this Act was decided against the defendants who took the matter on appeal to the Supreme Court which decided that the law was unconstitutional.

In discussing the question at issue the court says:

"The prohibition of the statute operates not directly upon the business of mining and manufacturing, but upon the individual, because of his participation in that business. It is not imposed for the purpose of rendering mining or manufacturing less perilous or laborious, nor to restrict or regulate the duties of employer and employe in respects peculiar to those industries, but for the sole purpose of imposing disabilities in contracting as to tools, clothing, and food, matters about which all laborers must contract and as to which all laborers in every other branch of industry are permitted to contract with their employers without any restriction.

"It is moreover difficult to comprehend how there can possibly be anything in the relations between employer and employe which renders it necessary to withdraw the power of contracting as to tools, clothing, food, etc., and yet allow them power to contract in all other respects. If there is capacity to contract for the payment of wages in money, why is there not capacity to contract for their payment in something else? If there is capacity to contract with reference to the sale of real estate, or of a horse or a cow, or of household furniture, why is there not capacity to contract with reference to the sale of clothing or food?"

The court furthermore says:

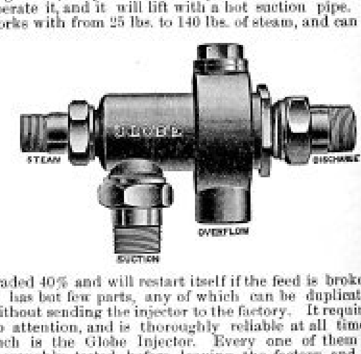
"Our constitution guarantees that no person shall be deprived of life, liberty, or property without due process of law, and the man or the class forbidden the acquisition or enjoyment of property in the manner permitted to the community at large would be deprived of liberty in particulars of primary importance to his or their pursuit of happiness.

"A person living under the protection of this government has the right to adopt and follow any lawful industrial pursuit, not injurious to the community, which he may see fit. And, as incident to this, is the right to labor and employ labor, make contracts in respect thereto upon such terms as may be agreed upon by the parties to enforce all lawful contracts, to sue and give evidence, and to inherit, purchase, lease, sell and convey property of every kind. The enjoyment or deprivation of these rights and privileges constitutes the essential destruction between freedom and slavery; between freedom and oppression."

The Globe Injector.

We herewith present an illustration of the Globe Automatic Injector, manufactured by the Eagle Lubricator Co., of Cleveland, Ohio.

Great as have been the improvements made in steam goods during the last ten years, probably no one article has advanced with such rapid strides as the steam injector. The clumsy and complicated, four and five handled injectors of a few years ago have been superseded by the automatic injector without handles, stuffing boxes, or packing. It requires but one valve to operate it, and it will lift with a hot suction pipe. It works with from 25 lbs. to 140 lbs. of steam, and can be



graded 40% and will restart itself if the feed is broken. It has but few parts, any of which can be duplicated without sending the injector to the factory. It requires no attention, and is thoroughly reliable at all times. Such is the Globe Injector. Every one of them is thoroughly tested before leaving the factory, and is fully warranted by the manufacturers, who will be pleased to send our readers descriptive circulars and price lists. As was stated before the manufacturers are the Eagle Lubricator Company, of Cleveland, Ohio. They also manufacture an improved ejector which will be illustrated in a future issue of THE COLLIERY ENGINEER.

A calamitous explosion of fire-damp occured in No. 3 pit of the Anderlues Colliery, in the province of Hainaut, Belgium, by which 152 miners lost their lives. Owing to the presence of fire in the pit the work of rescue had to be abandoned and the workings flooded.

THE WESTERN PENNSYLVANIA MINING INSTITUTE.

BY WM. SEDDON, SEC'Y.

(Transactions of Western Pennsylvania Mining Institute.)

From time to time there are rumors set afloat by certain mine officials not connected with this Institute, and who either have no intention of joining it, or are not eligible to membership on account of their general behavior and character, I deem it my duty as secretary of the organization to state that our motto is "*safety, economy, and perseverance.*"

It has always been the object of the members to first carefully consider *safety* as of the utmost importance in the working of the mines under their charge; and *not* as some people would have the public believe, the discussion of means whereby we can secure an advance of salaries. In the discussion of the best possible means of securing safety we derive benefit because we are preparing ourselves to overcome difficulties whenever they present themselves, and the miners under our charge and our employers are both benefited either directly or indirectly in proportion to our attendance at the meetings of the Institute.

Some colliery officials do not consider it necessary to study or discuss methods of mining after they have secured a certificate of competency as a mine foreman, thinking that because they are competent as far as the present mine law is concerned, that is all that is required of them. This is not the true spirit. The Board of Examiners that granted them certificates did not imagine any such line of thought, or they would not have granted the certificates to candidates of such a frame of mind. In passing an examination, we do not get a diploma guaranteeing that we are absolutely capable of managing a mine safely and successfully, and there are none that more fully understand this than the members of this Institute. Their attendance at our meetings proves to me that they feel the necessity for more extended knowledge.

For the past five years we have been holding these meetings to advance ourselves in the theory and practice of mining and its allied sciences.

I think we have a great deal to learn before we can assume to be even comparatively safe in our mines. In the matter of gases met with in mines, our theoretical knowledge is obtained from text-books which are very good in their way, but our knowledge is not as complete as it can be made by conference with our fellow officials on the practical experiences we have each had. I do not think we have, as yet, advanced far enough in our knowledge of gases to prevent serious disasters. It is only under certain conditions that we are capable of lessening fatal accidents in mines generating gas. It would appear that there is some gas present other than those we expect, or are taught to expect, and it is one with which we are not familiar, if the evidence offered from time to time after serious explosions is correct.

This evidence is to the effect that the mine was free of explosive gas shortly before the explosion. Admitting that a small percentage of gas and a highly volatile coal-dust will cause an explosion, I still think it possible that we could have gases present for which we have never searched and of whose nature we are ignorant. It is possible that there is a gas given off that owing to its affinity for the hydrogen present in fire-damp, or, the friction of its own atoms under certain conditions—such as a heavy blast, a blown-out shot, or a sudden fall of roof—will ignite with serious results. While we have gases taken from the mine and tested for their inflammable nature with certain quantities of air, we do not have them tested regarding their constituent parts and these are important factors.

All explosions do not occur in a like manner. At the time of the recent explosion at McAlester, Indian Territory, the manager ordered the speed of the fan immediately increased. This appeared at the time to be the most essential thing to do, and it proved to be the correct thing to do. I have, however, known instances where a similar action proved disastrous both to the rescuing party and the mine. This goes to prove that all explosions do not occur in the same manner, neither do they end with the same results.

Much more evidence could be offered on this subject, but as time is so limited I intend to touch on only a few of the important difficulties with which we have to contend. In ventilation the notion that one mine is as easy to ventilate as another is absurd. Though located side by side difficulties will present themselves daily in one mine which in the other mine may never be met with. The superintendent of one may not be as willing as the superintendent of the other to have the mine in a well ventilated condition. He may refuse to erect a furnace or fan where such is required, or he may insist on a furnace where a mechanical ventilator would be better. Our formulæ to find quantity, size of air-ways, power, etc., cannot be called, at all times, correct. While these formulæ may be useful, and may show the intelligence of the mining boss who is able to work them, it is only possible to arrive at approximate results by their use. I do not want to appear as condemning the works of Atkinson, Fairley, or Wilson. They are useful and have done a great deal of good, and will, I hope, continue to do so. They are undoubtedly right, if the air-ways and entries are driven as true and smooth as the entries on which these formulæ and co-efficients were based. This being the case, there is room for further study and advancement on our parts. We should arrive at some system whereby we can come nearer to what we want in calculating lengths, size, quantities, power, etc., in our crooked and usually jagged air-ways that we have in our mines at the present time.

Drainage is another important study, both theoretically and practically, for good drainage is essential for health and safety in mines. I do not hesitate to say, that a few lessons in this branch would do none of us any harm.

Timbering is a subject that I think has been neglected. We do not see many mines that can be truthfully said to be well timbered. In our River mines we stick to the old system of cross bar and post, no matter what the nature of the roof or floor may be. On the continent of Europe they have an entirely different system. I have heard professional men, who visited the mines, say that they work seams by using their method of timbering, that could not be worked at all if timbered by our method. There is no doubt, but that there is plenty of room for improvement in our manner of timbering.

Haulage is another subject that demands an important share of our attention. While we have in this vicinity some fair systems of haulage, we could improve them considerably if we visited mines where the most improved systems are in use, and discuss our experiences and the ideas gained at these meetings. Economy is one of the main requisites of successful mine management, and both operator and miner benefit by it. The one directly the other indirectly. I do not mean by economy, reductions of wages to make up deficiencies due to mismanagement. I mean economy in the use of men and material. The mine boss should look on all expenses as if they were to be paid out of his own pocket. A waste of material is no credit to an official, but on the contrary, it is injurious to his character, as well as a loss to his employer.

Where is there a better place to discuss economical methods of mining, than among the practical men composing the membership of this Institute?

The third point in our motto is "Perseverance". This is essential if a man wants to be successful in any avocation, but in none more essential than in the avocation of a mine foreman. No doubt it is disheartening to find yourself pressed on every side with difficulties over which you have no control. Your mine may not be in the shape you would wish it; You may be troubled with an excessive amount of water; your airways may need timbering or retimbering, and you cannot find time to attend to them or even give instructions as to the way you want the evils overcome because your time is all taken up by other equally important work. More coal is needed than you can produce owing to your entries striking the dip, and you have not the means to get the water out of them, or the entries have struck a rise and gas has begun to appear, and your ventilating power is insufficient. All this may happen, and considerably more. Under such circumstances the best of our mine foremen will at first become disheartened. But, by carefully considering the situation and with intelligent work and perseverance they will overcome the difficulties, and will have the mine in a fair, if not in a good condition, when the mine inspector pays him his next visit.

If I were asked the question, where could a man get better advice if placed in the position I have described, than by attending the meetings of this institute, I would be at a loss for an answer. In conclusion, I would say, there is a large field of knowledge in which we have never entered, and which we are not even acquainted with, that can be cultivated by attending our meetings, so as to bring forth fruit "an hundred fold." As we have done during the past five years, let us continue practicing our motto, and show by our actions and the transactions of our Institute, that our meetings are not to discuss the wage question, but to cultivate the acquaintance of each other and discuss the true theory and practice of mining with credit to ourselves, profit to our employers, and a deep regard for the welfare of the men under our charge.

BOOK REVIEW.

THE PHOSPHATES OF AMERICA, Where and How They Occur; How They are Mined; and What They Cost, with Practical Treatises on the Manufacture of Sulphuric Acid, Acid Phosphate, Phosphoric Acid, and Concentrated Superphosphates, and Select Methods of Chemical Analysis. By Francis Wyatt, Ph. D., Pp. 178; profusely illustrated. The Scientific Publishing Company, New York, Publishers. Price $4.

This book will undoubtedly fill a long-felt want. Until now the literature on this subject has been scattered, being mostly confined to articles published in scientific journals, and in the proceedings of societies of different nations, and in different languages. Dr. Wyatt has collected and epitomized what has already been written on the phosphates of North America and supplemented it with the result of his own large and varied experience.

Since the nature and extent of the Florida deposits were discovered there has been a "boom" in phosphates, and more attention has been attracted to the mineral than ever before. As there has been no authoritative book of reference on this subject the general ignorance concerning it is enormous, and as a consequence unscrupulous or oversanguine promoters and landowners have been able to sadly mislead the trusting investor with illusive statements. At the present time manufacturers, chemists, and farmers are all agreed that the supply is not being economically used, and this book, in showing the way to the right path, should prove a boon to all interested. It is written chiefly for the non-scientific and non-technical, explaining chemical reactions when necessary, lucidly and simply, and illustrating by plain diagrams the construction of apparatus and machinery.

A PRELIMINARY REPORT ON THE COAL DEPOSITS OF MISSOURI FROM FIELD WORK PROSECUTED DURING THE YEARS 1890 AND 1891, with 131 illustrations by Arthur Winslow, State Geologist. This book is interesting throughout its entire pages. Even the preface, an extract from which appears in another part of this journal, is an instructive essay which will be appreciated by all students of geology, and contains many valuable hints to prospectors and those in charge of the opening out of new mineral fields. Chapter III. is devoted to a description of the coal industry of the State of Missouri, and chapter IV. is a detailed systematic description of the coal-beds now operated.

HOW TO RUN ENGINES AND BOILERS. Practical Instruction for Young Engineers and Steam Users. By Egbert Pomeroy Watson, Editor and Proprietor of *The Engineer*. Published by *The Engineer*, 150 Nassau St., New York. Price $1.50 by mail.

This book of 125 pages is neatly got up and is full of valuable hints and information to those for whom it is written. It treats on all the ills that engines and boilers are heir to. It shows the young engineer how to clean boilers, and pipes of scale and describes the safety valve and other boiler fittings in a way that makes one feel more at home with these parts, than heretofore. Mr. Watson gives a good deal of space to the construction of the various parts of the steam engine, and describes the different hitches that occur in the working of machinery and how to repair the parts out of order. This book is a valuable addition to the library of technical schools and will prove of service to engine drivers &c.

FIFTH ANNUAL REPORT OF THE STATE MINE INSPECTOR OF THE STATE OF MISSOURI FOR THE YEAR ENDING JUNE 30, 1891.

Mr. C. C. Woodson, the State Mine Inspector, presents a very interesting and well prepared report. It shows an increase of production of coal of 8½ per cent. over the previous year. The lead and zinc industry has been exceedingly active the output having surpassed any previous year in the State's history. The iron product shows a decrease as compared with 1890. The report affords full information as to the general character and location of all mines, the methods of mining and of ventilation, and gives a complete list of all improvements, &c., &c. The number of tons mined is

Coal	2,650,018
Lead	16,925
Zinc	121,725
Iron	138,356

The number of fatal accidents in coal mines during the year was 30, an average of 1 for every 413 employes as compared with 1 for every 448 in 1890. There have been 12 fatal accidents in lead and zinc mines.

COAL: ITS ANTIQUITY; DISCOVERY AND EARLY DEVELOPMENT IN THE WYOMING VALLEY. A paper read before the Wyoming Historical and Geological Society, June 27, 1890, by George B. Kulp, Historiographer of the Society.

The research and industry displayed by the author in gathering together and arranging these historic facts and narrative are deserving of high commendation. Its perusal will be found instructive and interesting.

As an illustration of dispatch in supplying repairs we heard of a man who recently went to the shops of the Lidgerwood Manufacturing Company to get two cross head gibs, which were to replace worn ones from an engine made by the company ten years ago, and since became obsolete. The pattern was found, brass castings made, put into shaping machine, and finished and delivered in one hour and a half.

Another case a few days before, the Empire Construction Company, of Orange, N. J., bought a double drum hoisting engine and boiler, and upon erecting boiler on the bedplate, it fell (a rope breaking) and broke about ten or a dozen parts of the engine. A man was quickly dispatched to the Lidgerwood shops and carried away every part required in less than half an hour. The engine was running the next morning.

A WELL DESIGNED ENGINE.

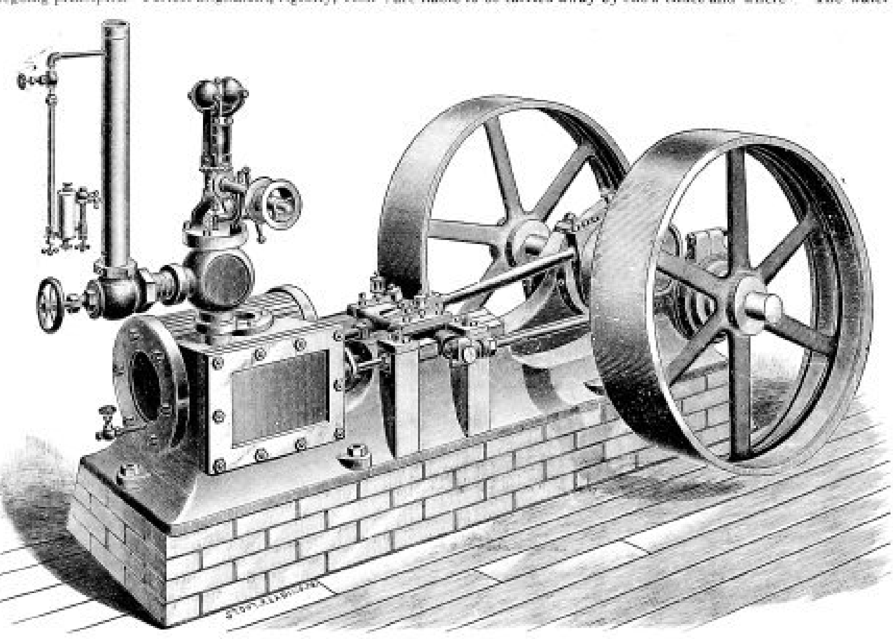
And one that is Peculiarly Adapted for Fans and Breakers.

A long felt want around collieries has been an engine combining the old principles of plain slide valve, and box bed frame, with modern taste and economy of steam. That result has been practically secured in the production of the engine illustrated in the accompanying engraving.

The cylinder is securely doweled to the bed frame and its proportions are made to comply with the best practice of steam engineering. The cylinder of twenty five years ago with its stroke three and frequently four times the bore, allowed the steam to follow almost the entire length of the stroke before cutting off. The pressure, therefore, at the end of the stroke was almost equal to the initial pressure and the benefits of the expansive qualities of the steam were thus wasted through the exhaust pipe. In the modern plain slide valve engine it is the intention of the designer to so proportion his cylinder that the steam supply shall be cut off at from one-half to two-thirds of the stroke and then utilize the expansive force of the steam to complete the stroke. The exhaust pressure is thereby reduced to about one-half of the initial pressure. To do this effectively and maintain the power, the diameter of the cylinder is increased and the stroke decreased. And in place of 10″ × 30″, 8″ × 20″, and 6″ × 15″, we find 12″ × 15″, 10″ × 12″, and 8″ × 10″, as the popular proportions of the cylinders for 40, 25, and 15 horse power, respectively.

Another leading economy in the modern cylinder is the fact that as the diameter of the cylinder is increased the percentage of friction is decreased.

The engine here shown has been designed on the foregoing principles. Perfect alignment, rigidity, economy, and durability, at the lowest possible cost, are what the makers claim for it.



The rods are all of steel, the "Brasses" of the best gun metal and the shaft of hammered iron. A critical steam test is made of every engine, at the works, before shipping, the adjustments are all carefully made and the engine is ready to run the moment it is placed in position and given steam.

They are adapted to all classes of duty and are guaranteed to give as satisfactory service as any plain slide valve engine of similar capacity and in the majority of cases will show an economy of fuel.

These engines are carried in stock and are at all times ready for immediate delivery. A full line of vertical engines from three to thirty five horse power and hoisting engines of almost any description from five to fifty horse power are also carried in stock.

A full line of vertical and horizontal tubular boilers are also kept in stock for immediate delivery. The boilers are made of steel with a tensile strength of 60,000 lbs. per inch of section. They are well braced throughout and the workmanship and material are of the best.

Any further information will be cheerfully furnished by Mr. C. B. Scott, Scranton, Pa., who will willingly furnish estimates to buyers on any part of the continent.

S. B. Stine, of Osceola Mills, Pa., reports a gratifying number of replies to his advertisement of mine cars and patent car wheels which has appeared in THE COLLIERY ENGINEER for several months past. He has received a number of orders through it, and at present is making estimates on a lot to go to New Mexico. Mr. Stine has had long experience in the business and builds many different kinds of cars. Owing to his works being situated where both lumber and iron are cheap and freight rates reasonable, he is able to furnish cars at the lowest possible prices.

A SUCCESSFUL ELECTRIC MINING PLANT.

Erected and Running Under Most Adverse Conditions.

The utilization of sources of power remote from its point of application has, during the past two years, received considerable attention from electricians in this and other countries; and repented experiments have demonstrated the practicability of utilizing power, by the adoption of electrical methods, which would otherwise be wasted, and of its utilization to such advantage that projects may be, and have been, carried out which, without the application of electricity, would have been impossible. This has been particularly the case in the mining industry. Lodes of metal are frequently found at great altitudes, where, unless some cheap power can be applied at the required spot, they can never repay working. It is not so long ago that a project to generate power for mining purposes at the foot of a mountain and utilize it economically and midway, or at the summit, would have been scoffed at as visionary; but this feat has been accomplished and with complete success.

Probably the best example of this, at the present time, is the large plant which has been installed by the Edison General Electric Company at the Virginius group of mines near Ouray, Colorado. It is one of the largest, if not the largest, purely mining plant in the world. Every difficulty likely to be met with in work of this nature was encountered in the installation. The pipe line is laid along the side of a rocky canyon; the wires from the power house to the mine, are strung partly through dense timber, where they are exposed to damage from falling trees, and partly above timber line, over rocks and snow banks, where the poles and wires are liable to be carried away by snow-slides and where lightning storms are frequent and violent. The line is nearly four miles long, the voltage of the current eight hundred volts, and the mine is wet. The relative advantages of the ground return and complete metallic circuit are illustrated, and switches are so arranged that either may be employed, the metallic circuit being used at present. The plant includes a variety of machinery, comprising two pumps, one hoist, one blower, and two motors running mills, indeed, almost everything except locomotives and drills, and these will probably be added shortly. Lastly, the enormous saving that can be effected in many places by the utilization and transmission of water power by means of electricity is strikingly manifested. Coal at the mines costs eighteen dollars per ton, and before the installation of this plant was made, the cost of the power amounted to nearly $40,000 per annum. This sum is saved by the adoption of electric power. An instance is also afforded of unprofitable mines being rendered profitable by the use of cheaper power, for while some of the mines of this group are rich enough in metal to repay working under the most adverse conditions, there are others of lower grade which would have been shut down in case the electric plant had proved a failure, but which, with the plant, will now yield a satisfactory profit.

The foregoing gives a general idea of the nature of the plant and the difficulties encountered in its installation, but an actual visit to the mine is necessary to give a correct conception of the real character of the plant, which is undoubtedly one of the most remarkable in existence. Great credit is reflected on the managers of the mine, who possessed the requisite enterprise and sagacity to expend a large amount of money on a purely speculative experiment, the success of which was regarded as uncertain by even the strongest advocates of electric transmission of power.

If a careful search of the Rocky Mountain Region had been made with a view of selecting for the first extensive experimental mining plant, a location presenting every conceivable difficulty and one which would prove a crucial test to electric power at the very outset, it is very probable that the Virginius mine would have been chosen.

The Virginius and neighboring mines, owned by the Caroline Mining Company, are situated near the summit of Mt. Sneffles, in the region of perpetual snow at an altitude of 12,700 feet above the sea, and about 5,000 feet higher than timber line. They are reached by a wagon road, open in the summer, but impassable in the winter, when the only route to the mines is by a difficult trail, the lower part of which, denominated the "zigzag," winds up a declivity so precipitous that burros with their packs, slipping from a trail frequently roll down past several branches of the zigzag before they are stopped by a tree or rock. The upper part extends over a rocky plateau above timber line, and along cliffs where the snow is frequently over 20 feet deep on the level, and where terrific wind and lightning storms are frequent. The lower half of the line from the power house to the foot of the zigzag extends up a deep canyon through a forest of dense timber. The danger of breakage and grounds from falling trees which are frequently blown down by storms and rest on the wires for some time before they can be removed, is continually present. The constructions of heavy line work over nearly four miles of such ground is an undertaking, the difficulty of which is evident, but which can be fully appreciated only by an actual examination; while the maintenance and operation of the plant under the conditions just specified present even more serious difficulties. But although these difficulties are exceptionally great, the enormous expense of transporting fuel to the mines, rendered the advantages of an electric transmission plant so very striking, that the management was induced to make the trial.

The water power utilized for the plant is in Red Cunon Creek, nearly four miles from the mines. The water power plant consists of a small dam, an iron pipe line, extending along the sides of the canon, a distance of about 4,000 feet, giving an effective head of 485 feet, and two Pelton wheels, one five feet, the other six feet in diameter, capable of developing under that head 500 H. P. and 720 H. P. respectively, or a total of 1220 H. P., the two wheels being connected to separate shafts, so that either wheel may run the entire station. The electric generating plant comprises, at present, one 100 K. W. Edison dynamo and two 60 K. W. Edison dynamos, giving a total output of 298 E. H. P. The length of the line, as previously described, is a little over 19,000 feet. The electric machinery operated at the mines consists at present of two pumps, 60 H. P. and 25 H. P. respectively; hoist one (25 H. P.), 2 Edison motors, each of 60 H. P., running concentrators and stamping mills and a 15 H. P. blower. The large pump which was erected when the plant was first installed, raises 150 gallons of water 700 feet per minute, and is of the Knowles duplex type. An Edison standard motor is geared to it by a double worm, one right hand and one left hand, working into two spur-gears that mesh into each other and operate the pump, the object of the two worms being to neutralize the longitudinal thrust. The smaller pump, which was installed a few months ago, is somewhat similar, the motor, however, being mounted over the pump, with its armature vertical, the weight of the armature counteracting the thrust of the single worm employed. Both pumps have been working steadily and smoothly for several months, and have satisfactorily filled requirements.

The hoist consists of an Edison motor of standard type, but of street car winding and controlling switch, geared to the drum through the medium of a friction clutch. By means of the controlling switch and clutch, the hoist is under more perfect control than a steam hoist.

The motors for the mills and blowers are of the standard type, and present no exceptional features.

The most serious troubles have been caused by lightning, electric storms in that section of the country being frequent and very violent. This has formed the subject matter of particular study and special lightning arresters have been devised that give excellent protection. Since their adoption little or no trouble has been experienced from this source.

That difficulties were encountered in the early operation of the plant is not surprising, and the fact that these difficulties have been overcome and the entire plant operated successfully and satisfactorily under conditions that for severity are not likely to be exceeded anywhere, demonstrates the practicability of electric power for mining, and guarantees its success in this field.

Messrs. Abendroth & Root Manufacturing Company 28 Cliff Street, New York, send to our desk an interesting and handsomely illustrated pamphlet, telling all about the manufacture and uses of their celebrated Spiral Riveted Water Pipe, also giving numerous views of situations where it is employed.

There is an admirable illustration of the St. Clair Tunnel, Port Sarnia, Canada, showing Root's Spiral Riveted Pipe as used therein for ventilating purposes.

The pamphlet is well worth obtaining and can be had upon application. Ask for "Spiral Riveted Water Pipe" pamphlet.

EASY LESSONS FOR BEGINNERS

IN THE STUDY OF THE

ART OF MINING

AND THE

SCIENCES RELATED TO IT.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the theory of mining and to learn how to answer the questions in ventilation, mine surveying, and mechanics which are asked at the examinations for mine manager's and mine foremen's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine manager's and mine foreman's certificates and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and the calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

To write well consists in training the hand to obey the will, so that whatever form may be fixed upon the mind, the hand will readily reproduce it. To illustrate the importance of this statement write your name with the pen in the right hand, then in the left hand, and see if the results are alike. If not, it is not that you have any less perfect knowledge of what is undertaken, but the muscles do not obey the commands of the will, because not trained. To make these muscles subject to the will requires practice and *much* of it. This can not be emphasized too strongly, as penmanship, like any other study, requires close application.

The capital letter S, Fig. 40, is written correctly in the first letter at the left. It consists of a right curve extending upwards the full height of the letter, at the top it is joined by a narrow turn to the capital stem which it crosses midway between the bottom and full height of the letter. The oval is terminated just before it reaches the intersection of the curve and stem. Letter 2, counting from the left, is a deformity arising

Fig. 40.

from the imperfect development of the lower ellipse; it is made too large and on the wrong inclination. Another error is the crossing of the stem at too great a height. In letter 3 the downward line is made too straight, producing an angular turning at the base. In this letter, as in letter 2, the lower oval is divided unequally upon left and right of first curve. In the fourth letter the upper loop is too large and the lower loop too small, which produces a manifest deformity.

The capital T is shown as it should be written in the first letter, counting from the left, of Fig. 41. It consists of a capital stem and a cap. Usually the cap is written first, but it is optional, some preferring to write the capital stem first. In studying this letter it would be well to practice upon the parts of the letter separately, observing the proportionate length and position of

Fig. 41.

the lines. In letter 2, counting from the left, the capital stem is made too nearly straight, and the cap piece is imperfectly developed. Letter 3 shows the stem and cap connected, which is a careless way of writing this letter. In letter 4, the fourth law of penmanship is violated in making the cap piece, namely: all curves should be elliptical. In the stem the oval is contracted and brought to a close by a dot.

In Fig. 42 the first letter U satisfies the requirements of the four laws of penmanship, and is pleasing to the eye. Its development consists of a capital loop, the same as is employed in making the letter V, which unites at the base with a right curve which extends upward two thirds the height of the letter, at the termination of this curve a slanting straight line is drawn to

Fig. 42.

the base and there unites with a right curve drawn upwards one-third of the full height of the letter. Letter 2 is a violation of the first law of penmanship, namely: all strokes must be parallel. Letter 3 shows an error to be guarded against in writing this letter, that of making it too much like the capital W, so that it is mistaken for it. In letter 4 the capital loop is imperfectly developed, and the straight line retraces the right curve one-half of its length.

POWER IN MINING.

The Elementary Principles of Mechanics—Steam—Boilers—Engines—The Machinery Employed in Mines.

36. But in example under Question 33 you forgot that the weight of car and so on, hung from a pulley at the top of the head gear?

That pulley, or sheave, did not alter the case. The rope pulls with 9,000 pounds whether it is straight to the drum or not.

37. Then is a pulley or sheave of no account?

All that one fast pulley does is to change the direction of the motion. The engine and drum could not be placed on top of the derrick.

38. Is that always the case, that a sheave only affects the direction not the amount of the power?

Yes, I will prove it. A power pulling on the rope at P has the same lever arm as the weight which is hanging at W. (Fig. 5), because the pulley is round.

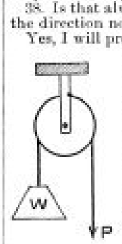


Fig. 5.

39. Suppose the pulley is not fast, what then?

If the pulley is loose and one end of the rope fast as in Fig. 6, then the power is different. The pulley revolves by climbing up the rope A B so that P has a lever arm equal to the diameter of the pulley, and the weight, which hangs from the center, has a lever arm equal to the radius. So, P $= \frac{1}{2}$ W. $P \times 2\,r = W \times r$.

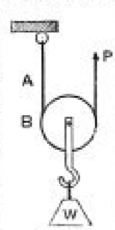

Fig. 6.

40. How is it with the block and tackle?

Similarly, only with two sets of blocks, one fixed and the other set loose, the power required to hoist any weight with the combination is as much smaller than the weight raised as the number of branches of rope. A pair of blocks with 4 pulleys above and 4 below will have 8 branches of rope (Fig. 6 has 2). So the power can, by the combination, raise a weight 8 times as great, but, of course, you must haul in 8 times as much rope as the distance through which the weight is lifted.

41. What is the strongest combination of pulleys?

What is known as the differential pulley, Fig. 7.

A large pulley, B, and a small one, A, are fastened on the same axle. An endless chain goes around them, as is shown, and also under the pulley. Now, if you pull on the chain at the arrow, you raise the weight a small distance. A power applied there will raise a weight equal in amount to the power multiplied by twice the diameter of the pulley B, and divided by the difference between the diameters of the pulleys A and B. This is a very powerful and useful arrangement for lifting great weights like pump rods, column pipe, or machinery.

Fig. 7.

42. How is it with spur wheels? Do they obey the same rule?

Yes, the rule is the same. The power multiplied by its lever arm is equal to the weight multiplied by its lever arm. Also, that the distance traveled by the power multiplied by the power equals the distance traveled by the weight times the weight.

43. Does not the number of teeth have anything to do with it?

Yes it has. Two wheels gearing into one another have their teeth the same distance apart. So the number of teeth the two wheels will have depends upon their diameters. If one wheel is 5 feet across and the other is 20 inches across, then the big wheel has 3 times as many teeth as the little wheel, because it is 3 times as broad.

44. Suppose a spur wheel 9 inches diameter engages with another star wheel 72 inches across, how much weight can I raise with it?

That depends upon how the power is applied. As for these two spur wheels, one wheel turns around once while the other turns 8 times, because the big wheel has 8 times as many teeth as the small one.

45. Then let us assume a second motion hoister with 5,000 pounds pressure on the crank pin which is 1 inch from the edge of the spur wheel?

That is a poor relation of parts but I will take that case. The crank turns once while the small spur wheel turns once. Now the crank being 1 inch from the edge, is $3\frac{1}{2}$ inches from the center. The lever arm of the power is $3\frac{1}{2}$ inches. So $5{,}000 \times 3\frac{1}{2} = 17{,}500$ foot-inches. The spur wheel turns once and could raise a weight on its teeth equal to 17,500 divided by $4\frac{1}{2}$ inches (see Fig. 5). So the weight it could raise at its teeth is 3,888 pounds which is the effort made upon the teeth of the large wheel. Now 3,888 multiplied by 36 inches the radius of the large wheel equals the effort upon the drum. If the drum is on the same shaft as the big spur wheel, it revolves as often as the spur wheel. The weight of the rope, cage, and car which is hanging from the drum with a lever arm equal to its radius, balances the 3,888 multiplied by 36 inches. So, if the drum equals 5 feet, the weight times $2\frac{1}{2}$ ft. balances 3,888 times 3 feet. The weight would then be 4,666 pounds. Fig. 8 would illustrate this case. (See page 153, of the February, 1892, number of THE COLLIERY ENGINEER.)

Fig. 8.

46. Then do all the calculations in mechanics and power depend upon the one principle of lever arms?

Yes. Whether it is a crow-bar you are using or a pulley, or any similar arrangement, the rule is to multiply the power you must use by its lever arm and that must be equal to the weight you lift multiplied by its lever arm.

47. Would it make any difference in the calculation whether the second motion engine has its two wheels spurred or only friction wheels?

No. Whether the pinion wheel A gears by teeth into the tooth wheel on the drum, or if A is a paper wheel pressing against the iron band of the drum, the result must be the same.

48. Is there no difference at all between spur wheels and friction wheels for transmitting the power?

The only difference is that the pinion wheel pays out power to the spur wheel by contact of the teeth, and each tooth must be strong enough to stand the pressure. When two friction wheels are in contact, the power paid out by A depends upon the friction, or bite, that the paper can be made to have on the iron band of the drum. To get this amount of friction you must use great force at the brake lever to throw the drum against the pinion.

49. Then what is the idea in having a small crank wheel and pinion and a large drum?

The crank arm can only be half as large as the length of one-half the stroke. The pinion wheel is on the same shaft as is the crank wheel. Now, the longer the stroke of the engine the longer is the crank arm and the greater weight the drum can hoist. Or the larger the diameter of the iron friction band on the drum, and the smaller the diameter of the drum, the larger is the weight that you can hoist.

[TO BE CONTINUED.]

METHODS OF MINING.

Shaft Sinking—Tunneling—Systems of Working Coal and Metals—Timbering in Mines.

27. What are the sills for?

With a soft floor the posts will sink unless they rest on sills. I have seen six feet galleries nearly closed by the pressure of soft floor upwards and hard roof downwards. In lead mines these "creeps" are as common as they are in coal mines. The sills should be long and strong, and always placed with bearings on the ends, and the ground hollowed out under them at the center. Then they are not so liable to break if the posts force the sills down.

28. Are not sills sometimes placed lengthwise instead of crosswise to the drifts?

Yes, the foot of each post rests on unhewn logs which are placed along the two corners of the floor. On each log several posts rest. If the pressure is also great from the sides, the sills are kept apart by wedge-braces every seven or eight feet, fitted to the sills. (Fig. 9.)

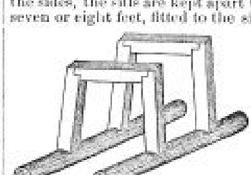

Fig. 9.

29. How far apart should the frames be?

That depends upon the nature of the ground. If the rock is firm, the sets may be three or four feet apart. If the pressure is great they must be nearer together.

30. Suppose the ground is crumbling?

Then on the outside of the sets lagging is placed, resting against the posts, and on top of the caps.

31. What is the lagging made of?

Slabs from the sawmill, or somewhat light cord wood. The lagging should always be weaker than the timbers of the sets so as to break first if the pressure comes. After the crush the lagging can be more readily replaced than could the sets if they broke.

32. Suppose the ground is very weak and soft, how would you timber?

If I were driving a gallery through very soft ground, I would use spilling. That method protects the miner while he is working and makes a permanent strong timbering. Fig. 10 is a fair drawing of it. Under the

Fig. 10.

cap of one set and over the cap of the next, I would drive spillings; that is, laths, somewhat pointed. The length of the laths is greater than the distance between two sets. As the men pick out the face they have a roof overhead, and when they have gone ahead far enough to put in a set it is done. In the meantime not only are the roof laths driven, but also those at the sides, in front of one post, and behind the next one in advance. When the roof or sides press upon the laths, they are bent so that the front end is forced down on the forward set, and the rear end upward against the cap. The cap is not raised out of place because on top of it two other laths are pressing downward. The laths are driven by mallet or hammer.

33. How large are the laths?

They may be of any size that you can drive. But not much over three inches thick.

34. What kind of ground would you use this method for?

Soft shaly ground, broken stuff, and moderately stiff clay.

35. Will it do in very soft clay?

Yes if the ground does not run like quicksand, for example, or if it does not melt after it has been opened into.

36. Suppose you strike the kind of ground that runs, what then?

For the purpose of driving through such soft ground, you would have to use some of the more elaborate methods which employ iron and masonry.

37. Are drifts, galleries, and entries all timbered alike?

Yes, unless they are so wide as to require very stout caps, or else a center prop. The center props are not desirable, because of the room they take, and also because they are the cause of so many accidents if cars are run on both sides of them. In metal mines the timbering is of a different style.

38. Why is that?

Because the veins are steep, and because the floor and roof rock is stronger than you find in coal mines. Flat beds, whether of coal or of zinc, have soft roof and floor, and require sets to be of four pieces. When the vein is tipped up steep, the floor and roof are on the sides of the gallery, and are called foot wall and hanging wall. As they are strong and firm, there would be no timbering required on the sides. The only pieces then are the cap, called a stull, and the floor sill.

39. How is the stull fastened?

A hitch is cut in the foot wall to rest one end of the stull while the other end is hammered down against hanging wall. The stull is cut much longer than the width of the vein between walls. Sometimes a wedge-block is driven at head, as shown in Fig. 11. (See page 163, February, 1892, issue.)

Fig. 11.

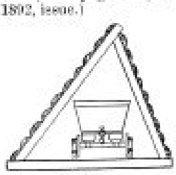

Fig. 12.

40. Suppose the walls are brittle, or soft?

Then a large head block is used beside the stull, just as the post and collar arrangement would be used in coal veins. If that will not do, the gallery is timbered by three pieces, as in Fig. 12. By the way, remember that the triangle is the strongest form you can have for frames.

41. Would this be used if one wall is loose?

Perhaps, though a common plan then is to put a post along the wall that is not strong, and have the cap rest on it at one end, and on a notch in the other wall.

42. In all of these forms of timbering I see no arrangement for carrying off the drainage water?

In the coal mines you do not want to cut the gangways or entries any higher than you have to for the car or man to get through. So a gutter is arranged for down in the lower corner of the timbering sets. In ore mines and in steep veins it makes no difference if you cut a high gallery, so then the gutter is cut under the sill and under the ties of the track. This is better than making the gangway wide, which you do not want in steep veins.

43. How are slopes or inclined shafts timbered?

Very much like the tunnels, only great care must be used in placing the sills. You must have sills in slope-timbering but you do not have to use them in tunnels. If the roof is bad you must give attention to its support. If it is not, then the frame is not strong, or else only props are used in the center with a partition nailed to them if the ladder-way is to be separated from the gangway.

44. How are shafts timbered?

Some shafts in firm rock are not timbered at all, but these are not safe. Besides, the hoisting can not be very fast in such a shaft. A bucket is the only conveyance that can be used then, and it is not safe to hoist buckets faster than 200 feet per minute. An untimbered shaft is therefore only for small mines. For large mines the shaft must be well timbered to allow of the use of a cage for hoisting, and to give a secure outlet for the men. The varieties of form for shaft timbering are numerous.

45. Which is the simplest?

The simplest and quickest to build is that composed of posts in the four corners standing upright, and five feet long. On these there rest two long wall plates and short sticks across. These pieces are about six or eight inches square or round. (See Fig. 13.) Above again come the corner posts with wall plates and crosspieces. At every thirty feet or so there are three very heavy timbers fitted into notches in the walls. These support the entire weight of the timbers. Back of the timbers the shaft is lined with two inch planks placed vertically, with the space behind them filled up with waste rock.

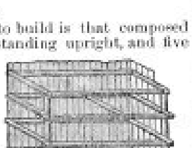

Fig. 13.

[To be continued.]

GEOLOGY

In its Relation to Coal, Iron, Oil, Gas, and Ores.

28. Is the whole crust of the earth stratified above the granite?

Yes, and all are called sometimes *sedimentary* rock as well as stratified. The first name refers to the mode of formation, the second to the manner of its occurrence.

29. How thick is the stratified series?

The crust of the earth is 50 miles thick and the stratified rock varies from a mile to ten miles.

30. Has any one ever seen the bottom granite?

Oh yes. Sometimes the stratified rocks on the granite are not deep and a bore hole has been drilled down into it. Sometimes very deep holes, nearly a mile, have failed to reach even the carboniferous. In other places there are no stratified rocks to hide the granite.

31. Why is that?

Such places may have been the original hills of the earth against which all the seas have beaten. In Canada and the Adirondack Mountains are remains of these primitive hills.

32. May they not have been thrown up through all these strata?

Not there; but the Rocky Mountain range was formed in that way.

33. Did the mountains break right through all the strata?

Yes, for all along them North and South you will see the rocks standing up on end like in Figure 8. At places the walls stand 300 feet high. It is this which makes the Garden of the Gods so famous. There, the rocks stand hundreds of feet high in walls and towers.

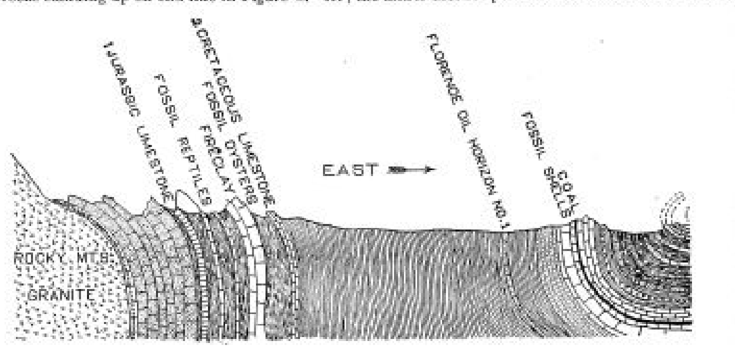

Fig. 8.

34. Is the Silurian next to the granite?

No, not here. Elsewhere it is next. The carboniferous was broken off below, but was not pushed up to the surface. You will notice to the right the rocks become flat and so they extend all the way for 2,000 miles to the Allegheny Mountains where they again stand up. Some of the Anthracite coal seams are steep instead of flat. The coal marked to the right is cretaceous. We know, too, that the Rocky Mountains were tipped up because on the other side the rocks are broken off dipping toward the West. And also a few patches were carried up on the tops.

35. I should think the strata would be broken up by this uplifting. Are they?

Yes they are. You must remember that the quiet depositing of mud as I explained was going on while the earth was cooling. As it cooled, the strata shrunk and in doing so became squeezed. The layers were bent and distorted just like a number of sheets of paper would behave under a side pressure that squeezed them.

36. What are these called?

They are called "folds" or "rolls." You must have noticed them in the mine. Fig. 9 is from an actual case. Fig 10 is also another case from on top of the Rocky Mountains a mile above sea level. The dotted lines show where it is believed the strata united. A B and C are valleys and creeks. At Tamaqua, Penn., the Mammoth coal bed, as it is called, is bent like the letter U coming out on Sharp Mountain at one end and Locust Mountain at the other.

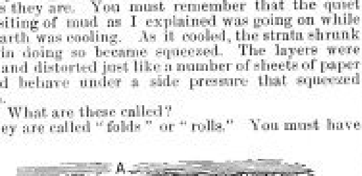

Fig. 9.

37. With these bends and rolls I should think the strata might be broken?

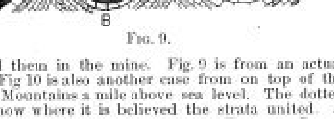

Fig. 10.

They often are broken fine or else they crack just as is shown in Fig. 11. (See page 163 and Fig. 4, p. 147, of February, 1892, number.)

38. What are the cracks called?

"Faults" is the proper name for these breaks but miners call them "thrusts," or "throws."

39. Why are they so called?

Geologists call them faults. They are breaks in the strata, across them. For example, if the rocks in Fig. 9 were to break, the fault would be along A B. But it seems that besides cracking, the strata fell and are misplaced as in Fig. 11, where A and B are coal seams. The right hand side slipped on the fault line. As these faults generally cause a settling of one side or the other, the miners have called them "throws" as if one side was thrown up or thrown down.

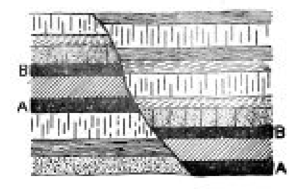

Fig. 11.

40. What do the miners mean by "rock faults" or "slate faults?"

These are not, truly, faults but they are names which the miner uses for portions of the coal beds which are thinner and have slate or sandstone where some of the coal ought to be, as S in Fig. 12. They call them "horses" in ore mining.

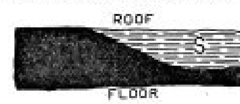

Fig. 12.

41. Faults, then, are places where the rocks have been broken and afterwards displaced? Is there ever anything in these cracks?

Oh, yes. In regions where volcanoes exist and where earthquakes are common, the faults are often filled with lava from the volcanoes or with silver and lead ores. In the coal regions, however, they rarely have anything but dirt and fine rock.

42. Are faults common?

I know of only three in Pennsylvania Bituminous region. There are several in the Anthracite districts. They are quite numerous in the Western States but not common in Virginia, Illinois, or Missouri.

43. How far do the rocks slip?

The limits are 1 foot and 20,000 ft. The average may be said to be 20 feet. But in Utah there is a throw of 10,000 feet. And in Pennsylvania and Virginia the sinking is over 30,000 feet.

44. Are they ever near together?

Look at Fig. 13 which is a good example from England.

45. How do you know but they may be separate beds which never were connected?

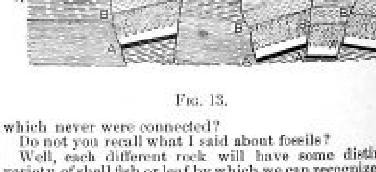

Fig. 13.

Do not you recall what I said about fossils?

Well, each different rock will have some distinct variety of shell fish or leaf by which we can recognize it. When the rocks are similar they have the same kinds of fossils.

46. Then by the fossils you know where to look for the rest of the coal seam?

Yes, if I am mining one of those coal seams and strike a fault, I go over to the other side, examine the rock and then by its fossils I can tell whether the thrust has been up, or down. And I go accordingly, Don't you see how important fossils are?

[To be continued.]

ANALYSIS OF COAL, ORES, ETC.

Instructions in Sampling and in Making Analysis to Ascertain the Quality and Value of Coal, Ores, &c., &c.

An analysis as defined by the dictionaries as the separation of a compound substance into its elements. As applied to chemical work, it is more than this. Not only are the simple substances separated from one another but they are also measured or weighed, so as to know the relative amounts. Gases are not easily weighed, so they are measured by the quart or cubic foot. Solids and liquids are weighed.

First in taking samples for analysis the attempt should be made to get as near an average of the material to be tested as possible so that the sample will give a fair idea of what the mine will ship. To get this, the rooms or stopes, which have working faces exposed, should be visited and broken down over the entire face of the exposure, up, down, and across. Each drift or tunnel should be similarly sampled so that the average of the vein is obtained. In coal seams, small partings that are likely to be removed and shipped with the coal should be included in the sample. Wherever samples may be taken, entries are made in the note-book of the appearance, size, and character of the face, partings, etc. If the partings are very large, the sample from them is not mixed with that from the vein. In sampling lead and silver veins the care taken is greater in order to take away for analysis a sample that will have a fair average of the mineral streak. The streak is separately sampled from the vein rock on the sides. Iron ores or clay are sampled in the same way. The endeavor must always be to have the sample, as far as possible, to be of *the same average as that of the ore which will be shipped*. If a shipping mine is being tested, numerous samples are taken from the cars, buckets, or out of the chutes or bins.

Samples taken from the different faces ought to be kept separate, packed up into sacks or boxes and analyzed separately, but if that is not desirable the method of quartering is adopted. The mineral to be tested is mixed thoroughly and broken up somewhat finely and carefully gathered on a canvas. The pile is then divided by a shovel into halves. One-half is rejected and the other again piled up on the canvas. The pile is then divided by a shovel into quarters and the opposite quarters A and B (Fig. 1) taken. If this is not too large an amount, the sample is boxed up in a very close box and analyzed.

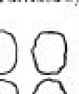

FIG. 1.

In any analysis the object to know is what there is in the mineral, how much of it is good and how much valueless; what impurities are in the specimen; and in silver ores, which part carries the silver. (See also questions under Surface Arrangements in the March issue of THE COLLIERY ENGINEER, page No. 188).

The impurities of coal which it is desirable to analyze are pyrites and ash. A coal is also analyzed to know how much fixed carbon and how much volatile matter the fuel contains. By reference to the questions 8, 59, etc., on geology you will see that in the process of coal making from peat that a great deal of marsh gas and other volatile matter was produced and liberated. It is this which gives so much trouble in the ventilation of collieries, besides being always a menace to the safety of the mine. The harder the coal, that is, the more nearly it approaches to being Anthracite, the more of this volatile matter has been driven off. In Bituminous and in lignite coals, it exists in quantity not as a gas but as a form of compound; chemists call the compound hydro-carbon. The presence of this volatile matter is not exactly deleterious but is productive of smoke and causes the coal to burn with a long flame. As the volatile and combustible matter is driven off, the coal hardens and becomes porous, and produces what is called coke. All coals having volatile matter will coke—some more readily than others. The best coke is obtained from those which cement when the gas is driven off. Some coals which do not cement, or clog up in the furnace, may also produce coke, but it is of poor quality. They burn free and may be used without coking. To ascertain, then, the amount of volatile matter and the tendency to coke, the coal must be analyzed. (See also p. 18, August, 1891, number of THE COLLIERY ENGINEER.)

Again, the amount of pyrites or sulphur must be determined, because it is very objectionable wherever the coal is to be used. Its iron melts out and fuses with the ashes to "clinker" the coal. Sulphur attacks iron, so neither the blacksmith nor the iron furnace man wants a coal of this kind.

The ash of the coal must be determined for several reasons. The quantity of ash and its character gives an index of the heating value of the fuel. The more ash there is the less carbon there remains for fuel. A red ash proves that pyrites is in the coal. The red color is made by the iron.

The amount of moisture in the coal must also be weighed. Not only does it make the coal heavier but its presence is objectionable. It takes some of the heat of the coal to drive off the water—and the amount is not insignificant, either. Many coals have 7% of water—or they have 150 pounds to every ton. Some lignite coals of the West have 450 pounds in a ton.

In analyzing a coal, the Ohio Geological Survey Bureau grinds the sample to about a ⅛ inch mesh. It is then thoroughly mixed and quartered down to a pound, which is bottled. It is further pulverized till it will go through fine bolting sieve of 100 mesh, and then 6 or 8 ounces are bottled.

(1). Of the pulverized sample, about 30 grains are weighed out carefully and placed in a small platinum crucible which has already been weighed. The whole is placed in an oven and the water boiled out of it for half an hour or so. The crucible is allow to cool and is weighed. The loss of weight is water.

(2). It is then placed over a flame and heated. The gas is driven out and burns at the top of the crucible. After five or six minutes the gas will no longer escape So the crucible is covered and again weighed. Now the loss, since the water was boiled off, is the volatile and combustible matter (or what the Chemist of the Survey, N. W. Lord, calls the volatile carbonaceous matter). It is not such an easy matter to know just when the gas ceases to escape, but one can come very close to it. It is for this reason that analysis of coal is called a proximate analysis. Quite concordant results can be obtained if the chemist is at all careful. The character of this coke that remains must be carefully examined and noted in the report. It gives a good idea of the coking quality.

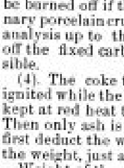

FIG. 2.

(3). The crucible still contains the "fixed" carbon and ash. The term, fixed, is used simply to distinguish the carbon that was volatile from that which resisted the moderate heat of the last test. But the carbon can be burned off if the heat is sufficiently high. An ordinary porcelain crucible would withstand the heat of the analysis up to the present time, but if one is to drive off the fixed carbon, a platinum crucible is indispensible.

(4). The coke that remains in the crucible is now ignited while the lid of the crucible is off and the whole kept at red heat till there is no trace of any carbon left. Then only ash is in the crucible. To know its amount first deduct the weight of the crucible, lid and ash from the weight, just after the volatile matter was driven off.

Weight of the platinum crucible is W.
Weight of the coal taken 20 grains.
Weight after driving out moisture is m.
Weight afrer driving out volatile matter is v.
Weight after igniting the coke is c.
Then $W + 20 - m =$ water in 20 grains of the coal.
$W + 20 - m - v =$ volatile matter in 20 grains of the coal.
$v - c =$ carbon in 20 grains of the coal.
$c - w =$ ash in 20 grains of the coal.

[TO BE CONTINUED.]

SURFACE ARRANGEMENTS.

The Preparation of Coal and Ores for Market.

21. How is this washing done?

There are three distinct methods. And there are several patented machines for each method.

The first method is to rest the coal or ore on a sieve and then forcing through it, upward, quick currents of water.

The second method is to force a constant current upward against a stream of falling ore or coal downward.

The third method is identical in behavior with that of the creek we spoke of. The material to be washed is floating in a current of water, or is carried by it, nearly horizontal. At various points are troughs for receiving the material which settles and the current of the stream is varied to assist the settling.

22. Which is the commonest plan?

The first. Perhaps nine-tenths of all the ores and three-fourths of all the coals are treated by the machines depending upon this principle. The second method treats nearly all the rest of the washed material, while the third method is quite rare in this country.

23. What is the first method called?

The machines used are called jigs because of their motion being a jigging one. (See page 162, February, 1892, number).

24. Now is the coal just as it comes from the mine washed at once by the jigs?

Oh, no. The coal and so also the ore, must be broken up and afterwards screened so as to separate the broken stuff into sizes. This process is called sizing or classifying.

25. Will you please explain what is done first?

The ore, or coal, comes up to the surface and is dumped upon a platform or into bins. From there the stuff goes to breakers. Here the coal is screened over bars, crushed, and again screened to sizes.

26. Why would not screening without crushing do?

Because there is a larger demand for the medium sizes of coal than comes from the mine. So some of the large lumps must be broken up. The screening over bars sorts out some of the mined coal into uniform sizes. The lumps that do not go through pass by men who pick out the slate and throw it away. The coal that goes through the first sets of bars is very dirty and is cleaned over mud screens which sort out the fine dust and clay from the pea and egg sizes which are sold.

27. How is the lump coal treated?

Some of the lumps go through a chute to the steamboat rolls, which crush it to small size; after which the coal passes to screens of different sizes.

28. Are Anthracite breakers the same as Bituminous breakers?

Yes, but larger and more elaborate.

29. I should think that these breakers would be expensive?

They cost more for wet coal than for dry coal and can not be built for less than $50,000.

30. Why are they so high?

Because it is better to have the mine run coal start at the very top and go down hill as it passes from rolls or bars to the different screens. Of course the hoisting engine has to raise the coal so much higher, but when once started, it hoists cheaper than the elevator belts and cups could. And if the breaker were not built so high, then the coal would reach the level of the floor before all the screening was done and the rest would have to be elevated again.

31. How are the rolls made?

They are steel barrels with movable steel teeth. As the two barrels turn, the coal is caught between the teeth and crushed. These give less waste than the old style roll- cast with iron teeth on them.

32. What are the screens?

They are simply frames of iron on which wire cloth is stretched. They are set on a shaft which is inclined so that the coal can slide down as the screens turn. They receive the coal through a hopper at the higher end and all the coal that does not go through is discharged at the lower into a chute that feeds to the next screen. Sometimes the finest screen comes first and all that does not go through it is sorted in the next which is a little coarser and so on. In other works the coarsest screen comes first, all that passes through goes to the next which is a little finer and so on. The first scheme is not so wearing on the iron and is therefore cheaper.

33. Which sizes of coal are sold?

Everything has been screened out into various sizes except the coal from the mud screens. To save this requires washing. Often, in Bituminous coals, the smaller sizes will all require washing.

34. What is the next step after screening?

Washing. You remember that the coal is in different sizes. Now if you will refer to Q. 8 of this subject and to Q. 23 of "Geology of Coal" you will see that the washing action of water depends upon the size and the lightness of the material. You will find that the current of water washes away the light fine stuff and leaves behind the heavy, coarse material. Each screen now feeds to a jig that treats one size of stuff that has been classified.

35. How does the jig work?

Look at the drawing on page 162, of February, 1892, number, and you will see that a jig is a tank full of water and in two parts. In one part a piston plays up and down; while the coal is in the other resting on a wire cloth. When the piston goes down, it forces water up through the bed of coal and lifts everything a little way. But the coal being lighter than the slate and pyrites is raised higher up to the top. Each time the piston goes down it raises the coal a little higher until all of it is soon on top. When the piston goes down, the stuff all settles down for the next stroke. The operation would now be complete, and you might stop the jig, shovel off the cleaned coal and then get the slate and pyrites at the bottom and throw them away. But that would be expensive so the jig is arranged to be automatic. A very heavy current of water is continually fed to the jigs and as it escapes over the end, it takes the cleaned coal with it. Now to keep up the supply a hopper, H, feeds from the screens continually and just as fast as the cleaned coal reaches the surface, the water washes it away into a bin. The slate and pyrites are meanwhile collecting on the bottom. A slide is raised at A, Fig. 1, and then they rush out into a trough to be thrown away.

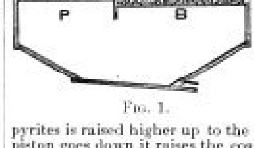

FIG. 1.

36. But does not some material get through the wire cloth in B?

Not very much for the holes are smaller than those of the screen feeding the jig.

37. What becomes of the dirt and clay that sticks to coal?

If that sort of dirty coal had been delivered to the jigs then the washing would not remove the dirt because it would wash off with the clean coal because it is lighter than pyrites. The dirt is usually washed off before the coal is crushed and screened. Jets of water from wooden troughs or iron pipes are thrown upon the coal and remove the dirt.

38. Does it make any difference whether mine water or creek water is used or not?

Yes, it does because the mine water is usually very acid. Water is water and would wash the coal all the same, but the acids, coming from the pyrites, eat iron away very rapidly. So the mine water is very destructive to the machinery and makes the repairs very costly. This makes the cost of washing dearer where mine water is used than where pure water is employed. Mine water is often so bad that it eats through an inch thick iron pipe in a couple of weeks. Many mines have to use wooden column pipes because the pumped water is so bad.

39. Which are the best jigs?

For coal, the best are the Clark and the Bradford patterns. For ore, the Collom and the Hartz jigs are most used. There are hundreds of styles patented, but the simpler the arrangement, the better, and those I have named are very simple.

40. What other ways are there of washing coal?

The cheapest, simplest and oldest scheme is one that is shown in Fig. 2. A long trough set at angle steep enough that the water will carry the coal down to D, where there is a bin for receiving it. The slate and pyrites, being heavier, settle on the bottom and are not carried off. The hopper, H, feeds the coal from the screens. Generally, however, the finer screens feed here while the coarser coal goes to the jigs.

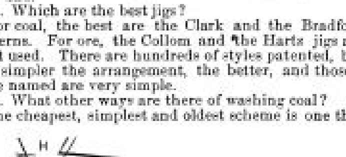

FIG. 2.

41. What prevents all the materials, pyrites, as well as the coal, from being emptied at D?

The heavy stuff settles behind the cleats B, B, and accumulates there. When these are full the lever, at right of hopper, is pulled and the water washes the slate into the car at C. Then the cleats are closed again and go on collecting pyrites and slate.

42. How is this arrangement regulated so as to give clean separation?

Easily enough. You raise the trough and the current is not swift, if you use only a little water the current can not be swift. If you lower the end or use much water you get a strong current. So you can regulate the current all right. Now, a strong current will carry away more stuff, heavier or larger, than a mild current can. So you see that it is possible to feed just the right amount of water as will wash the coal properly.

[TO BE CONTINUED.]

VENTILATION IN MINES.

Including a Description of the Gases Met With in Mines and the Atmospherical Conditions Necessary to Be Known to Understand the Laws of Ventilation.

1. What is air?

Air is the name given to the compound gas that surrounds the earth.

2. Why is it called a gas?

Because the matter of which it is composed is light, transparent, and has the property of expanding.

3. What are the kinds of matter?

Solid, liquid, and gas. All matter must be one of these three.

4. How do they differ?

A solid requires no vessel to contain it and force is necessary to separate its particles. A fluid requires a vessel to confine it. There are two varieties of fluids—gases, and liquids. These two can be poured but unless received *in* something can not be preserved. The liquids require no force to separate their particles. They pour with ease. Gases prefer to be separated while liquids are neutral, and solids, require force to accomplish it.

5. What keeps a gas in place?

You must lock it up in a tight reservoir or else it will be continually moving in order to get away.

6. What keeps the air from leaving us, or does it fill all space between us and the sun?

Air fills all space but that air is very thin; astronomers call it ether. The ether is much thinner than that we breathe.

7. How do you account for any about the earth?

The air around the earth is kept here by the attraction of the earth for it. Thin as the air seems, it contains matter in it, but very finely divided. And in just the same way that the earth attracts the falling apple so it draws the matter of the air down to it.

8. Then the air is acted on by two efforts, an internal one that naturally expands it and another, an external one, that draws it to the earth?

Yes, that is the idea. The nearer air is to the surface the more compact it is. In Colorado at Denver, the air is only four-fifths as heavy as it is in Scranton. And on top of our high peaks, it is only a little more than one-half as heavy as in Scranton. If we go down underground the air is still heavier.

9. How much heavier is it in our deepest shafts?

The deepest mines to my knowledge are about 3,900 feet. In the lowest level the air is one seventh heavier than at the surface.

10. How heavy is air?

That depends upon how hot it is. A cubic foot of air from Scranton at freezing point of water, 32° Fahrenheit, weighs 0·08073 of a pound. If the air is taken on a hot summer day when the thermometer reads 100° Fahrenheit, a cubic foot weighs 0·0703 of a pound.

11. How heavy is the air on the top of mountains?

At a height of 14,000 feet above the sea, the air we breathe weighs 0·3511 of a pound per cubic foot.

12. Does it ever become so light as to weigh nothing?

No, not absolutely nothing, but nearly so. The moon has an atmosphere about it so very light that no human beings could exist there. It weighs very nearly zero.

13. Does it weigh the same at all places on the sea level?

Yes, in Wales, in the United States, or in Australia the air weighs just the same at the sea coast.

14. Why should it weigh more at the sea level than at Denver which is 5,000 feet above the sea?

Look at Fig. 1 and imagine a high pile of cotton. The layer at the bottom has a lot of cotton pressing down on it to compress it. Half way up there is less cotton above, so the layer at B is squeezed a little only. On top there is nothing to press it down and the cotton is very puffy. A cubic foot of cotton from A would be very heavy while that from B would not weigh so much, and that from C would be very light. So it is with air on the earth. There are about 120 miles of it piled up like the cotton. At the sea level the air is like the cotton at A, Fig. 1, pressed by the 120 miles of weight above it. The air of Denver, or that on the tops of our mountains behaves like that cotton near B. It has only half the air above it and it is not so dense as that at A, and so weighs less. Points on the earth's surface above the sea level have lighter air than that at Philadelphia.

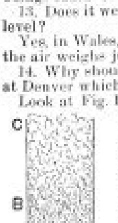

FIG. 1.

15. Then I am receiving upon my shoulders and head the pressure of all the air above me?

Yes, you are carrying the weight, not of the world, but of all of its atmosphere upon your shoulders.

16. How much does it weigh and what is the pressure?

The air above the level of the sea extending 120 miles up presses down with a weight of 14·7 pounds per square inch.

17. Is there a pressure of 14·7 pounds on every square inch of my body?

Yes. Every square inch of your body is receiving a pressure of 14·7 pounds, upward, downward and sidewise.

18. Is that the case also on a mountain?

No, instead of 14·7 pounds it is, perhaps, only ten pounds to every square inch.

19. How can you prove it?

By the barometer which indicates the amount of the pressure. Pour water into a U tube of glass or into a hose and you will find that it rises to the same level in both arms, Fig. 2. The air is pressing on A just as hard at it is on B. But imagine the top of the tube above A to have no air in it, and imagine its arm to be extended 150 miles up above the earth. Then at B the air is pressing and at A there is no air to press on it. Then the water will lower to N, Fig. 3, while the other side will rise up to M, Fig. 3, 34 feet high. At that it will stand. If mercury were used instead of water the level of M would be only 30 inches above N. The water from the level of N to that of M weighs 14·7 pounds, so also, the 30 inches of mercury will weigh 14·7 pounds. If these experiments were performed in Denver, instead of at the sea level, the water would only be 28 feet high and the mercury 24½ inches. Now these 34 feet of water or 30 inches of mercury balance the weight of the air above, or *represents the weight of the atmosphere*. That is what the barometer indicates—the weight or pressure of the atmosphere.

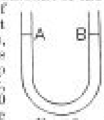

FIG. 2.

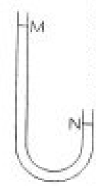

FIG. 3.

20. But a barometer is closed at one end.

Yes, so it is. Take the tube in Fig. 3, seal up the top of the tube above M and you have a barometer. There is no air above M in the 150 mile tube, so if we pump out the air from the tube after it is sealed, leaving the end N open you have on one side a column of mercury, or water, balancing at N the pressure of the air.

21. Does the barometer always stand at 30 inches of mercury?

No. When a wind is blowing, or when a storm is brewing, the barometer falls and there will be, perhaps, 29 inches of mercury. The severest storm known lowered the barometer to 28·5 inches.

22. Does the height of the barometer indicate anything besides weather?

It does in this way. If the barometer falls suddenly, it means that there is less pressure of air outside. Now, gas in a goaf, or in coal, is under a heavier pressure than the air. So, when any cause releases the outside pressure, the gas can get out readily and the amount depends upon how far the barometer lowers. For this reason the ventilation of a mine should be plentiful when the barometer is seen to fall.

Again the barometer indicates the amount of water that can balance the atmosphere or that the atmosphere can lift.

23. Is that what is meant by the suction of a vacuum?

Well, a vacuum is a space having nothing in it, not even air. If then I draw the air out of a tube I have produced a vacuum. If the lower end is under water, the vacuum of the tube is like that in the arm M of Fig. 3. "Nature abhors a vacuum," and the weight of the air outside *forces the water up* into the tube. Though the result is the same as if I "sucked" the water up, yet the real truth is that the atmosphere forced the water. No matter how long or how large the tube may be, the water is driven up into it. But the water will never rise over 34 feet under any conditions. Generally it will not be raised that high, even on account of friction and the leakage. At Denver the "suction length" is not over 28 feet. With a siphon the highest point of the bend must not be over three-fourths of the theoretical suction lift.

24. How can I know the amount of the suction lift?

By looking at the barometer and multiplying the number of inches of mercury on it by ⅞.

25. Please give me an example?

I want to know the practical height of the suction lift of a pump when the barometer reads 28½ inches.

$$28\tfrac{1}{2} \times \tfrac{7}{8} = 24{\cdot}9 \text{ feet.}$$

That is the lower clack of the lift can not work if it is more than 25 feet above the level of the water in the sump.

[TO BE CONTINUED.]

Compressed Air.

The use of compressed air for the transmission of power in mines, and for supplying motive power for mine locomotives, and all kinds of stationary machinery is gradually but surely extending in all coal fields of the continent, and it is not now a question of "will it work?" but the question is, "which is the best compressor, and can I understand the use of compressed air?" Compressed air acts practically the same as steam, except that its exhaust does not vitiate the air in the mine, or rot timbers and disintegrate the roof. On the contrary, if the exhaust is conducted into the intake air, it improves the ventilation of the mine to a certain extent. Every colliery official in the country should be posted on the use of compressed air, and compressed air machinery. The lately issued catalogue of the Norwalk Iron Works Company, of South Norwalk, Conn., will give him a large amount of information on this subject, and he can get it free by merely writing a postal card for it. It contains besides, a number of useful tables, conveniently arranged.

EXPLOSION IN A COAL BOX.

BY SAMUEL OAKLEY, SCRANTON, PA.

No question is more important, and none perhaps is receiving more attention, than that of the part which coal-dust plays in mine explosions.

Few, if any, mining engineers now deny that coal-dust may be the cause of augmenting and extending an explosion after it is once initiated, but a great many decidedly object to the theory that coal dust alone—without any small accumulation of gas—may become ignited, say by a blown-out shot, and if present in large quantities thus cause a disastrous mine explosion.

As one who believes strongly that coal dust is capable of itself, when mixed with air in sufficient quantity to cause an explosion, I hereby give a detailed and correct account of an explosion, which occurred in a coal box at the surface at the Brancepeth C. Pit, operated by Straker, Love & Co., in the County of Durham, England, and which, in my opinion, was a coal-dust explosion.

This mine is very shallow as compared with the mines near the East coast of the same county; its depth being about 120 or 130 feet, but though not deep its workings are very extensive, as somewhere near 350 miners are employed, besides the necessary number of company hands.

The seam of coal worked is known as the "jet seam" and varies from 2 to 3 feet in thickness. The top part is "jet" (the *parrot* coal of Scotland) and is from 6 to 9 inches thick. No outbursts of gas have ever occurred in the workings, naked lights exclusively being used.

The coal is loaded separate from the jet or *cannel*, and on reaching the surface, is passed from the cleaning screens, through Carr's disintegrators or coal crushers, and is crushed into powder or dust, and is then lifted by elevators to the coal box wherein the explosion occurred, so that all the coal was in a finely divided condition when placed into the box. The box was made large in order to always have a good stock of crushed coal on hand for the coke-ovens when from any cause the output might be too small to load the ovens. Dimensions of box were as follows: 24 ft. × 31 ft. × 31½ ft.

Near the top of the box windows were placed to admit light to certain parts of the elevator machinery that required oiling two or three times per day. Ladders were placed on the outside of the box for ready access to the top, and ladders were also placed on the inside so that a person could pass up the outside and down the inside whenever required.

This caused four small landings or platforms to be placed inside about equal distances apart.

A few iron tie rods passed through the box.

Now, it will readily be seen that on the upper landings and rafters of box a quantity of very fine dust would accumulate. Slides, or movable doors, were placed at the bottom of the box by which the coal was taken out of box by cars to load ovens.

Just previous to April 24, 1889, the day of the explosion, a dispute arose between the workmen and the company which ended in a strike, and the whole of the coal the box contained had been taken out by the slides at bottom except that resting on bottom corners of box, and that on the rafters and platforms referred to previously. Opportunity was therefore taken to have the box thoroughly cleaned out, and for this purpose five laborers were instructed to take shovels with them and clean all coals from the box. These five laborers entered the box at about 10 A. M. through the slides at bottom, and the "boss" or chargeman, Mr. Mills by name, entered by means of the ladders up the outside. Seeing that a large quantity of fine dust had accumulated on the upper platforms he called two of the laborers to come up and clean it down.

Four oil lamps or open torch lights had been hung upon one of the tie rods about 7 ft. from the bottom of the box.

The two men commenced throwing down the coal to those below, causing such a thick cloud of dust that those at the bottom, according to their evidence, could not see each other, and before they had been more than ten minutes in the box the explosion occurred, severely burning the six persons inside, breaking the glass in the windows, and partly dislodging the top of the box.

The report of the explosion was a low rumbling noise, not such as would be expected from a gas and air explosion and the damage was not near so great to the box. The two laborers at the top part of the box were thrown to the bottom and were rescued from the slides, but the chargeman, Mills, appears not to have been knocked down as he came out from the top by means of the ladders, as he had shortly before entered. Mills and the two laborers who were with him on the upper platform all died from the effects of burns and shock received, but the three laborers at the bottom of the box recovered; thus it seems as though the flame was not so intense near the bottom as it was further up.

One of the survivors says that he noticed the dust as it was ignited at the lamps; then there came a second larger flame, and then the whole box suddenly seemed filled with flame and he felt he was burned, and he sank on one of the slides falling through when some person opened it from below letting him out to daylight and pure air.

Another of the survivors in his evidence said that he was holding his cap over his mouth to keep out the dust, it seemed so dense, and that he noticed nothing until he felt the sharp sensation of burning behind his neck.

In my opinion this explosion is proof positive that coal-dust is of itself explosive, for the fittings of the top and windows were not sufficiently close to allow gas to accumulate, and besides, that same morning before daylight, the person who oiled the machinery had been up at the top of the box oiling the elevator machinery, previously referred to, with an ordinary oil lamp. This would have readily ignited any gas had it been present.

HOW TO LIVE

What Food to Take.

Whether the old saying that a man's heart is reached through his stomach is or is not a true one, it is a scientific fact that the stomach is a highway to the brain. The exhilarating influence of a good dinner is sometimes shown in brilliant impromptu speeches, without a doubt. The cook is responsible for many of the accidents, the failures, and successes of life. Not long ago a well known lawyer in summing up a case acquitted himself so wretchedly that the jury promptly brought in a verdict against his client. The lawyer afterward acknowledged that hot muffins at breakfast were responsible for his having lost the case. They made him irritable and insolent.

Curious to know upon what sort of food men of note do their best work, I recently interviewed some of the lights of the medical profession, law, commerce, theology, and society.

Genial Dr. George F. Shrady, President Grant's stanch friend, declares that he must vary his food in order to develop, and nourish, separately and collectively, the organs of his body.

"I have an excellent digestion and can take all kinds of food without feeling any discomfort", said he "but I believe that the brain is most nurtured by sleep and rest. If we gratify our intellectual tastes we are feeding the brain vastly better than by any sort of material food, and consequently obtain better results.

"A friend once had as a patient a young author, who had been recommended to follow a strict diet of pumpkins. On this sort of fare he wrote a novel. Well, the offspring of pumpkins—roasted, boiled, and stewed—is still looking for a publisher to launch it on an unsuspecting public!

"No one kind of food exclusively is good for the ordinary man. 'To be healthy, wealthy and wise', as the old maxim goes, study the likes and dislikes of your stomach and regulate your diet accordingly (as I do) and all will go well."

DEPEW'S ADVICE.

Chauncey M. Depew adheres religiously to simple fare—a cup of coffee and an egg for breakfast, a chop or some chicken for luncheon and a roast or other plain food for dinner. He believes that upon plain food the brain becomes most responsive to the demands made upon it.

"If men would avoid gorging, overfeeding, and otherwise abusing their system", he said, "they would find that in so far as the mind is developed so far can it be depended upon in every emergency and at all times.

"We all know that man's brain power is not in accordance with the capacity of his stomach. I know two men of wonderfully clear minds who could write a logical essay on political economy after two plates of corn beef hash which might place another man of ordinary capacity on the verge of apoplexy, and therefore every man must be a 'law unto himself'. Care of the body in the hosts of ways that we all neglect will give to its organs, one and all, a vigor and power hitherto unsuspected".

Judge Roger A. Pryor laughed heartily when told that every briefless lawyer in town was anxious to know whether his spirited speeches might be attributed to squab, lobster, or partridge.

"Tell them from me", said Judge Pryor, "that I am extremely fond of birds and dainties generally and that lobster *a la* Newburg is a toothsome dish I don't despise and that my brain works best when I'm free from indigestion. Tell these young men to follow the old Roman maxim and secure for themselves 'a sound mind in a sound body'.

"Hot breads, salads, ices, and sweets form part of my daily menu, and as they give my body strength I am able to do my allotted share of mental labor. The body must first be ministered to by food and exercise, and then the mind will soon be ripe for cultivation. The reason, memory and imagination must each be nourished with the food it requires—logic, law, mathematics, poetry or art. Upon the idiosyncracies and constitutional peculiarities of each man depend the kind of food he assimilates".

DON'T WORRY.

Dr. H. P. Loomis thinks men pay too much attention to the specific uses of certain foods.

"Look at the enormous sale of phosphates and so-called brain foods", said he. "There is nothing in them. If instead of wondering whether this, that, or the other is good for him a man would simply follow the dictates of his own appetite we would be much better off. Nature places a safeguard upon excess by creating the sensation of satiety.

"When I have eaten some rich food that causes me some annoyance I take a horseback ride or other pleasant exercise and rid myself of the ill-feeling, and in the future avoid that Welsh rarebit or venison that caused the trouble. Rest is really the best tonic for the brain. In two words I would give this prescription for happiness—'Avoid worry.'"

A prominent member of Sorosis, a really brainy woman, declares that the amount of food people require or think they require, is largely a matter of habit. Said she: "It is possible to train the stomach to do with very little or to make its requirements border on the margin of gluttony. When the hunger is satisfied, brain achievements depend upon heredity and environment, and to them must be attributed all success or failure. The gardener who only cares for the blossom of his plant instead of directing his efforts to the root, will have but sorry fruit as a reward. Let mankind look to their physical perfection, and the mental and moral are sure to follow".

MENTAL PABULUM.

The Rev. Dr. Henry Van Dyke, the author and clergyman, believes the brain to be touchingly appreciative of all kindness shown to the stomach, and sullen and unmanageable when the latter is oppressed. At the same time allowance must be made for individual tastes.

"My food", he said, "must be taken at regular intervals and be largely of the farinaceous kind, while yours, possibly, may be taken when and as you choose. A single sandwich of caviar would incapacitate me for several hours. So, I say, be kind to the machinery of the body. After all, the best diet for the brain is a constant variety in the quality and quantity of our intellectual food".

There seems to be no particular edible which holds a magic power over the realm of thought but by selecting food with a view to digestibility. In individual cases the body is aided in performing its various functions and the brain with its other organs is thus enabled to discharge its duties properly as well.

The Enervating Energy of Americans.

In thirty years time, less than half the Biblical allowance of man's life, the United States has multiplied its wealth six times, and has nearly trebled that per capita. What energy, what work, what unceasing effort has been needed to bring about this marvelous result! What can we do to retard this development of the brain and nerves at the expense of the body? Obviously it is impossible to change our surrounding, to change our food, to lessen the drive of our modern life, to relieve the strain on the mind, to make the competition less fierce. It is apparent, then, that as we cannot lessen the strain we must increase the ability to undergo it. We must, as a people, learn to understand this, that while we drive the brain we must build the body. The methods of doing this are so simple that they are apt to be overlooked; they may be summed up in two words—exercise and fresh air. As we teach our children to wash their hands and faces in the morning and continue our teaching until ablutions become a habit so fixed as to produce positive discomfort if they are omitted, so we must teach them to exercise until this, too, becomes a habit, a second nature, a something that when omitted causes real physical distress, and we must choose a form of exercise which is adapted to persons of middle age as well as to children. . . . . . Build up the body, build up the body! In our modern life this should be dinned into the ears of all until it is obeyed, for, verily, unless we build up the body, the strain on the brain will ruin the American people. The very elements in ourselves that have made us great, the push, the drive, the industry, the mental keenness, the ability and the willingness to labor—these contain in them the seeds of national death. No race may endure that has not the stamina and power of the healthy animal. The American race has run too much to brain.—*Dr. Cyrus Edson in North American Review for March.*

Indian Surgery.

It is a mistake to suppose that the Digger Indian is entirely ignorant of how to proceed in cases of broken bones. A correspondent of the *Scientific American*, who once had some experience in sawmills in California, writes that journal as follows: On one occasion, while a number of Indians were curiously watching the operations of the mill, and standing near the double-flue boiler to keep warm, one of the flues suddenly collapsed in such a manner as to fatally scald one of the owners and hurl a poor old Indian woman some 20 feet away, breaking one of her legs below the knee. In the excitement of the occasion and the necessary care of the injured owner, the injury sustained by the woman was not observed and she was taken quietly away by the other Indians. Three or four days later quite a large number of Indians appeared in a hostile attitude on a near-by elevation which overlooked the mill. After taking their station, a tall chief approached and inquired for the "sawmill man", complaining that he had "shot off his sawmill" and broke the leg of a *mahala*, and he, the chief, was ready for a fight. The foreman took in the situation at once, invited the chief into the house adjoining, and showed him the stricken owner in the agonies of death. The chief then, in his turn, took in the situation from the opposite standpoint, and immediately exclaimed: "No intendi, accidenti. Me safe, no fite, all samo". We now append the interesting and surgical part of the story as given in the *Scientific American*: In a day or so after Mr. Hoxey's burial, the surgeon went to the *campoodie*, and there sat the poor broken-legged *mahala*. The physician told me that the Diggers measured around the leg in several places, then cut a piece out of a slippery elm tree, near the size and shape of the leg, took the bark off, shaved off the outside and made as fine a splint as he ever saw, and fitted it around the broken limb, leaving the space open about one quarter of an inch on the top, and were pouring in a little water to keep down the fever heat, and that in a few weeks the squaw was limping around town again.

Typhoid Fever.

The following memorandum on typhoid fever and its proper treatment was given to Major-General Ellis by the late Sir William Gull, M. D., two years after he was in attendance on the Prince of Wales during his illness in 1872. It was suggested to Major-General Ellis recently that the publication of this memorandum might prove useful, and it appeared in the *Times*. Sir Williams Gull's suggestions with regard to the treatment of typhoid fever have been observed in the case of Prince George:—

I. Typhoid fever is a disease which runs a more or less definite course. It cannot be stopped or cured by medicines.

II. The chief thing to be done at the outset of an attack is to send the patient to bed, so as to save strength from the beginning.

III. No strong purgative medicines are desirable.

IV. As the fever develops, and the strength grows less, light food should be taken at short intervals—*i. e.*, water, toast-water, barley-water, milk and water, light broths (not made too strong, or too gelatinous).

V. If there be restlessness or much agitation of the nerves, wine (port, sherry, or claret) or brandy in moderate doses at short intervals. This must be directed medically, but in general it may be said that the amount required is that which induces repose and sleep.

VI. The bowels may be left to themselves. If unmoved for 24 or 36 hours a lavement of warm water may be necessary, but this will be directed medically.

VII. The restlessness or wakefulness in fever is best remedied by the careful giving of wine or spirit with the food, or in water. Sedatives, such as opium, are inadmissable—mostly injurious.

VIII. The bedroom to be kept at a temperature of 62 to 64 degrees.

IX. Great care necessary to keep the bed clean and sweet. This is most easily done by having a second bed in the room, to which patient can be removed for two or three hours daily, whilst the other is thoroughly aired, and the linen changed.

X. All fatigue to be sedulously avoided. No visitors admitted, and no other person but one nurse and one attendant to help her.

XI. Patient's room never to be left unattended for a moment, as in the delirium of fever patient might jump from bed and injure himself.

XII. As to medicines and the treatment of complications, the immediate medical attendant must be responsible.

XIII. As it is probable that the discharges from the bowels in typhoid fever may be a source of contagion, it is desirable that before being thrown down the closet they should be largely mixed with Condy's fluid or some other disinfectant. On the same principle, the strictest cleanliness must be observed in the sickroom.

XIV. There is no reason to believe that typhoid fever is contagious from person to person in the ordinary way. The largest experience shows that it does not extend, like an ordinary contagious disease, to nurses or others attending upon patients suffering under the disease.—*National Labor Tribune [England.]*

USEFUL INFORMATION

"In God we Trust."

The motto "In God We Trust," which is now stamped upon all gold and silver coins of the United States, was suggested by an old farmer living in Maryland. This conscientious Christian gentleman thought that our currency should indicate in some way the Christian character of our nation, which he argued, could be best done by putting a motto upon our coins expressing a national reliance on divine support in governmental affairs. It was in 1861, when S. P. Chase was secretary of the treasury, that this man wrote to Washington respecting his pet idea. His letter was referred to Mint Director Pollock, who discussed the question in his report of 1862.

Pollock and Chase were in favor of introducing the motto at once, but Congress gave the suggestion no attention whatever. In his next annual report Director Pollock again referred to the matter, this time in firm theological argument, saying, "The motto suggested, 'God Our Trust,' is taken from our national hymn, 'The Star Spangled Banner;' the sentiment is familiar to every citizen of our country; the time is propitous; 'tis an hour of national peril. Let us reverently acknowledge his sovereignty, and let our coinage declare our trust in God."

A two-cent bronze piece was authorized by Congress to be coined the following year, and on April 22, 1864, the first United States coin was stamped with the legend, "In God We Trust."—*St. Louis Republic.*

Wonders of the Grave.

The tomb of Edward I, of England, who died in 1307, was opened on January 2, 1770, after 463 years had elapsed, and his body found to be almost perfect, the face even retaining its expression. Canute the Dane, who crossed over to England in 1017, was found in 1776 by the workmen who repaired the Cathedral. His body had reposed in the grave for nearly 750 years, but was perfectly fresh and life-like. In 1569, three Roman soldiers were dug out of a peat bog in Ireland, where they had in all probabilities lain at least 1500 years, yet they were perfectly preserved even to skin, hair, eyes, and nails. In the reign of James II, of England, the big church at Warwickshire fell. In clearing away the debris it became necessary to move the tomb of Thomas Gray, at one time Marquis of Dorsetshire. When this had been done it was found that the body of the Marquis was as fresh as a corpse newly buried, the joints even being pliable. this discovery was made exactly seventy-eight years, three months and two days after the burial. Robert Braybrook, who was bishop of London in 1381, and who died in 1404, was found to look perfectly natural. When removed from the tomb after the great London fire of 1666; even the color of the eyes could be distinguished.

The "Trackless" Ocean.

That it is a mis-use of language, in these modern days, to speak of the ocean as "trackless," is ably argued by our esteemed contemporary, Goldwaite's Geographical Magazine. It proceeds to show that the routes taken by vessels, under modern conditions, even between points so distant from each other as New York and Calcutta, will coincide so nearly as scarcely to show at any point a divergence of fifty miles. A sailing vessel, taking what is called the southern route from Liverpool to New York, would sail about 4,500 miles to cover a direct distance of less than 3,000 miles, yet would in all that devious journey follow a path well understood and established in the Sailing Directions. Science has well served mankind in thus overcoming the mystery of the ocean wastes; but, even so, we cannot perceive the unfitness of the word "trackless," as customarily used in this connection. Wherever else man journeys, he beats a path or leaves a trail, and the next comer may be guided by the print of his foot or the mark of his wheels. That is a track, as commonly under-tood. But when a vessel cuts her way across the main, her course is "writ in water," and she makes no track save her fast vanishing wake. Men have sought out devices, it is true, by which her path may again be traced with exactness and certainty, and may be implicity followed. But the track is only on paper after all; and he who in mid-ocean, his eye assuring him of the fact, speaks of it as trackless, is not guilty, we submit, even of poetic license.—*Mechanical News.*

Virchow's Attack on Darwinism.

In recent years Darwinism has received some telling blows, which its over-zealous adherents affect to despise. But the latest criticism of its assumptions by Professor Virchow, in his address delivered at the Vienna Anthropological Congress, cannot be answered by a sneer.

Prof. Virchow said:

Since the Darwinian theory of the origin of man made its first victorious mark, twenty years ago, we have sought for the intermediate stages which were supposed to connect man with the apes; the proto man, the *pro anthropos*, is not yet discovered. For anthropological science the *pro anthropos* is even a subject of discussion. At that time in Innspruck the prospect was, apparently, that the course of descent from ape to man would be reconstructed all at once; but now we cannot even prove the descent of the separate races from one another. At this moment we are able to say that among the peoples of antiquity no single one was any nearer to the apes than we are. At this moment I can affirm that there is not upon earth any absolutely unknown race of men. The least known of all are the people of the central mountainous district of the Malay Peninsula, but otherwise we know the people of Terra del Fuego quite as well as the Esquimaux, Bashkirs, Polynesians and Lapps. Nay, we know more of many of these races than we do of certain European tribes; I need only mention the Albanians. Every living race is still human; no single one has yet been found that we can designate as simian or quasi-simian. Even when in certain ones phenomena appear which are characteristic of apes—*e. g.*, the peculiar ape-like projections of the skull in certain races—still we cannot say that these men are ape-like.

Of course, Darwinians retort that the absence of proof does not necessarily disprove their theory. But, if, after so many years of world-wide research, no single race "has yet been found that we can designate as simian (ape-like) or quasi-simian," the theory must be in a very sorry plight, when the verdict of its own advocates is "Not proven." —*New York Herald.*

Definition of a Cold Wave.

The Weather Bureau definition of a cold wave is a fall in temperature of 20 deg. or more in twenty-four hours, free of diurnal range, and extending over an area of at least 50,000 square miles of country, the temperature somewhere in the area going at least as low as 36 deg. Marking on a map where a cold wave has occurred by lines through the places of equal fall of temperature the areas are seen to be enclosed and something very great in extent. In one of the greatest cold waves in recent years, that of Feb. 17, 1883, the temperature at 7 a. m. was 20 deg. lower than at the same hour on the day preceding, throughout an area of 1,065,000 square miles, extending from Lake Superior and Georgian Bay on the north to the Rio Grande on the south, and from Kansas City to Cincinnati. Inside of the area of twenty-degree fall there was an area of forty-degree fall of 187,000 square miles; inside the forty-degree fall there was 31,000 square miles of fifty-degree fall, and inside of the fifty-degree fall a fall of sixty degrees at Keokuk, Iowa, the center of the cold wave, the temperature which was 60 deg. on the morning of Feb. 16, being zero the next day.

A theoretical treatment of the motions of the air involved in cold wave production is entirely out of the question in present state of the science of physics. The areas of high and low pressure that traverse the earth are probably connected in some way, as yet unknown, with the general circulation of the whole atmosphere. At the equator the air is heated more than at the pole, and, being expanded, it rises higher in the upper level in the upper layers. There is a continual flow of the upper air from the equator toward the poles, deflected to the right by the rotation of the earth.

In the northern hemisphere outside of the zone of trade winds there is a general motion of the air from west to east around the earth, resulting in a more or less permanent area of low pressure over the North Atlantic Ocean. In this region there are three centers where the low pressures are variously developed at different times: one near Davis Straits, longitude 60 deg. west; one south of Iceland 26 deg. west, and the other near the White Sea, north of Russia, 40 deg. east. The greater or less development of low-pressure area near these places in winter has an important bearing on the occurrence of cold weather in Europe. Low temperatures occur differently in Europe and the United States. In Europe the change mostly advances from the east toward the west and is slow and gradual. In the United States the change is almost always from the north and west towards the south and east.—*Engineering Magazine.*

Early Steel.

The Chinese, who in very early ages, had attained to some degree of understanding in the elementary principles of science and their applications, possessed also a comparatively advanced amount of knowledge in the manufacture and use of steel. Of its origin among them we have no account; but it is quite conceivable that its discovery preceded that of the lodestone, which under the name of Tche shih (direction stone), was in use among them fully 2,600 B. C. There is mention of steel in very ancient Chinese writings, and on account of the process of manufacture by one writer about 400 B. C.; and various descriptive illusions to it, implying a considerable amount of knowledge and power of discrimination in reference to its properties, occur at various subsequent periods down to the present day, when it is still a flourishing branch of their manufacture.

Inferentially, it is perfectly clear that the Phenicians were acquainted with the use of extremely hardened iron (properly speaking, steel), as their numerous and beautiful works in ornamental metallurgy, and the cutting and engravings of precious stones, for which they were conspicuously eminent among the nations of antiquity, necessarily involved, as also do the inscriptions which exist in the Phoenician language. Phoenicia, as represented by its famous daughter City of Tyre, was at the height of artistic celebrity in the time of David and Solomon (1050-1000 B. C.) With them, as powerful neighboring monarchs, Hiram, the ambitious young King of Tyre, found it wise to enter into a friendly alliance, and concluded an arrangement which proved to be for the mutual advantage of both communities, in the numerous works of art and value, especially in metallurgy, executed by his trained artificers for the furnishing and enrichment of the temple, capital, and palace at Jerusalem.—*Chambers' Journal.*

A Large Wire Rope.

At the Globe Works, Bankhall, Liverpool, there is in course of manufacture one of the largest steel wire cables that has been made in this country. When completed it will be three and a-half miles in one continuous length without a joint or splice, and will weigh about twenty tons. It is 3½ in. in circumference, made from the finest quality of patent crucible steel wire, and having a tensile guaranteed strain of over 40 tons. Some idea may be formed of the immense amount of labor required for the manipulation of an order of this kind, when it is mentioned that the total length of wire in the cable would measure something over 300 miles. The machinery employed by Messrs. W. B. Brown & Co., for this heavy work is of special design.—*National Labor Tribune, England.*

Evolution of Inventions.

A new departure will be made by the patent office at the World's Fair in Chicago. Hitherto it has never attempted to go beyond an exhibition of photographs and drawings. In this instance it will offer an elaborate and comprehensive display of models. The show will be designed to illustrate as completely and as vividly as possible the age of mechanical civilization. It will give in concrete form a picture of the progress of invention.

The Commissioner of Patents says that the great exhibit of the Patent Office will not be displayed. All that will be attempted in the show proper of his bureau will be to illustrate the processes through which those achievements have been perfected. For this purpose groups of models will be prepared. For example, one group will represent the progress of the steam engine beginning with the first one, which was built one hundred and fifty years before Christ, by a Greek named Hero. It had a boiler, and was able to do work by means of a shaft and belt attachment. From this primitive contrivance to the modern Corliss engine, in miniature, an interesting series will extend.

Other groups will be similarly arranged. One will represent the printing press, all the way from Guttenburg's original invention to the rotary Hoe machine, which turns out newspapers at the rate of many thousands per hour and folds them ready for delivery. In electricity wonders of all sorts will be illustrated by progressive series. There will be telephones running all the way from the primitive conception to the perfected instrument now in use. The telegraph will be introduced with the actual instrument made by Morse, by which the first experimental messages were sent over the wire from Washington to Baltimore, this line of discovery culminating with the latest devices for printing messages at any distance with type and transmitting one's own handwriting across thousands of miles of space in a fraction of a second. The growth of the locomotive will be shown in like manner; also that of the sewing machine; of the marvelous modern agricultural implements from primitive types; of clocks, from the water clock of ancient Babylon and the later hour-glass, etc.

Many of the models required for these groups are already in the possession of the Patent Office, but a large number will have to be constructed especially for the purpose. Manufacturers all over the country will be asked to supply specimens of their products for representing the latest developments of inventive art. The locomotive works will be requested to lend miniature models of their newest engines. Makers of agricultural tools and sewing machines will contribute the most improved specimens of their handiwork. Likewise with printing presses and everything else. Few, if any, of the mechanical models will be set working, however.—*Washington Star.*

Wire-Wound Guns.

The idea of making wire-wound guns first occurred to an American by the name of Dr. Woodbridge, as far back as 1850. Ever since that time a number of ordinance and artillery officers have believed that the wire gun will be the great artillery weapon of the future. Hence it is not surprising that numerous attempts have been made both in this country and in Europe to invent a system of wire gun construction which would give better results than the system of the built-up steel rifle. These attempts, however, have been unsuccessful, and not one of the wire-wound guns made up to this day has offered such advantages as to justify so great a change in gun construction.

The ideal cannon of the future, no matter whether it is a wire-wound or any other kind of gun, must be both a military and economical success. This at once shows the requirements which the cannon of the future must meet, namely: It should be able to withstand a higher powder pressure, and thus give a greater initial velocity and consequently a greater penetrating power to the missile; it should be lighter in weight, cost less money, save time in construction, while the material used should retain its commercial value after the gun is no longer serviceable. High as these requirements may seem, all of them are essential in order to justify a change in the present methods of ordinance construction.

The Brown segmental gun, the invention of John Hamilton Brown, seems to fulfill these conditions. Lieutenant G. N. Whistler's "Theoretical Discussion" of this system of gun construction has been assailed by many, including the writer of this article, but has not yet been disproved. In this meritorious paper, Whistler theoretically proved that the Brown segmental wire gun is possible, and also that it meets all the above mentioned requirements of the gun of the future. All that remained to be seen was whether the inventor and the constructor of the gun would be able to carry out practically their theoretical propositions. This has now been done, though most ordinance experts ridiculed the idea of a segmental wire-wound gun. Among the many reasons of the opposition it was claimed that, since the segmental core of a gun in itself has no circumferential strength, it was therefore a mistake at the very start to choose segments instead of a solid core. The recent successful test at Birdsborough of the powder chamber of the new 5-inch segmental gun which is now being constructed at that place for the United States Government, under the supervision of Lieutenant Whistler, settles definitely and conclusively the strength of the Brown system of wire-gun manufacture. This test was anxiously anticipated by many experts, as it was known that both the inventor and the constructor of the gun had been experimenting for more than two years in order to find the best methods of construction.

The Training of Mechanics.

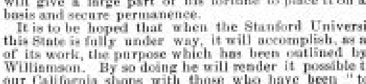
The lack of thoroughly trained artisans in the various trades is one of the greatest drawbacks on the progress of American industry. We have very few apprentices nowadays. Boys usually "pick up" trades. Not one in a hundred of our alleged "masters" of trades of American birth has had any systematic instruction. The most of our best trained mechanics are of foreign birth and learned their trades in foreign shops. The "ironclad" rules of the "Trades Unions" render it impossible for any considerable number of our American boys to learn trades in regular shops. The result of this has been to create a wide demand that the deficiency be made up by training boys in the rudiments of mechanics in the common schools; and there have sprung into existence many college annexes, where the scientific principles of physics are taught in connection with the practical application.

Every section of the country ought to encourage every movement intended to train our youth in handicraft, and every large city in the Union ought to have one or more echnological schools similar to the Sheffield annex at Yale, and the scientific and practical schools at Cambridge, that are under the control of Harvard.

A contemporary, in alluding to this matter, makes reference to the munificent bequest of Mr. I. V. Williamson, a wealthy philanthropist of Philadelphia who has determined to found a free school for the training of boys in all branches of mechanical business. He will put into the enterprise at the start $2,500,000 or $3,000,000, and if the school meets his expectations, or comes near doing so, he will liberally extend and endow it by donations in his will.

Mr. Williamson's plan is not to establish a "Manual Training School" as that term is generally understood and as it is exemplified in many of our public school systems. Such "training schools" come very short of the requirements necessary to turn out such workmen as are sought for and must be had in order to carry on in a successful manner the great workshops of the present day, which are so immensurably in advance of similar establishments as they existed fifty years ago. The intention of Mr. Williamson is to teach boys thoroughly in the mechanical trades, in order that when they enter upon life they may be able at once to secure employment. He deprecates the tendency of the day to despise hard labor, and thinks that the condition of the laboring class will be immeasurably improved if the workmen are bred up from boyhood to take pleasure and satisfaction in their work. It is with this view that he will establish his school, and the common belief is that he will give a large part of his fortune to place it on a firm basis and secure permanence.

It is to be hoped that when the Stanford University of this State is fully under way, it will accomplish, as a part of its work, the purpose which has been outlined by Mr. Williamson. By so doing he will render it possible to fill our California shops with those who have been "to the manor born," and make useful to themselves and the State thousands who would, under the present condition of things, become a burden to themselves and a possible detriment to the public.—*Mining and Scientific Press.*



The Allied Powers.

Under the above suggestive title, Mr. D. Ashworth, at the Buffalo Convention, discussed the closely interwoven relations of steam and electricity. We do not believe that our friends who have devoted themselves for years past to steam engineering, half begin to realize the actual importance of electricity as a co-worker with steam in the arts and industries of the future. Some of the more far-seeing and enterprising of them do perceive the real state of the case, and are moving to meet the growing demands of the electrical service. It is not to be supposed that the development of electricity as a motive power is as yet commensurate with that of steam, but it is rapidly becoming so, and it does not require a strong prophetic vision to anticipate the time when there will be a hundred electric motors where there is one steam engine; or, if that be an unfair basis of comparison, when nineteen-twentieths of the power plants for which steam is now utilized will be operated through electric generators and motors, and when the application of power for manufacturing purposes will be enormously extended by reason of the superior facility with which electricity adapts itself to the needs of the situation. It is the manifest destiny of the steam engine to be the handmaid of the electric generator in the application of power. To this end more attention should be given to the mutual adaptations of the two machines, from the point of view that electricity is not a rival of steam, but that the two are allied powers whose combined forces are capable of conquering territory which neither could alone put under subjection.—*Electrical Progress.*

The Relation of Electricity to Mechanics.

Electricity may, and is certain to revolutionize many of the industrial methods and conditions of life and have a powerful effect on all. Yet, howsoever great this effect may be, it can but intensify and make more certain our dependence on machinery. Electricity, the great revolutionizer, banding together for instant communication the utmost parts of the earth; transmitting at our pleasure speech, light, heat, or power. In the hands of the physician or surgeon, a gentle messenger of mercy; in those of the executioner, an avenger. Most simple of all power in its practical application; most wonderful in the diversity of its uses; most mysterious in its methods of operation; who can but watch with an absorbing interest its development in the service of man, fascinated by its mystery and marvelous works; already exerting an influence in industrial affairs little realized, except by a few. Yet this influence only faintly foreshadowing that of the near future.—*The Northwestern Mechanic.*

Electricity on the Railroad.

We have already, in previous issues, alluded to the new possibilities of what electricity may shortly accomplish in the way of displacing steam on our great railroads. There is only one man in the world whose opinion would be accepted for what he promises in the near future. That man is Thomas A. Edison. Mr. Edison, in speaking of electricity displacing steam, says: "It will displace it, if economy as well as speed and safety, is a factor of locomotion, not because it will make easily a speed of 100 miles an hour, while steam strains itself to make 60, but because it will get one-horse power out of from one to two pounds of cheap coal (water power), while out of six pounds of dear coal a locomotive engine can only get that same one-horse power. It will displace it because it will be cheaper."

Thus this greatest of inventors unhesitatingly announces the early ending of the present era of steam, and the birth of the new and improved, but not yet perfected era of electricity.

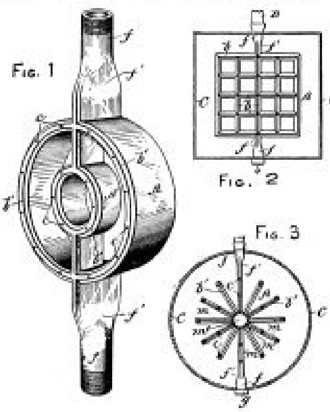
It is expected that the first authoritatively practical evidence of its wonderful achievement will be made at the Columbian Exhibition in Chicago—a most appropriate beginning of a new era of progress at the ending of the first 400 years of any real industrial progress which the world has ever made.

Mr. Edison declines to go into full details of all that he has in hand at this time, as he has not secured European protection and possibly has not fully perfected all his details in regard to moving overland trains. "But," he says, "I will say briefly that the current will pass from the stationary engine to a central rail between the tracks, thence through the mechanism attached to the bottom of the cars or motor (a freight train, of course, would need a motor, because of the number of cars, although a single passenger car could be run, carrying its own motor beneath it), thence to the wheels and thence back by the side rails to the power house or stationary engine. Three of these stationary engines with a horse power of 10,000 or 12,000 each would run the whole Pennsylvania Railroad system between Chicago and Philadelphia; freight, local, express trains, and all, at a great reduction of expense."

In alluding to this street car problem, Mr. Edison illustrates his low power system, which makes the transmission safe and at the same time all powerful, as follows: "You see I employ the heavy current with the low pressure. That is the whole secret of safety. The principle is this, that a stream of water 100 feet wide, which falls a foot, gives the same power as a stream one foot wide which falls 100 feet. The wide stream is my way, the high fall some other people's and the allowance of such pressures in public streets as some that are used, is like letting a man place a boiler in a vault under a street and put on 1,000 pounds of steam if he wants to do so. Electricity has developed too fast, you see, for the law to keep up with it. The whole question is one of expense. A low pressure trolley wire, for instance, occupies four times as much copper as a high pressure one. This system is the cheapest known and does not cost half as much as the cable.

STEAM JET BLOWER.

No. 467,427. WILLIAM MCCLAVE, SCRANTON, PA. *Patented January 19, 1892.* Fig. 1, is a perspective view of the blower as commonly made for operating in a conical pipe, which leads into the space below the grates of furnaces. Steam is taken in at one of the vertical ends *f*, and the other end is covered by a screw cap, which is removed whenever it is desired to blow steam through the device to remove rust, dirt, or sediment that may have lodged in the passages. All the passage-ways are flattened as much as



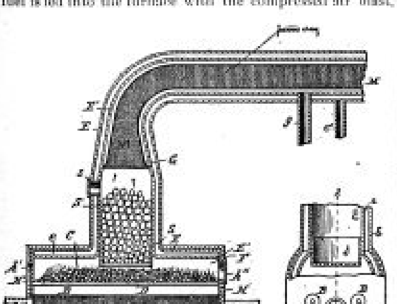
possible, and the edges are made V-shaped, so as to reduce the obstruction offered by them to the passage of air, to the least practicable amount. The jet holes *c* are drilled in the front edge of the passage-ways as shown.

Fig 2 shows a blower made on a rectangular plan to suit large square air flues, and Fig. 3 shows a construction in which the passage ways all radiate from a central hub. These blowers can also be used for exhausting, ventilation, etc.

GAS PRODUCER.

No. 466,603. CHARLES FIESSE, NEW YORK, N. Y. *Patented January 5, 1892.* This apparatus is designed to make fuel gas composed mainly of hydrogen and carbon monoxide, and to separate the two gases as far as possible. A fire is made on a grate D, of coal dust balls, coal, or coke. Above this fire is a pot S having a perforated bottom, and which is filled with broken stone, or clay, and oxide of iron, to serve as a strainer and purifier of the gases passing through. A pipe M made of porous material conducts the gas away. The furnace E^1 is jacketed by a shell E, and all the air used is drawn through this jacket by a fan so as to save the heat radiated from the furnace walls. The fuel which may be coal dust, or poorer stuff loaded with Lima oil or other hydro-carbons, is blown in through the pipe A below the grate D. Steam is blown in by means of porous pipes B. The operation is as follows: The bed of coal dust balls, charcoal, or coke on the grate D is blown up to a state of incandescence by a forced draft.

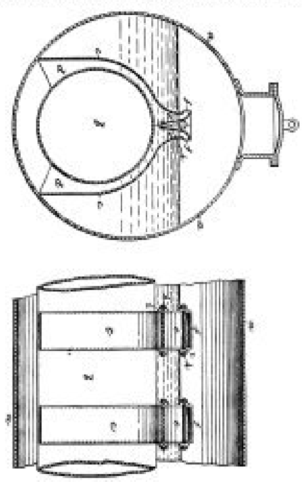
After the fuel is sufficiently incandescent, the pulverized fuel is fed into the furnace with the compressed air blast,



through A. Entering into the furnace the compressed air blast, loaded with pulverized fuel, diffuses itself all around the outlet, thus avoiding any destructive effects of the blast, and is ignited. The pulverized fuel burns out very fast in producing carbonic acid. By rising up through the bed of glowing fuel in the upper part of the furnace the carbonic acid takes up another atom of carbon, which converts it into carbonic oxide. After a run of about five minutes the blower is stopped. Then the steam is introduced into the porous cylinders B by means of the pipe *b*. The radiation of the heat in the lower part of the furnace having highly heated the porous cylinders B, it follows that said steam is readily superheated and passes through the pores of the pipes B nearly dissociated. In rising through the bed of glowing fuel the oxygen of the steam will combine with the carbon of the fuel, because of the high temperature and volatilization of the carbon in the furnace. Carbonic oxide will thus be produced and the hydrogen of the steam liberated. The transformation of the carbonic acid into carbonic oxide and the decomposition of steam to form carbonic oxide and hydrogen, said transformation and decomposition taking place in alternate runs of about five minutes each, the furnace being fed with pulverized fuel in the first run and with steam in the following run, will give off a great and even flow of gases, in which the nitrogen of the air, the only non-combustible element, will amount to less than thirty-five per cent. of the whole product. The heated air passing up through the space *e* can be drawn off through pipe e^{11} by a suitable exhauster and used for heating purposes, or as a hot blast to aid in the combustion of the gases generated by the apparatus. The gases generated in the furnace pass up through the pipe M. This pipe being porous, the hydrogen passes more freely through its pores than the heavier gases by reason of its feeble density, and by osmosis, and by the action of a suitable exhauster fixed to the pipe *g*. The gases collected in the annular space G, have therefore a higher percentage of hydrogen than those remaining in the pipe M and can be drawn off through pipe *g* and burned or stored separately from the gases delivered by pipe M. The heavier gases pass on through a metallic extension of the pipe M (not shown), and may be burned in any suitable apparatus or stored up for future use.

STEAM BOILER.

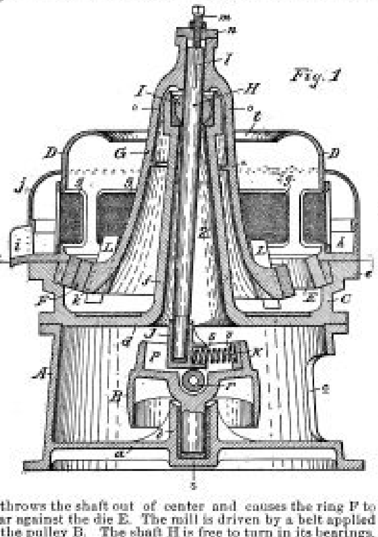
No. 440,780. JOHN GAMGEE, LONDON, ENG. *Patented Jan. 17, 1892.* This invention applies to boilers having one or more internal flues, and consists of tubes designed to regulate and assist circulation. The tubes *c* are made in sections which are bolted together as shown, upon the flue. Each piece is made of such a size that it can be taken in through the manhole and be applied to boilers already in



use. The tubes terminate in two spouts *f*, which shoot the mingled water and steam horizontally, thus liberating the steam from the water very thoroughly. The water passes down between the successive pairs of tubes and comes in again under the bottom ends *d*, to repeat the movement. A slight modification enables the tubes to be applied to boilers having two flues.

PULVERIZING MILL.

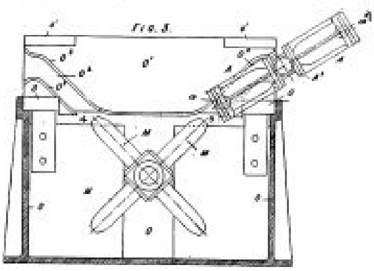
No. 466,864. EMORY I. NICHOLS, SAN FRANCISCO, CAL. *Patented Jan. 12, 1892.* The grinding is done between the roller edge F and the die E. The body or hub G of the roller is made bell-shaped as shown, and is keyed to the top end of the shaft H. The shaft turns and swivels in the ball bearing I, which is supported in the top of the cone 2. The cone is attached to or is cast in one piece with the pan C. The lower end of the shaft turns in a box J, which moves in an oblong slot *p*, formed by flanges cast on the top side of the driving pulley B. The weight of the box, with the shaft H, and roller G and F, is borne by the roller *r*, and the spring

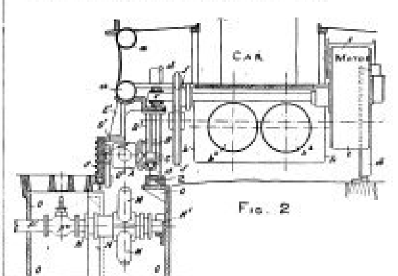


K throws the shaft out of center and causes the ring F to bear against the die E. The mill is driven by a belt applied to the pulley B. The shaft H is free to turn in its bearings, and as the driving pulley revolves, the roller turns on its axis, at the same time that it rolls around on the inner face of the die E. Scrapers L serve to stir up the pulp in the bottom of the pan, and also to throw the dust against the screens *g*. All that passes the screens falls in the circular chamber *h*, and is washed out at the spout *i*. Centrifugal force also assists to keep the roller edge in good contact with the die.

PROPULSION OF CARS BY COMPRESSED AIR.

No. 466,415. JOHN HUGHES, CHESTER, ENGLAND. *Patented Jan. 5, 1892.* In this system, compressed air is conveyed in pipes below the surface of the ground, and along the track, either between the rails or along one side, as shown in the drawings. Each car is provided with tanks b^2 as large as practicable, to store up air and thus obviate the necessity of too many charging stations. Each car carries an automatic apparatus which makes a connection between the air main and the tanks on the car, every time it passes a charging station, without stopping the car. Fig. 2 shows a cross-section of a car and a charging station. The car is provided with a double-ended sleeve or socket A, shown clearly in Fig. 3, which turns on the end of a pipe A^1 which goes to the tanks b^2. The air main P^1 runs into the box O, which is sunk in the ground alongside of the rail 2. The end of the air pipe carries a four armed nozzle M, which is free to turn on the pipe, and is provided with stuffing-boxes to prevent leakage as shown. Holes are provided in the end of the air pipe, marked N^1, upon which the nozzle turns, and corresponding holes are made in the hub of the nozzle in such position that no air will pass through while the nozzle stands in the position shown, but will pass air freely into the branch which is passing

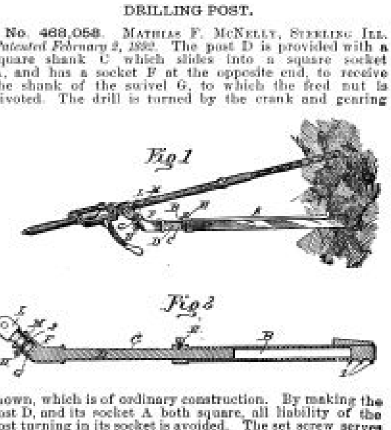




between 3 and 4. The box O is provided with a hinged cover O^1 which ordinarily lays down and covers the nozzle M. The car is provided with a kind of plow-bar D^1, which the motorman lowers by suitable levers, which catches the beveled end of this cover and turns it up vertically, as shown in Fig. 2. The under side of the cover is provided with grooves O^2 (see Fig. 3) which engage roller-pins a^1 at either end of the sleeve A, and guide the sleeve onto the nozzle M. The sleeve A is carried by a strong bracket B on the frame of the car, and as the car continues to move, the sleeve A and the nozzle M turn together on their bearings, and air passes from the mains into the tanks while they are turning. The groove at the other end of the cover guides the sleeve properly out of the box, and both A and M are left in position for future operation. The connection between the sleeve A and the nozzle M is made tight by large cup leathers in the end of the sleeve. Each half of the sleeve contains a check-valve to prevent back flow of the air in the tanks. The motor is a rotary engine. If the tanks are exhausted, the motor man can stop his car over the box and get as much air as he wants; or if he is running down grade and does not need any air, by holding up his plow-bar he can skip as many boxes or charging stations as he wants to.

DRILLING POST.

No. 468,058. MATHIAS F. MCNELLY, STERLING ILL. *Patented February 2, 1892.* The post D is provided with a square shank C which slides into a square socket A, and has a socket F at the opposite end, to receive the shank of the swivel G, to which the feed nut is pivoted. The drill is turned by the crank and gearing



shown, which is of ordinary construction. By making the post D, and its socket A both square, all liability of the post turning in its socket is avoided. The set screw serves to adjust the length of the post to the length of the auger, and the swivel G permits the drilling to be done in any direction.

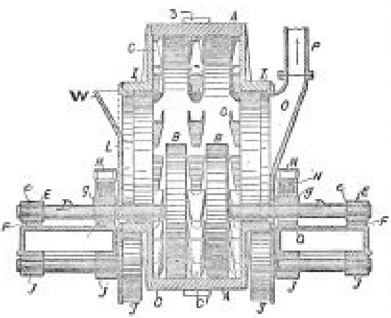
GRINDING MILL.

No. 467,368. William H. Coward, Bath, England. *Patented January 19, 1892.* A is the drum, revolved on a horizontal axis by peripheral spur-gear 3.

B are two sets of edge runners rolling upon paths side by side within the drum, and guided, so that bodily motion of the roller is permitted only up or down.

C C^2 are sets of elevating-cups fixed near the periphery of the drum, their mouths being in the direction of rotation of the drum, in order to catch the material after it has been crushed and carry it up and throw it down again in front of the edge runners, and at the same time expose it to the winnowing action of the air current.

Each edge runner B is fixed to the end of the shaft D, which passes out of the drum through a large circular opening in the side, and is journaled at its outer end in a swivel bearing E, which has lateral gudgeons *e*, pivoted in a rigid bracket F. So that while the edge runner and shaft are free to revolve the edge runner is prevented from deviating from its path, but is free to rise and fall on passing over the roughly-broken material, the slight lateral motion of the edge runner due to angular motion about the axis *e* of the



swivel-bearing E having the effect of supplementing the crushing action of the edge runner by an abrasive or rubbing action between the edge runner and the drum, which conduces to the more rapid reduction of the material. Each shaft D is guided by a bearing *g*, free to rise and fall in guides G, and pressed upon by an adjustably-weighted lever or by a spring H, regulated by screws *h*, in order to increase the crushing power of the edge runner.

The openings at the two sides of the drum are closed by stationary covers L, fitting within the surrounding flanges I, which are cradled upon sets of friction-rollers J, carried by shafts turning in bearings *j* on the bed-plate, the drum being thus wholly supported on the two sets of friction-rollers. The drum has three sets of elevating-cups—a set C, fixed to each side of the drum, as before, and a middle set C^2, fixed to the periphery of the drum and passing between the two sets of edge runners, the cups C^2 being larger than the cups C.

The cover L at one side of the drum is provided with a feed-hopper M, while the other cover N has an aperture at the upper part leading through an upwardly extending and gradually-contracted spout O into a vertical pipe P, which is carried up to a suitable height and then connected to an exhaust-fan. The current of air passing up this flue carries away the finely ground material, and no screens are needed.

ORE FEEDER.

No. 466,881. John R. Russell, San Francisco, Cal. *Patented January 12, 1892.* This apparatus is designed to feed ore into the mortar of a stamp battery, and is operated by the tappet on the stamp stem. The ore is placed in the hopper C and is fed down into the barrel B. The shaft D carries an oblique disc E, which operates at each rotation to push the ore forward toward the mouth of the barrel B. The front end of the shaft carries a spider F having suitable

Fig. 1.

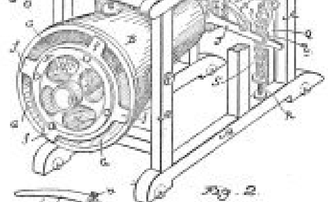


Fig. 2.

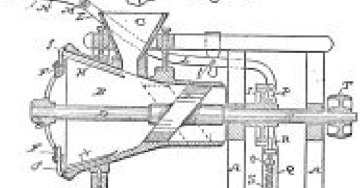
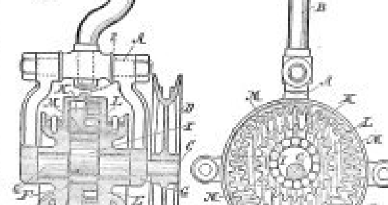


openings for the escape of the ore. When the ore is pasty or sticky, curved scraper arms H are attached to the spider to assist the delivery of the ore. The shaft D is rotated by a pawl K and ratchet wheel I. The pawl lever J is worked by the levers L, which are united at the front by the rod M. A toe or arm N is adjusted on this rod so as to follow the tappet on the stamp stem O, up and down continuously. The rotation of the feeding device depends upon the amount of motion given to the arm N by the tappet, consequently the feed is automatically adjusted to the stroke of the stamp and the condition of the mortar, feeding slowly when it is full, and fast when it is empty. The spring S compels the arm N to bear against the tappet at all times, and there is none of the jarring and racking of the feeder common to machines of this class in which the tappet strikes the feeding mechanism.

DIFFERENTIAL HOIST.

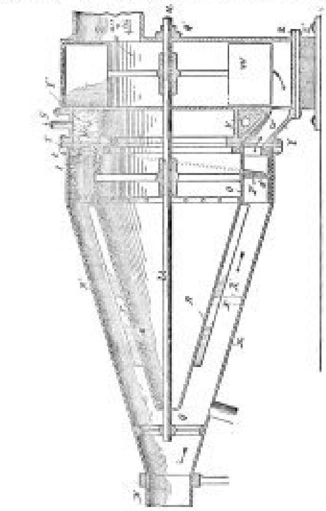
No. 467,513. Edward Y. Moore, Milwaukee, Wis. *Patented January 26, 1892.* This hoist consists of two chain wheels E and F, each of which has an internal spur gear E^2 and F^2 cast on one side, and a double spur pinion L and K which meshes with them. The chain wheels turn on bearings G which are made solid with the side frames A. The double gear L K turns on the eccentric I, running on the rollers M. The eccentric is keyed on the shaft C which runs through the bearings G, and carries the wheel D for the operating or hand chain. The hoisting chain H is double, both ends being attached to the hook; and it is so reeved that the load is suspended from both chain wheels, on one side of E, and on the opposite side of F. By this arrangement all tendency to run down is avoided. As the eccentric is revolved by the hand chain and wheel D, the gears L and K are compelled to mesh with all the teeth in the rims E^2 and F^2 at each revolution. L has 22 teeth, E^2 28, K



32 and F^2 has 38 teeth. In rolling once around the rim F^2, K makes 1[illegible] revolutions, as does L also. But the number of teeth in L multiplied by 1[illegible] = 30[illegible] teeth. The rim E^2 contains only 28 teeth, and consequently it is compelled to forge ahead 2[illegible] teeth at each revolution of the eccentric. This causes the chain wheels E and F to slowly revolve in opposite directions, but as the hoisting chain H hangs one strand on sheave E and the other on the opposite side of F, it follows that both strands go up or down together. As both sheaves are loose on their bearings they readily adjust themselves to the inequality in the motion of the two strands. Two separate chains may be employed—having hooks at each end—thus having one hook always down ready for use. The ratio between the gears employed may be varied to any extent, to secure any desired proportion between the load to be lifted and the pull required on the hand chain. Being composed wholly of spur gearing there is a minimum loss from friction.

BLOWER FOR PULVERIZED FUEL.

No. 466,603. Charles Fiesse, New York, N. Y. *Patented January 5, 1892.* The shaft U is horizontal and is turned by a belt and pulley not shown. It carries a fan wheel W, a drum O, O^1, having a spiral blade P between the rims, and a long conical drum R having a number of vanes *r* on its outer surface. Between the fan-wheel W and the drum O, a water block Y, Y^1, is provided, through which water can be circulated to keep the parts from getting too hot. The fuel which is pulverized is fed in through



the pipe 2 along with the air for burning it and is driven by the fan-wheel through the passage n^1 into the spiral passage formed by the blade P between the rims O, O^1. This spiral serves to make the delivery of the fuel uniform, and corrects the irregularity of the first feeding into the pipe 2. The mingled air and fuel passes onward over the drum R and out by the pipe N to the furnace. The air used is preferably heated as highly as possible in a regenerator connected to the furnace to which the fuel is supplied, thus securing a high degree of economy, and making it practicable to use a very low grade of fuel.

SAFETY LAMP.

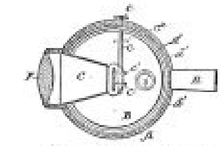
No. 467,193. George T. Parry, Philadelphia, Pa. *Patented January 19, 1892.* The case A is provided on its bottom plate with feet *a*, on which rests an ordinary lamp B, around which air can pass to the flame, and which is provided with a filling hole *b* and a ratchet-wheel shaft *c*, with ratchets c^1 to raise or lower the wick. The shaft *c* may be adjusted from the outside by a button c^2 on its end or on the inside of the lamp-case by a button c^3, located as indicated by dotted lines.

To the case section A an upper metal case section A^1 is screwed fast at *d*, as shown, making with an india rubber washer d^1 an air tight joint or connection.

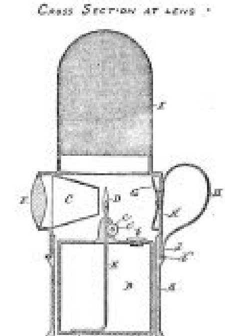
C represents a conical tube arranged in the front part of the section A^1 of the metal case and firmly secured therein in any suitable manner. The small end of this tube extends nearly to the flame D of the wick E and serves for concentrating the light from flame D.

In the front end of the tube C, a bull's eye F is placed, as shown. By means of the tube C the concentrated light is, thrown upon the bull's-eye in such a manner as to secure a brilliant illumination in the mine, a result that would not be accomplished without this tube in so perfect and effective a manner. Behind the flame D a reflector G may be arranged, the same being fastened to the metal case A^1.

Outside of the section A^1, at the rear of the lamp, a loop-handle H is provided. The upper part of the lamp above the case section A^1 is, as usual, formed of wire-gauze I which is fastened by its lower edge to the upper edge of



Cross Section at Lens.



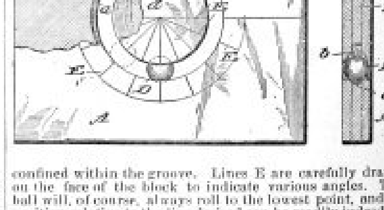
the section A^1, as shown. In the bottom of the section A a draft opening J is provided, and this opening is covered with wire gauze K of about the same mesh as the wire-gauze I. Under this construction in order to fill the lamp at the opening *b* the sections A^1 A^2 are separated by unscrewing the same at *d*.

It will be seen that all parts of the case containing the lamp are air-tight, excepting the wire-gauze I and the draft opening J, covered by the wire-gauze K. It will also be seen that the flame D from the lamp B will light up the safety covering gauze I the same as in the ordinary Davy lamp, while the projection of light from the bull's-eye F will be a bright and steady light for aiding workmen in their operations in the mine.

It will be further seen that the outer case of this lamp is constructed to form a chamber in which a reservoir lamp is placed, and that the reservoir lamp is a distinct structure from the case, and when placed within the case it is surrounded on all sides and at bottom by a large air space, through which air circulates for promoting combustion at the wick, and thus cools the body of the lamp.

PLUMB AND LEVEL.

No. 466,380. Newel H. Spencer, Elmira, N. Y. *Patented January 5, 1892.* This device is intended for attachment to straight edges or squares or other tools, or it may be constructed within the body of such tools. It consists of a block of metal having a circular groove accurately formed about the center *d*, and a ball of accurate shape which is



confined within the groove. Lines E are carefully drawn on the face of the block to indicate various angles. The ball will, of course, always roll to the lowest point, and its position relative to the line desired can be readily judged by the eye, quite as easily as the bubble in an ordinary spirit level can be centered; with the additional advantage that the ball will indicate as many different angles as there are lines E drawn upon the face of the instrument.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 10. SCRANTON, PA., MAY, 1892. WITH WHICH IS COMBINED THE MINING HERALD

THE ECONOMIC GEOLOGY OF COPPER.

The Mineralogy, Mode of Occurrence, and Production of Copper.

BY H. A. WHEELER, E. M., OF ST. LOUIS.

The number of copper-bearing minerals is very large, most of which have a green color, but until the opening up of the large deposits in Arizona and Montana within the last fifteen years, there were only two that were found in sufficient quantity in this country as to be of much importance as ores, or the native and "yellow-copper." Since the Far Western mines have become such heavy copper producers from the oxides, carbonates, silicate, and black sulphides, the number of important copper ores has considerably increased, so that it will be necessary to consider all of the following as now being of commercial importance.

Native Copper, as its name implies, is pure copper, which occurs naturally in very large quantities at Lake Superior, and in very small quantities, as mere specimens usually, at or near the outcrop of nearly every copper bearing vein. If untarnished, it has the characteristic copper red color, is very tough and malleable, rather soft, and very heavy (specific gravity is 8·9).

Chalcopyrite, or "Copper Pyrites," or "Yellow Copper Ore" is a sulphide of copper and iron, consisting of about equal parts of copper, iron, and sulphur. It is the most abundant ore of copper, and on account of its bright, metallic luster and brass-yellow color, it is very easily recognized. It is somewhat hard, rather heavy specific gravity is 4·2), gives a greenish-black streak, and is very brittle, by which it is quickly distinguished from native gold, which it resembles in color and for which it is occasionally mistaken.

Bornite, or Erubescite, or "Purple Copper Ore," or "Peacock Ore," is a sulphide of copper and iron that contains a variable amount of copper ranging from 50 to 70 per cent. It has a bright metallic luster, varies in color from purple to brown to bluish black, usually has a variegated tarnish and gives a black streak. It is rather soft, quite heavy (specific gravity is 4·4 to 5·0) and not very brittle.

Chalcocite, or "Copper-glance," is a black sulphide of copper that contains 80% of metal. It has a dull metallic luster, while the color and streak are black to lead-gray. It is quite soft, very heavy (specific gravity is 5·7), and is slightly sectile or is tough enough to be cut into small shavings.

Cuprite, or "Red Copper Ore," is the red oxide of copper and contane about 89% of copper. It has a non-metallic luster, varies from bright red to very dark red in color, and gives a brownish-red streak. It is rather hard, very heavy (specific gravity is 6), and very brittle.

Melaconite, or "Black Copper Ore," is the black oxide of copper and contains about 80% of copper. It has an earthy luster, a dark-brown to black color, and gives a black streak. It is usually very soft, very heavy (specific gravity is 6·2,) and very brittle.

Azurite is the blue hydrous carbonate of copper, and contains about 55% of copper. It has a non-metallic, vitreous to earthy luster, a deep blue color, and gives a pale blue streak. It is rather hard, not heavy (specific gravity is 3·7) and is very brittle.

Malachite is the green hydrous carbonate of copper, and contains about 57% of the metal. It has a non-metallic, silky to vitreous luster, light to dark green color, and gives a pale green streak. It is rather hard, not heavy (specific gravity is 3·8) and is very brittle. The compact varieties take a fine polish and are highly prized for ornamental purposes as a semi-precious stone.

Chrysocolla is a hydrous silicate of copper that varies considerably in its composition, ranging from 22 to 36% in copper. It has a non-metallic, vitreous lustre, varies from blue to green in color and gives a white streak. It is somewhat hard, very light (specific gravity is 2·2) and usually very brittle. It is very common, as a green wash or staining, along the outcrop of copper bearing veins, but seldom occurs in sufficient quantity to be of value as an ore, and it is an expensive ore to smelt on account of its low grade and high silica. It has deceived many a prospector by the conspicuous way in which it will make a great showing on the surface, but on assaying the green stained rocks they are usually found to be too poor to work.

Chalcanthite is the hydrous sulphate of copper or is the same as blue-vitriol. It is not often found as a vitreous, blue, soft solid, but frequently occurs in solution in the waters of old copper mines, from which it often pays to extract the copper by means of scrap-iron, on to which the copper is thrown down on prolonged standing. It is this mineral that gives the highly nauseating, metallic taste to the drainage from copper mines and causes the miners to break out in pimples and sores from the poisonous action of such waters when in contact with the skin.

Tetrahedrite, or "gray-copper," is a sulphide of copper and antimony that may contain as high as 42% of copper. It has a bright metallic luster, a steel-gray color, and gives a dark red to gray streak. It is rather hard, quite heavy, (specific gravity is 4·8), and is very brittle. It seldom occurs in large quantities and makes a very inferior quality of copper on account of the antimony it contains, but it so frequently carries silver as to often be a very valuable silver ore.

All the copper minerals are frequently found to contain paying amounts of gold and silver, and should always be assayed for the precious metals, which are rarely entirely absent, though in undisturbed regions the amount of the precious metals is usually too small to pay to extract.

In considering the deposits of copper, the most unique in character thus far found in the world, as well as of the greatest importance in regard to quality, are the famous deposits of the Lake Superior region, where all the copper is mined in the native or metallic condition. Native copper occurs in at least specimen quantities in many other places, and at Santa Rita, New Mexico, and some parts of Arizona, in even appreciable amounts; but thus far such natural occurrences of the metal elsewhere have never held out to any depth or been of much commercial importance. But the entire heavy output of the Lake Superior district is obtained exclusively from this ore, and it is found to be of exceptional purity, which is so important for the enormous electrical demand that has recently sprung up. Other ores of copper have been found in the Lake Superior district, but thus far in such small amounts as to be of no commercial value, and the profitable mines have all been opened on only the native copper veins. Another interesting feature about the copper lodes of Lake Superior is the fact that they are so low grade, as with one exception the average yield does not exceed 2%, and in one case a mine has paid regular dividends from an ore that yields only three-quarters of one per cent. of copper. Omitting the one lode that carries from 3 to 5% (the Calumet and Hecla), the Lake Superior copper companies are working lower grade ores than are worked any where else in the world. The uniqueness of the deposits, the permanence of the lodes, and the important position that "Lake" copper commands in the world's copper market, which until recently was the heaviest output from any one district, entitles this region to special consideration.

The present history of the Lake Superior copper region dates from the year 1845, when it made its first appearance in the copper market with an insignificant output, at a time when our country was producing a small amount of copper from a few mines in the Appalachian belt, but mainly depending on foreign sources for its supply. Though the occurrence of native copper in that region had been reported two centuries earlier by travelers, it was not until that late date that determined, vigorous efforts were made to open up mines in what was then an unknown wilderness. Since that year more and more mines have been developed, many of the old ones have enlarged their facilities, and so few of the lodes have thus far become exhausted, that the output has steadily risen until last year (1891) the output had increased to about 58,000 tons, and the preparations now being made at the Lake indicate that this heavy output will be considerably exceeded in the immediate future. But the past history of this region as a producer, when it was worked by the prehistoric miners, who have left such abundant evidence of their workings, is at present unknown, but some of the best lodes have been found by means of the remains of the workings of these ancient miners. None of these old workings are deep or very extensive, but considering the rudimentary methods they possessed of working these hard copper lodes by means of their stone implements, they must at least have given considerable attention to them.

The geological formation in which these highly productive copper lodes occur consists of a series of parallel beds of rocks of very great age (probably Cambrian) that extend from the end of the peninsula that juts out from the middle of the south shore of Lake Superior, known as Keweenaw Point, for a distance of at least 150 miles to the Southwest. This range of copper-bearing rocks is made up of alternating beds of compact lava known as "trap," of amygdaloidal lava known as "melaphyre" or "amygdaloid," and of coarse red conglomerates and brown sandstones. The copper rocks are from 3 to 7 miles wide, and have a general dip to the Northwest that varies from 20° to 55°.

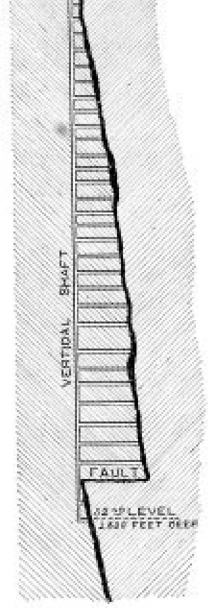
The copper occurs in these rocks in three classes of deposits: As (1) *fissure veins*, that break across the formation at right angles, and which are usually vertical; (2) as *contact veins*, or ore-bodies that lie along the plane of contact of the trap and conglomerate belts; and (3) as *impregnated deposits*, in which the old steam cavities in the amygdaloidal lava belts, or the interstices between the gravel and sand in the conglomerate belts have been more or less completely filled by copper.

The fissure and contact veins were most actively worked in the early history of the region, as they carry their copper largely in the form of solid masses that vary from a few pounds in weight up to 600 tons, and were therefore thought to be far more profitable than the amygdaloid and conglomerate belts in which the copper mainly occurs as small disseminated shots or granules. But the stern lesson of experience has shown that the expenses of mining such heavy masses of copper are much greater than when it occurs as small, scattered pellets, so that with the low prices of copper that have now ruled for some time, almost all of the vein mines have had to close down from their inability to compete with the belt mines. The vein mines are usually very narrow, or from one to three feet wide, rarely over five feet, while the belt deposits usually range from ten to thirty feet wide. While the fissures are found running across the formation throughout its entire length, they are much more numerous at the northern end of the range in Keweenaw County, where they have been very extensively worked, while the contact deposits, which are few in number, have only been worked at the southern end of the range, in Ontonagon County. The belts are found to run continuously from one end of the range to the other, but it is only in places that they are found to be rich enough in copper to pay to work, and thus far all the profitable belt mines have been opened up along the central part of the range, or in Houghton County. On account of the fine condition of most of the copper in the belt mines, it is necessary to crush the low-grade rock into sand, and then concentrate the heavy copper on jigs and slime tables, by which treatment the light rock is washed away, yielding a copper sand that will assay on an average about 70% in copper. For this purpose large mills are to be found along the lake shores, adjacent to, and connected with the mines by railroads, where powerful steam stamps are employed to perform the crushing that are capable of reducing from 150 to 300 tons of two and one-half inch rock to three-sixteenths inch sand in twenty-four hours per stamp. More or less pure copper is also found associated with the masses in the vein mines, but as the amount is comparatively small, the vein mines still use the old fashion drop stamps to crush the disseminated rock, which have a capacity of only two to four tons per stamp in twenty-four hours. The rich copper sands, or "mineral" produced by the stamp-mills merely requires melting to free it from the associated matter, to be put into merchantable condition as ingots for casting, bars for wire-drawing, and cakes for rolling into sheets.

The most prominent of the fissure vein mines are the Cliff, Phoenix, Copper Falls, and Central, all of which are in Keweenaw County, at the northern end of the range. The *Cliff Mine* was the first regular copper producer of Lake Superior, beginning its career in 1845, and was the first, and for a long time the heaviest dividend paying property of Lake Superior. The vein, which is about vertical, has been worked to a depth of nearly 1,700 feet, and as it has pinched and grown poorer with depth, work on it was finally abandoned in 1885, after it had produced about 19,000 tons of copper, from which it paid a total of $2,627,000 in dividends, or nearly 2,400% on the capital stock paid in.

The *Phoenix Mine* is better known by the 500 ton mass that it produced than by a brilliant record for either a large product or dividends. For while it was one of the very first to be worked, dating back as far as 1844, the vein has on the average been so poor that it had produced less than 8,000 tons of copper when it was shut down in 1887, after attaining a vertical depth of about 1,200 feet, and only $20,000 has been declared in dividends, while the assessments amount to about $1,000,000. It is an interesting instance of the expense of working the large masses that occasionally occur in the fissure veins that this 500-ton mass which was found in 1870, cost more to mine, cut up into manageable chunks, and raise than it finally realized, though copper was selling in those days for more than twenty cents a pound.

The *Central Mine* is the only other fissure vein property in the Keweenaw District besides the Cliff, that can make a satisfactory showing as a financial investment and it is now the "Last of the Mohicans," as it is the only fissure vein property being actively worked to-day in the State of Michigan. It was discovered in 1854, and has been worked continuously to date, having produced a total of about 22,000 tons of copper, and has now attained a depth of over 2,800 feet. It paid its first dividend in 1862, since which time it has returned from $1 to $8 per share per year, aggregating $1,970,000 in all, on a capital investment of only $100,000. The vein runs about north and south, dips to the east at the rate of 10 feet per 100 from the vertical, and like all the fissure veins, has a vein filling of calcite, quartz, and zeolitic matter, in which are found the masses and disseminated copper. This mine has produced a large number of masses, which were larger and much more abundant in the upper part of the mine than in the lower workings. One of these masses was a huge slab found lying against the wall of the vein that proved to to weigh about 600 tons, after it had been slowly and laboriously cut up into chunks of five to ten tons each. In mining such unmanageable slabs, it is necessary to stope away all the ground in front of one face of the mass, when by drifting behind the middle of it and filling a chamber with black powder to the extent of twenty-five to fifty kegs, it can be blown out free from the rock and is ready to be cut up. The cutting is done by special miners, who with long, sharp chisels and eight pound striking-hammers, slowly cut off pieces small enough to be hauled out through the drifts, and hoisted by a special engine of great power. The cutting is done by contract, and as high as $14.00 per square foot of face cut is paid, as the cutting has to be done chip by chip, which is very slow on such tough material. Recently the Central vein was found to be faulted, or lost, on the thirtieth level, or apparently the fissure extended no further; but later explorations have shown that it was "heaved," or thrown about 300 feet, from whence it again continues, as shown in sketch A.

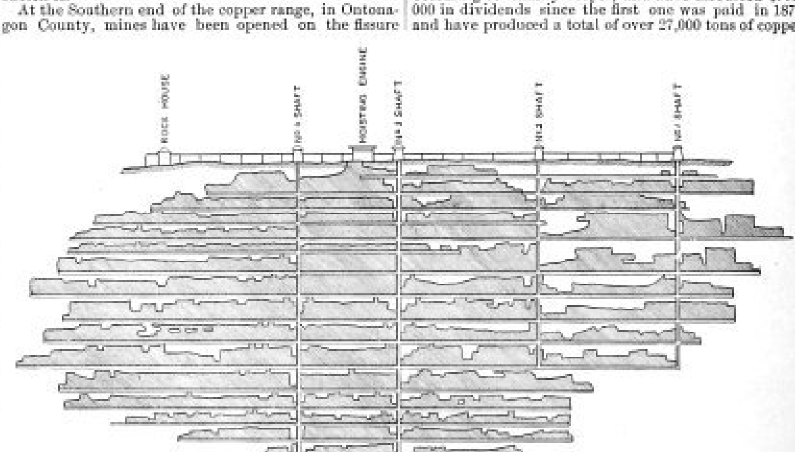


SKETCH A.—CROSS SECTION OF THE CENTRAL VEIN.

At the Southern end of the copper range, in Ontonagon County, mines have been opened on the fissure veins, on the amygdaloid belts and on the contact veins, and while quite extensive work has been done, the only successful enterprises have been the Minnesota and the National Mines, which are adjacent properties on the same contact lode that have both repaid all the money put into them and three times more in the latter case, and thirty times more in the first. The Minnesota Mine was very successful in its day, and has left a brilliant record. It was discovered in 1847, by the remains from the workings of the prehistoric miners, and a mass of about six tons weight was found already mined and blocked up by the aboriginal workers, who seemed to have been unable to utilize such a massive piece. After assessing to the extent of $900,000, the mine began paying dividends in 1852, which were regularly continued until 1865, a total of $1,920,000 having been disbursed from an output of over 17,000 tons of copper, besides putting about a third of a million into plant. The mine was shut down in 1870, after reaching a depth of 1200 feet, and only tribute work has been carried on since in a small way. The vein lies between a trap hanging-wall and a conglomerate foot, is from 2 to 8 feet wide, has a dip of 52° to 64°, and trends with the formation. The vein filling is mainly calcite, in which occurred many large masses, one of which was 45 feet long, had an average width of 13 feet, and an average thickness of 4 feet, with an estimated weight of 500 tons; it took 20 men 15 months to extract this one mass, which is famous as being the most solid mass ever found on the Lake, as it had a maximum thickness of 8½ feet. Almost the entire output of this mine has been from "*heavy*" copper or pieces of several pounds weight and upwards, the fine, shot copper having been of very minor importance.

Youngest in age but most important in the magnitude of its output and the magnificence of its dividends is the central portion of the copper range, in Houghton County, where all the mines work either belts of conglomerate or belts of amygdaloid. While this portion of the copper range has the largest number of dividend paying mines, it also has an abundance of properties that have failed to repay the large sums that have been put into many of them. One of the oldest mines of this district that as yet ranks next to the world famous Calumet & Hecla, is the Quincy, which operates a belt of amygdaloid that averages about 2% in copper, but which is found to be very bunchy in its copper contents and therefore neccessitates extensive exploration in the search for new ore-bodies. Unlike most of the belt mines, the Quincy lode carries considerable heavy copper, masses of five to even twenty tons not being infrequent, though its principal product is obtained from the stamp-rock or the finely disseminated copper. It began producing in 1856, since which time it has produced over 60,000 tons of copper, and paid dividends therefrom with great regularity that now aggregate the handsome sum of $6,170,000, besides paying for plant investments that exceed $1,500,000, on an invested capital of only $200,000. It is one of the deepest mines in this country, as its lowest level, the 41st, is 3200 feet deep as measured on the dip of the vein, which averages about 54°. Adjacent to the Quincy and operating the same belt is the Pewabic Mine, which after prolonged litigation and idleness, has been absorbed by the Quincy people; it paid $400,000 in dividends since it began operations in 1855, and produced about 14,000 tons of copper. Adjoining the Pewabic Mine and also operating the same lode is the Franklin Mine, which since 1857 has produced over 35,000 tons of copper, and paid $1,120,000 in dividends.

An admirable instance of the success of good management is to be seen in the Atlantic mine, which started in 1872 on the financial wreck of two previous administrations that had spent $1,000,000, and then failed when copper was high and the mine shallow, has become a decided financial success and one of the beacon lights of low grade mines. The lode is a very uniform belt of amygdaloid, about 15 feet wide, that yields only about ⅔ of one per cent. of copper. Yet by very careful management and operating on a large scale, they have been able to finally put it on a dividend paying basis, in spite of the low prices lately ruling and the mine becoming constantly deeper, and have disbursed $700,000 in dividends since the first one was paid in 1878, and have produced a total of over 27,000 tons of copper.



SKETCH B.—LONGITUDINAL SECTION OF THE ATLANTIC MINE.

For a longitudinal section of the mine, showing the regularity of the stopes and the mode of working, see sketch B.

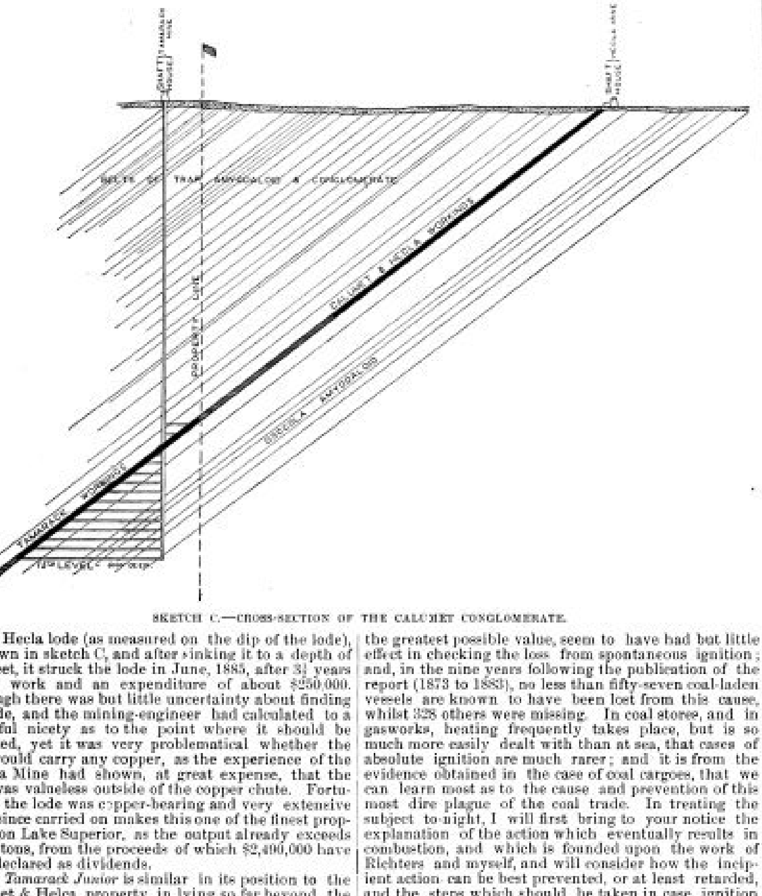
The *Osceola Mine* is a well managed property that was opened on the famous Calumet & Hecla conglomerate belt in 1873. Though it adjoins the Hecla mine, and the lode was very rich at first, it was soon found to have only the Southern end of the Hecla copper chute, and while the lode continues uninterrupted, it is practically barren of copper after a small portion adjacent to the Hecla property line had been exhausted. The mine would have been a failure if a new amygdaloid belt had not been discovered, on which a new mine has been opened since 1878, which has already attained a depth of 2500 feet on the lode. The total production of this property exceeds 30,000 tons, from which $1,547,000 has been paid as dividends.

The giant of the copper world when production and dividends are considered, is the famous *Calumet & Hecla Mine*, which began operations in 1865 on a conglomerate belt that has been proved to carry a very extensive chute of copper that yields from 3 to 5%. Originally started as two separate mines, the Calumet and the Hecla, which subsequently consolidated with an invested capital of $1,200,000, the annual output now exceeds 30,000 tons a year, which is more than the combined product of all the other mines on the Lake, from which $2,000,000 a year is usually paid in dividends, while the total output exceeds 350,000 tons, and the total dividends aggregate the enormous sum of $36,850,000, besides paying several millions more for one of the largest and most extensive surface plants to be found in the world. The lode varies from 10 to 20 feet wide, and the workings now extend to the 42d level, or over 4000 feet on the dip, which here amounts to about 38°; over 3000 tons of ore are hoisted a day, and about 25 acres are exhausted a year in maintaining this enormous output.

Adjoining the Calumet & Hecla property on the dip of the lode, are the *Tamarack* and Tamarack Junior Mines, which are remarkable instances of very bold and fortunately very successful prospecting. The Tamarack Mining Co. started a vertical shaft in February, 1881, about half a mile beyond the outcrop of the Calumet & Hecla lode (as measured on the dip of the lode), as shown in sketch C, and after sinking it to a depth of 2270 feet, it struck the lode in June, 1885, after 3¼ years steady work and an expenditure of about $250,000. Although there was but little uncertainty about finding the lode, and the mining-engineer had calculated to a beautiful nicety as to the point where it should be expected, yet it was very problematical whether the lode would carry any copper, as the experience of the Osceola Mine had shown, at great expense, that the lode was valueless outside of the copper chute. Fortunately the lode was copper-bearing and very extensive work since carried on makes this one of the finest properties on Lake Superior, as the output already exceeds 30,000 tons, from the proceeds of which $2,400,000 have been declared as dividends.

The *Tamarack Junior* is similar in its position to the Calumet & Helca property, in lying so far beyond the outcrop of the lode as to necessitate very deep shafts in order to reach the lode, with a by no means small possibility of finding the lode barren after the heavy outlay involved in reaching it. However, two shafts were started in May, 1888, and one of them struck the lode at a depth of 2,400 feet in a little less than 3 years time, and luckily found it copper bearing. The other shaft will have to go 2950 feet before it strikes the lode, and until then the property will not have had an opportunity to produce much copper.

[TO BE CONCLUDED.]



SKETCH C.—CROSS-SECTION OF THE CALUMET CONGLOMERATE.

THE SPONTANEOUS IGNITION OF COAL AND ITS PREVENTION.

BY PROFESSOR VIVIAN B. LEWES, F. I. C., F. C. S.

(From the Proceedings of the Society of Arts, England, March 2, 1892).

Last Autumn I had the honor of bringing before the Chemical Section of the British Association certain views, which are now widely gaining ground, as to the cause of the phenomenon of spontaneous ignition of masses of stored coal; and, in the discussion which ensued, Sir Frederick Bramwell expressed the hope that the paper would be followed by a second, in which methods for the prevention of this too often disastrous action might be discussed; and it is at the invitation of your secretary that I propose to bring my views on the subject before you to-night. Ever since the general adoption of coal as a fuel, the storing and shipment of masses exceeding 2,000 tons has been recognized as requiring great care; and if much small coal has been present, or if it has been stored wet, firing, or at any rate heating, of the mass has frequently taken place. On shore this has led to much inconvenience and loss, but it is during shipment that the real danger has occurred; and many a fine vessel, with all hands, has been lost from this cause, without even a record of the calamity reaching the land. In 1875 the loss of life and property from this cause became so serious that a Royal Commission was appointed to report upon the possibility of preventing these appalling disasters; but the recommendations contained in the report, although of the greatest possible value, seem to have had but little effect in checking the loss from spontaneous ignition; and, in the nine years following the publication of the report (1873 to 1883), no less than fifty-seven coal-laden vessels are known to have been lost from this cause, whilst 328 others were missing. In coal stores, and in gasworks, heating frequently takes place, but is so much more easily dealt with than at sea, that cases of absolute ignition are much rarer; and it is from the evidence obtained in the case of coal cargoes, that we can learn most as to the cause and prevention of this most dire plague of the coal trade. In treating the subject to-night, I will first bring to your notice the explanation of the action which eventually results in combustion, and which is founded upon the work of Richters and myself, and will consider how the incipient action can be best prevented, or at least retarded, and the steps which should be taken in case ignition should result. Coal is a substance of purely vegetable origin, formed out of contact with air by long exposure to heat and pressure, from the woody fiber and resinous constituents of a monster vegetation, which flourished long before the earth was inhabited by man; and coal may therefore be looked upon as a form of charcoal, which, having been formed at a temperature lower than that of the charcoal burner's heap, and under great pressure, is very dense, and still retains a quantity of those constituents which, in the latter case, are driven off as tar, wood naphtha, &c. These bodies consists essentially of compounds containing carbon and hydrogen, together with a little oxygen and nitrogen, and form the volatile matter and hydrocarbons of the coal. Besides the carbon and hydrocarbons, coal also contains certains mineral bodies, which were mostly present in the sap and fiber of the original vegetation, and which gives the ash which is left behind when the coal is burnt. These substances consist chiefly of sulphate of lime or gypsum, silica and alumina, whilst in nearly all kinds of coal is to be found a substance called disulphide of iron, coal brasses or pyrites, which has been formed by the gradual reduction of the sulphates by carbonaceous matter in the presence of iron salts, and which, during the combustion of the coal, is decomposed, giving off sulphur compounds, and leaving behind oxide of iron, which gives the reddish-brown color to the ash of many kinds of coal. Of these constituents of coal, the only ones which play no part in the phenomena attending heating and spontaneous ignition, are the mineral constituents other than the pyrites, and we have, therefore, to deal with the chemical actions which take place when the carbon, hydrocarbons, and brasses contained in newly-won coal come in contact with air and moisture.

THE INFLUENCE OF CARBON IN PRODUCING HEATING.

Carbon is one of those substances which possess to an extraordinary degree the power of attracting and condensing gases upon their surface, this power varying with the state of division of the particular form of carbon used. The charcoal obtained from dense forms of wood, such as box, exhibits this property to a high degree, 1 cubic inch of such charcoal absorbing:

	Cubic inches.
Ammonia gas	90
Sulphureted hydrogen	55
Carbon dioxide	35
Ethylene (olefiant gas)	35
Oxygen	9·25
Nitrogen	6·5

whilst certain kinds of coal also exhibit the same power, although to a less degree. The absorptive power of newly-won coal due to this surface attraction varies, but the least absorbent will take up one and a quarter times its own volume of oxygen, whilst in some coals more than three times their volume of the gas is absorbed. This absorption is very rapid at first, but gradually decreases, and is, moreover, influenced very much by temperature, for reasons which will be explained later. The absorption is at first purely mechanical and itself causes a rise of temperature, which, in the case of charcoal formed in closed retorts, as in preparing alder, willow, and dogwood charcoal for powder making, would produce spontaneous ignition if it were not placed in sealed cooling vessels for some days before exposure to air. The rate of absorption varies with the amount of surface exposed, and, therefore, able to take part in this condensing action, so that, when coal or charcoal is finely powdered, the exposed surface being much greater, absorption becomes more rapid, and rise of temperature at once takes place. If, after it has been made, charcoal is kept for a day out of contact with air, and is then ground down into a powder, it will frequently fire after exposure to the air for thirty six hours, whilst a heap of charcoal powder, of 100 bushels or more, will always ignite. It is for this reason that in making the charcoal for powder, it is always kept, after burning, for three or four days in air-tight cylinders before picking over, and ten days to a fortnight before it is ground. In the case of coal, this rise in temperature tends to increase the rate of the action that is going on, but is rarely sufficient to bring about spontaneous ignition, only about one-third the amount of oxygen being absorbed by coal that is taken up by charcoal; the action also being much slower, tends to prevent the temperature reaching the high ignition point of the coal. Air-dry coal absorbs oxygen more quickly than wet coal.

THE ACTION OF THE BITUMINOUS CONSTITUENTS OF THE COAL IN SPONTANEOUS IGNITION.

All coal contains a certain percentage of hydrogen which is in combination with some of the carbon, and also with the nitrogen and oxygen, and forms with them the volatile matter in the coal. The amount present in this condition varies greatly, being very small in Anthracite and very great in cannel and shale. When the carbon of the coal absorbs oxygen, the compressed gas becomes chemically very active, and soon commences to combine with the carbon and hydrogen of the Bituminous portions, converting them into carbon dioxide and water vapor. This chemical activity increases rapidly with rise of temperature, so that the heat generated by the absorption of the oxygen causes it to rapidly enter into chemical combination. Chemical combination of this kind—*i. e.*, oxidation—is always accompanied by evolution of heat, and this further rise of temperature again increases rapidity of oxidation, so that a steady rise of temperature is set up, and this taking place in the center of a heap of small coal, which, from the air and other gases enclosed in its interstices, is an admirable non-conductor of heat, will often cause such heating of the mass that, if air percolate slowly into the heap, in sufficient quantity to supply the necessary percentage of oxygen for the continuance of the action, the igniting point of the coal will soon be reached. The effect of rise of temperature in increasing the rapidity of chemical actions of this kind can be realized from the effect which it has in the spontaneous ignition of oily waste or rag. If a substance like cotton waste be rendered oily with anything except the mineral oils, it acquires the power of taking up oxygen from the air, and this oxidizing the oil gives rise to heat. At ordinary temperatures this oxidation is slow, and, consequently, it may be days before the rise in temperature becomes sensible, but when this point is reached the oxidation proceeds with remarkable rapidity, and in a few hours the point of ignition is reached, and the mass bursts into flame, whilst if the oily waste be placed in a warm place at first, spontaneous ignition is only a question of hours, or sometimes even minutes. Galletley found that oily cotton at ordinary temperatures took some days to heat and ignite, whilst, if placed in a chamber warmed to 130 degs. to 170 degs. Fahr. (54 degs. to 76 degs. Cent.), the cotton, greasy, with boiled linseed, ignited in one hour fifteen minutes, and olive oil on cotton in five hours; and in a chamber heated to 180 degs. to 200 degs. Fahr. (82 degs. to 93 degs. C.) olive oil on cotton ignited in two hours. It has been suggested that very Bituminous coal, such as cannel, shale, and coals containing schist, is liable to spontaneous ignition from the fact that a rise in temperature would cause heavy oils to exude from them, which, by undergoing oxidation, might cause rapid heating. But experiment not only shows that this is not the case, but that the heavy mineral oils have a remarkable influence in retarding heating; cotton waste, oily with easily oxidizable oils mixed with 20 per cent. of heavy mineral oil, being exempt from heating.

THE ACTION OF IRON DISULPHIDE, PYRITES, OR COAL BRASSES IN PROMOTING SPONTANEOUS IGNITION.

The earliest theory as to the cause of spontaneous ignition in coal was, that it was due to the heat given out during the oxidation of pyrites (the disulphide of iron) into sulphates, and this idea has been adopted, and has held its own, in this country up to the present time, although the researches of Dr. Richters, some twenty years ago, clearly prove that the explanation was an erroneous one, and the late Dr. Percy, as early as 1864, pointed out that probably oxidation of the coal had a great deal to do with the action. This disulphide of iron is found in coal in several different forms, sometimes as a dark powder distributed throughout the mass of the coal, and scarcely to be distinguished from coal itself. In larger quantities it is often found forming thin golden looking layers in the cleavage of the coal, while it sometimes occurs as masses and veins, often 1 in. or 2 in. in thickness, but inasmuch as these masses of pyrites are very heavy, they rarely find their way into the screened coal for shipment, many hundreds of tons of these "brasses" being annually picked out from the coal at the pit's mouth, and utlized in various manufacturing processes. The yellow pyrites which form the large masses in the coal, and even the dark varieties when in the crystalline form, remain practically unaltered, even after long exposure to moist air, but the amorphous and finely divided portions, which probably contain lower sulphides mixed with the disulphide, will oxidize and effloresce with considerable rapidity when exposed to moisture and air, forming mixtures of ferrous sulphate and basic sulphates of iron, and it is during this process of oxidation that the heat supposed to bring about the ignition of the coal is generated. In some of the coals most subject to spontaneous ignition there is only 0·8 per cent. of pyrites, and if we imagined the whole of this to be easily oxidizable, and to be concentrated in one spot instead of being spread throughout the mass, and to be entirely oxidized in a few hours, the rise of temperature would only be a few degrees; whereas, under existing circumstances, it is manifest that practically no determinable increase can be generated by the action. Under certain conditions the oxidation of masses of pyrites first gives rise to the formation of ferrous sulphate, and sulphur dioxide with liberation of sulphur, and my early experiments led me to believe that inasmuch as sulphur has an igniting point of 250 degs. Cent., this free sulphur might play an important part in the action, by lowering the point of ignition; latter experiments, however, show that this could only take place with large masses of pyrites undergoing oxidation, and that with the amounts present in coal, if the air were present in sufficient quantity to oxidize the pyrites, the small trace of sulphur liberated would be oxidized to sulphur dioxide at temperatures as low as 60 degs. C. This oxidation of sulphur at low temperatures is not a generally known action, but my experiments show that it takes place with considerable rapidity. The only way in which pyrites can assist spontaneous ignition is that when they oxidize they swell, and cause disintegration of the lumps of coal, so exposing fresh surfaces to absorb oxygen and afterwards carry on chemical action. I have carefully determined the igniting point of various kinds of coal, and find that cannel coal ignites at 698 degs. Fah. = 370 degs. C.; Hartlepool coal ignites at 766 degs. Fahr. = 408 degs. C.; lignite coal ignites at 842 degrees Fahr. = 450 degs. C.; Welsh steam coal ignites at 870·5 degs. Fahr. = 477 degs. C. So that no stretch of imagination could endow the small trace of pyrites scattered through a large mass of coal, and undergoing slow oxidation, with the power of reaching the needful temperature. When coal is heating, it gives out a distinctive and penetrating odor, which is the same as that noticed when wood is scorched. The gases evolved by the heating coal consists of nitrogen, water-vapor, carbon dioxide, carbon monoxide, hydrocarbons of the paraffin series, and sulphureted hydrogen, the presence of the latter gas showing beyond doubt that oxidation of sulphur had nothing to do with the action. We can now trace the actions which cumulate in ignition. The newly-won coal is brought to the mouth of the pit, and at once commences, by virtue of its surface action, to absorb oxygen from the air; but unless piled in unusually large heaps, and a great deal broken, it does not, as a rule, show signs of heating, as the exposed surface is comparatively small, and the air, finding its way freely between the lumps, keeps down the temperature. The coal is now screened, and the obtrusively large lumps of brasses picked out; it is then put in the trucks, and enjoys the disintegrating processes of joltings and shuntings innumerable, every jar adding to the percentage of small coal present, and a corresponding increase in the size of the surface exposed to the air. Arrived at the docks, it has to be transferred from the truck to the ship, which is done by one of the numerous forms of tips, shoots, or spouts employed for the purpose, and it is during this operation that more harm is done than at any other period. The coal first shot into the vessel, by reason of the distance which it has to fall, is broken down into small lumps, and having to bear the impact of the succeeding load falling upon it from a height, rapidly becomes powdered into slack, whilst the succeeding loads falling in on the cone so formed get more or less broken down, so that by the time the cargo is all taken in a dense mass of small coal is to be found under the hatchway, and it is invariably at this point that heating takes place, as the large surface exposed fresh to the air by the breaking down of the coal causes rapid absorption of oxygen, and consequent rise of temperature. This sets up chemical combination between the oxygen absorbed by the coal and the hydro-carbons and coal brasses. On examining the evidence to be obtained as to the conditions under which spontaneous ignition of coal in ships usually takes place, it is found that liability to ignition increases with:

1. *The Increase in Mass of Coal.*—Thus, in cargoes of under 500 tons the cases reported amount to a little under ½ per cent. for shipments out of Europe; from 500 to 1,000 tons, to over 1 per cent.; from 1,000 to 1,500 tons, to 3·5 per cent.; 1,500 to 2,000 tons, to 4·5 per cent.; and over 2,000 tons to no less than 9 per cent. The evidence demonstrating this very remarkable result is to be found in the Report of the Royal Commission for 1875, p. 8, and clearly shows the influence of mass upon this action, which acts in two ways: (*a.*) The larger the mass, the more non-conducting material will there be between the spot at which heating is taking place and the cooling influence of the outer air. (*b.*) The larger the mass the greater will be the breaking down action of the impact of coal coming down the shoot upon the portions first loaded into the ship, and the larger, therefore, the fresh surface exposed to the action of the air.

2. *The Ports to which Shipments are made.*—26,631 shipments to European ports, in 1873, only resulting in ten casualties, whilst 4,485 shipments to Asia, Africa, and America gave no less than sixty. The startling result is partly due to the length of time the cargo is in the vessel, the absorption and oxidation being a comparatively long action; but a far more active cause is the increase in the action brought about by the increase of temperature in the tropics, which converts a slow action into a rapid one, and if statistics had been taken, most of the ships would have been found to have developed active combustion somewhere about the neighborhood of the cape, the action developed in the tropics having raised the temperature to the igniting point of the coal by that time.

3. *The Kind of Coal.*—Some coals being specially liable to spontaneous heating and ignition. This is a point on which great diversity of opinion exists, but I think it will be pretty generally admitted that cases of heating and ignition are more frequent in coals from east coast ports than in shipments of the South Wales coals. The idea that the percentage of pyrites present is any indication of the liability to spontaneous combustion must be entirely discarded, as experiments show that many coals poor in pyrites frequently ignite, whilst others rich in them are perfectly safe. A much surer guide is to be found in the quantity of moisture present in an air-dried sample of coal, which is a sure index to the absorptive power. The higher the amount of moisture held by the coal, after exposure for some time to dry air, the greater will be its power of absorption for oxygen, and the greater therefore its liability to spontaneous heating and ignition. This is beautifully shown by the following table, in which the percentage of pyrites and moisture present in some coals are contrasted with their liability to self-ignition.

Liability to Spontaneous Ignition.	Pyrites. Per cent.	Moisture. Per cent.
Very slight	1·13	2·51
	1·01 to 2·04	2·75
	1·51	3·90
Medium	1·20	4·50
	1·08	4·55
	1·15	4·35
Great	1·12	4·85
	0·85	5·30
	0·84	5·22
	1·00	9·04

The percentage of moisture shown in this table is not due to external wetting, but is moisture absorbed from the air and held by the coal, so that the amount of it present is an indication of the power of absorption possessed by the coal, and which will give it the power of taking up oxygen as well as water vapor.

4. *The Size of the Coal.*—Small coal being much more liable to spontaneous ignition than large. This, as has been pointed out, being entirely due to the increase in active absorbent surface exposed to the air, a fact which is verified by the experience of large consumers of coal on land; gas managers recognizing the fact that coal which has been stamped down or shaken down during storage being more liable to heat than if it has been more tenderly handled, the extra breakage causing the extra risk.

5. *Shipping or Storing Coals while Wet.*—The effect of moisture upon coal is very remarkable. At first external wetting retards the absorption of oxygen by the coal, but the presence of moisture afterwards increases the action of the already absorbed oxygen upon the hydrocarbons of the coal, and so causes a serious increase in the heating. Of late years the researches of Cowper, Baker, Dixon, and others have shown so fully the important part which moisture plays in chemical combination, that it is now fully recognized as a factor of importance in actions of this kind. During last autumn a very marked case of the influence of moisture in the action taking place came under my notice. A ship took in a cargo of coal at a South Wales port, the weather being fine and dry whilst she was loading at the main hatch, and wet whilst taking in the coal at the after hatch, with the result that the temperature after the first few days was uniformly about 10 degs. higher in the coal that had been loaded wet than in the dry portion of the cargo, spontaneous ignition being the ultimate result.

6. *Ventilation of the Mass of Coal.*—The so-called ventilation, which has from time to time been introduced into coal ships, is undoubtedly one of the most prolific causes of spontaneous ignition. For ventilation to do any good, cool air would have to sweep continuously and freely through every part of the cargo, a condition impossible to attain, whilst anything short of that only increases the danger, the ordinary methods of ventilation supplying just about the right amount of air to create the maximum amount of heating. The reason of this is clear. A steam coal absorbs about twice its own volume of oxygen, and takes about ten days to do it under favorable conditions, and it is this oxygen which, in the next phase of the action, enters into chemical combination, and causes the serious heating. A ton of steam coal occupies 42 to 43 cubic feet, and if properly loaded contains between the lumps, as nearly as possible, 12 cubic feet of air space—that is to say, of the 42 cubic feet, 12 cubic feet is air, and 30 cubic feet is coal. Thirty cubic feet of coal, with its fresh absorbing surfaces laid bare by the crushing incidental to loading, will in the first ten days after being taken on board, absorb 60 cubic feet of oxygen, if it can get it. Now, air contains only, roughly, one-fifth of its volume of oxygen, so that 60 cubic feet represent 300 cubic feet of air, or twenty-five times as much as is present. It is therefore evident that if the air could be excluded, there would be only one twenty-fifth the quantity of oxygen present that is needed for complete action, and any heating would, in consequence, be very slight, whilst to produce the greatest heating it would be necessary to change the entire air in the cargo twenty-five times in the first ten days, and this is just about what the old method of taking a box shaft along the keelson with Venetian lattice upshafts from it would give. The most forcible illustration of the evil of such ventilation is to be found in the case of the four colliers, "Euxine," "Oliver Cromwell," "Calcutta," and "Corah," which were loaded at Newcastle under the same tips, at the same time, with the same coal, from the same seam. The first three were bound for Aden, and were all ventilated. The "Corah" was bound for Bombay, and was not ventilated. The three thoroughly ventilated ships were totally lost from spontaneous ignition of their cargo, whilst the "Corah" reached Bombay in perfect safety.

7. *Rise in Temperature.*—It has been fully pointed out that anything which tends to increase of initial temperature increases the rapidity of chemical action, and in most cases of spontaneous combustion in coals stored in this country, the cause can be traced to a steam pipe or boiler-flue in contact with the mass of coal, or even fixed to a wall against which, on the other side, the coal is heaped. Sometimes the coal store is close to the benches of retorts, in a gasworks, or even against the wall of the benches, and in such cases, with certain classes of coals, ignition would be almost certain to take place. In a paper read at the last meeting of the Gas Institute, it was proposed to lead the flues from the benches under the coal store, in order to dry the coal, a device which would infallibly lead to spontaneous ignition. On colliers there are many causes for increased temperature, amongst them being the introduction of triple expansion engines and high pressure boilers. Steam at 80 lbs. boiler pressure has a temperature of 324 degs. Fahr. (162 degs. Cent.), and a common stoke-hole temperature, with boilers worked at this pressure is 100 degs. to 130 degs. Fahr. (or 38 degs. to 54 degs. Cent.) Steam at a boiler pressure of 155 lbs. has a temperature of 368 degs. Fahr., or 186 degrees Cent., and gives a corresponding increase of temperature in the stoke-hold and other adjacent portions of the vessel, the temperature in the stoke-hold under these conditions being from 110 degs. Fahr. (43·5 degs. Cent.) to 140 degrees Fahr. (60 degs. Cent.), an increase of about 10 degs. Fahr. Then, again donkey boilers will often be found recessed into bunker bulkheads, and steam pipes led alongside the bulkheads, with the cargo close up against them on the other side. The effect of temperature due to climatic influences has already been dealt with under the influence of ignition of ports to which shipments are made.

Having now discussed the chemical and physical conditions which lead to the phenomenon known as "spontaneous ignition," we can formulate precautions which will tend to prevent such disasters:

1. *The Choice of Coal for Storage or Shipment.*—The coal should be as large as possible, free from dust, and with as little "smalls" as can be helped. It is better as free from pyrites as possible, and it should contain, when air-dried, not more than 3 per cent. of moisture.

2. *Precautions to be taken in Storing or Loading.*—The coal store should be well roofed in, and have an iron floor bedded in cement. All supports passing through and in contact with the coal should be of iron or brick; if hollow iron supports are used they should be cast solid with cement. The coal must never be loaded or stored during wet weather, and the depth of coal in the store should not exceed 8 ft., and should only be six where possible. Under no condition must a steam or exhaust pipe or flue be allowed in or near any wall of the store, nor must the store be within 20 ft. of any boiler, furnace, or bench of retorts. No coal should be stored or shipped to distant ports until at least a month has elapsed since it was brought to the surface. Every care should be taken during loading or storing to prevent breaking or crushing of the coal, and on no account must a large accumulation of small coal be allowed. These precautions, if properly carried out would amply suffice to entirely do away with spontaneous ignition in stored coal on land, and we have now to consider a far more important phase of the question.

3. *Precautions to be taken on board Coal-laden Ships.*—This phase of the question is undoubtedly the most important, and in order to ensure any successful treatment of the coal cargo at sea, to prevent undue heating and ignition, the means adopted must be as nearly automatic in their working as possible, as it is useless to expect the master or any officer on board a collier during rough weather, &c., to comply with any instructions, such as daily taking the temperatures in various parts of the cargo, and so on. The iron bulkheads dividing the coal storage from the other parts of the vessel should be made double, and spaced 6 in. to 1 ft. apart, with openings (which could be closed water-tight) every few feet, to allow of the interior being from time to time coated with protective compositions. Through this double casing sea water would be allowed to circulate, and would not only effectually prevent any penetration of heat from the stokehold, boilers, or engine room to the coal, but also do away with any chance of leakage of gases from the coal cargo into others

portions of the vessel, and so would minimize the danger of explosions. A similar double partition should run down the center of that portion of the vessel in which the coal was stored, and it would be sufficient if this were packed with silicate wool; this partition would serve to prevent any heating which might take place in one part of the cargo being communicated to the other half, whilst it would also perform the important function of helping to prevent shifting of the cargo during heavy rolling. When the coal has all been taken in it should be battened down, and the hatches should not be again opened until the vessel reaches her destination, the only ventilation allowable being a 2 in. pipe just inserted into the crown of each coal compartment, and led 12 ft. up the nearest mast, the top being left open. This would be quite sufficient to allow free egress to any gases evolved by the coal, but would not allow undue excess of air. Into the body of the coal cargo itself would be screwed, at regular intervals of about 10 ft., iron pipes, closed at the bottom and containing alarm thermostats, so arranged that when a rise of temperature causes expansion of the mercury in rising in the tube it makes a contact; and the wires from these tubes are in connection with an electric bell, index board, and battery in the captain's room; so that the moment the temperature is reached to which the thermometers have been set the bell rings, and will continue to ring until the temperature again sinks, the spot in which heating is taking place being indicated by the index board. In the evidence given before the Commissioners in 1875, Mr. J. Glover strongly advocated the use of carbon dioxide, or carbonic acid gas, as it is more usually termed, for extinguishing ignition when it had broken out in a coal cargo, and for stopping heating when it had reached a dangerous pitch. His proposal was to generate the gas by the action of hydrochloric acid upon chalk, and to lead it by gas pipes to the compartment affected; and this gas, being heavier than air, and a non-supporter of combustion, was to displace the air and its contained oxygen, and so to prevent further action by surrounding the coal with an atmosphere which could not carry on combustion. The idea was a good one, but there were many difficulties in the way of carrying it out, one being that, for every 1,000 tons of coal carried, 80 cwt. of hydrochloric acid would have had to be shipped; also the gas could not have been driven down into the hold if any serious heating had taken place, as an up-current would have been formed, and would have carried it away; whilst in the state of gas it fails to give any great cooling effect and so would have exercised but little influence upon the mass of red-hot fuel. These objections weighed so strongly with the Commissioners that, in their final report, we find the following sentences: "Several methods for generating carbonic acid gas, and applying it to the ignited portion of a coal cargo, have been proposed for our consideration. We consider, however, that although this gas might be useful for excluding atmospheric air (which is essential to support combustion), yet it will not, as water does, exert any very sensible cooling effect, which is a point of vital importance in the case of a mass of ignited coal. We are of opinion that water and steam are the only agents practically available for the purpose of extinguishing fire in coal cargoes." Applied in the way which was suggested, there is no doubt but that the carbonic acid gas would have been practically useless; but there is another way in which it could be used, which would make it a most powerful cooling agent, an instantaneous quencher of fire, and would prevent any further tendency to heat on the part of the coal treated with it. If carbonic acid gas is compressed under a pressure of 36 atmospheres at a temperature of 32 degs. Fahr. (0 degs. Cent.), it is condensed to the liquid state, and can be obtained in steel vessels closed with screw valves. In opening the valve some of the liquid is ejected into the air, and, and in coming into the ordinary atmospheric pressure, is in a moment converted into a large volume of gas. Conversion from the liquid to the gaseous state means the absorption of a large amount of heat; and so great is this, that everything near the stream of new-born gas is cooled down, and some of the escaping liquid is frozen to a solid, having a temperature of—78° Cent., or—108·4 Fahr. This liquid carbonic acid gas is now extensively manufactured, and is used abroad to a large extent for aerating waters, driving torpedoes, and for freezing machines; and I should suggest its use in the following way for the checking of ignition in the coal cargo: The nozzle attached to the screw-valve on the bottle of condensed gas should have a short metal nose-piece screwed onto it, the tube in which should be cast in solid, with an alloy of tin, lead, bismuth, and cadmium, which can be so made as to melt at exactly 200 degs. Fahr. (93 degs. Cent.) The valve should then be opened, and the steel bottle buried in the coal during the process of loading. The temperature at which the fusible metal plug will melt is well above the temperature which could be reached by any legitimate cause, and would mean that active heating was going on in the coal; and under these conditions the pressure in the steel cylinder would have reached something like 1,700 lbs., and the moment the plug melted the whole contents of the bottle would be blown out of it into the surrounding coal, producing a large zone of intense cold, and cooling the surrounding mass to a comparatively low temperature. The action, moreover, would not stop here, as the cold, heavy gas would remain for some time in contact with the coal, diffusion taking place but slowly through the small exit pipe.

When the coal has absorbed as much oxygen as it can, it still retains the power of absorbing a considerable volume of carbonic acid gas; and when coal has heated, and then been rapidly quenched, the amount of gas so absorbed is very large indeed, and the inert gas so taken up remains in the pores of the coal, and prevents any further tendency of heating; indeed, a coal which has once heated, if only to a slight degree, and has then cooled down, is perfectly harmless, and will not heat a second time. It is not by any means necessary to replace the whole of the air in the interstices of the coal with the gas, as a long series of experiments show that 60 per cent. of carbonic acid gas prevents the ignition of the most pyrophoric substances. One hundred cubic feet of gas can be condensed in the liquid state in a steel cylinder 1 ft. long and 3 in. diameter, and it has been shown that a ton of coal contains air spaces equal to about 12 cubic feet; therefore, one of these cylinders would have to be put in for every 8 tons of coal, as, although the gas formed at the first moment would only occupy a small space, on account of its low temperature, it would rapidly expand in contact with the hot coal. These cylinders should be distributed evenly throughout the cargo and near the alarm thermometers, which should be set to ring a degree or two below the point at which the fusible plug would melt. The bell ringing in the captain's room would warn him that heating was taking place, and the bell would continue to ring until the cylinder had discharged its contents, and had cooled the cargo down to a safe degree, so that the whole arrangement would be purely automatic, and yet the officers would know if everything was safe. This liquid is now being made at a comparatively cheap rate, and, with any demand for it, machinery could be put up at the principal coaling ports to charge empty cylinders at a very low rate, so that the initial cost of the steel cylinders once got over, the expenses would not be worth considering, more especially as only one, or two at most, of the cylinders in use would be likely to go off. If the precautions advocated were taken, no danger could arise until the arrival of the ship at her destination, and the commonest precautions would then suffice. On removing the hatches no naked light must be allowed near them, and no one must be allowed to descend into the hold until all the gases have had time to diffuse out into the air. If the cylinders have gone off, there will be but little fear of explosion, as a high percentage of the carbonic acid gas lowers the explosive power which the mixture of marsh gas (given off from some coal) and air possess; but the carbonic acid gas would overcome and suffocate a man descending into an atmosphere containing any considerable percentage of it. When a safety-lamp, lowered into the hold, continues to burn as brightly as it did in the open air, then it is perfectly safe to descend. When once coal in a cargo has fired, pumping in water is of practically no use, as the fire is, as a rule, near the bottom of the mass of coal, and the flow of the water is so impeded by the caking of the heated mass above the fire, that in percolating through the interstices of the heated coal, it is converted into steam before it can reach the seat of combustion. The most effective way to apply water would be to have 3 in. pipes laid along the floor of the coal compartments, about 6 ft. apart, these tubes having a ½ in. hole bored in the upper side every foot or so, and each pair of pipes coming through the bulkhead, and connecting on to two 6 in. pipes, passing through the side of the vessel, the sea water being prevented from entering by means of screw valves. As soon as the alarm thermometer gave notice that heating had reached a dangerous point, these valves could be opened and the lower portion of the cargo drenched with salt water. This, evaporating rapidly, would give large volumes of water vapor which, passing up through the heated coal, would lower its temperature, but would not be nearly as effective as the method before advocated. It might, however, be used in conjunction with that method, and would, in many cases, save the carbonic acid gas. In the case of coal bunkers, in modern steamers and warships, the conditions under which the the coal is placed are so totally different from those existing in a collier, that no comparison can be drawn between them. In the coal bunker, the question of mass, which plays so important a part in a hold laden with coal, is almost entirely eliminated, as 50 to 400 tons would be about the capacity of any ordinary bunker, and it has been before shown that the cases of spontaneous ignition in masses of coal less than 500 tons does not amount to more than ½ per cent., and the question of initial temperature becomes the most important factor. A few years ago such an occurrence as a coal bunker on fire was rare, whilst at the present time hardly a week passes without some more or less serious cases occurring on the fast liners, and it is evident that there must exist some well-defined cause for this enormous increase in cases of spontaneous ignition. On collecting evidence on this point, the first thing that strikes one is that bunker fires are almost entirely confined to vessels in which the bunker bulkheads are only separated from the funnel by a narrow air space, or in close proximity to the boilers themselves, but where the bunkers are stepped back from the funnel casing and boilers, spontaneous ignition is a great rarity. Taking the case of a fast liner, it is found that the temperature in a coal bunker varies very considerably according to its proximity to the air channel round the funnel casing. Close to the outside of the bulkhead the temperature is often as high as 200 degs. Fahr. (93 degs. Cent.), whilst inside 120 degs. would be a fair estimate, and from the center of the bunker to the side of the vessel it is seldom above 75 degs. Fahr. (24 degs. Cent.); the temperature, however, being higher near the iron decks, which, being in contact with the heated bulkhead, conduct the heat through the coal and raise the temperature often up to 100 degs. Fahr. It has been pointed out that if coal be kept at a high temperature, even though it be far below its igniting point, ignition is only a question of time; and if the bunker coal next the bulkhead be kept at 120 degs. Fahr., any coal with a tendency to absorb oxygen will run a great chance of igniting within a few days. It is manifest that if this is the real cause of ignition, the seat of the fire ought to be found close to the heated bulkhead, but this is very often not the case, the mass of fire being found near the centre of the bunker, and sometimes even towards the sides of the vessel; but careful examination soon reveals the cause of this, as a line of charred coal is mostly to be found running from the heated bulkhead to the seat of active combustion, showing that the fire, started by the high initial temperature, has not had sufficient air near the bulkhead to do more than smoulder, but that as soon as it came in contact with a current of air passing up through the coal from the hatches in the decks, the smouldering mass began to burn fiercely. In order to prevent spontaneous ignition of the coal under these circumstances, all that is necessary is to reduce the temperature of the bulkhead in contact with the coal, as, if this is kept at a temperature not exceeding 82 degs. to 90 degs. Fahr., there is little or no fear of the oxidation of the hydro-carbons of the coal proceeding with such rapidity as to cause ignition in such a quantity of coal as can be carried in the bunkers—the iron decks, by sub-dividing the mass, also helping to reduce any risk. In order to reduce the temperature to the required extent, it would be necessary to make the bulkheads close to any heating surface, such as the funnel casing, double. Through this double casing sea water would be allowed to circulate very slowly, and would effectually prevent any undue rise of temperature; whilst to make the arrangements complete, a thermostat should be fixed on the inner plate of each bulkhead, which, if the temperature rose to a hundred degs. Fahr. (38 degs. Cent.), would ring a bell in the captain's room, when the rate of flow of water could be increased until the required fall in temperature took place. Should this arrangement prove impossible from any structural cause, then a rapid current of air forced through the bunkers by means of a fan, or even an up-current formed by a good air pump ventilator in the crown of the bunker, would go far to keep the temperature within safe limits. In a coal cargo perfect ventilation is impossible, on account of the mass of coal present, and, therefore, the hold should be battened down, and everything done to prevent imperfect ventilation, gas-tight bulkheads being a necessity for this purpose. In coal bunkers, on the other hand, on account of free access being obtained to both top and bottom of the coal, and also the small mass present, perfect ventilation is possible, and should be attempted, whilst the water bulkheads will do away with any undue rise of temperature. Chemists have been repeatedly asked if analysis gives no indications by which a coal liable to spontaneous heating, can be distinguished from another which is perfectly safe for storage or shipment in bulk; but up to the present time the action has been so little understood, that no such differentiation was possible, but with a clear conception of the causes which lead to heating, it should be quite possible to do so. As I have shown, all coals, when heated to a temperature a little above that of boiling water, have their power of absorbing oxygen so increased that they will, in a few hours, absorb sufficient to give a perceptible increase in weight, and the greater their absorption power the greater will the increase be; and as it is upon this that the liability to heat depends, the amount of increase in weight would give a sure indication of the liability to spontaneous ignition. We have at present, however, no data to show what is a safe amount of absorption and with what amount danger commences, and the owners of collieries yielding coal liable to heating are so anxious to prevent the fact leaking out that there will be considerable difficulty in obtaining authentic samples to make the determination with. My own experience, however, leads me to think that if an air-dry coal does not contain more than 3 per cent. of moisture, and when powdered and heated to about 250 degs. Fahr. in an oven for three hours does not increase more than about 2 per cent. in weight, it may be looked upon as a safe coal to store in bulk. I am perfectly aware that the precautions I have suggested will never, unless pressure is brought to bear upon them, be adopted by the owners of colliers, on account of the slight extra expense and trouble they would envolve; but if Lloyds could be prevailed upon to lower the rate of insurance upon coal cargoes treated in this way, and substantially increase the rate upon cargoes in which these precautions had not been adopted, a class of disaster as appalling in nature as it is destructive in result would soon be entirely done away with.

Electric Mining Machines.

The Jeffrey Manufacturing Co. of Columbus, Ohio has now in successful daily use 51 Electric Mining Machines.

Up to the present time, this company has sold, and has in actual daily use more electric mining machines than all their competitors combined. With experienced men, together with their business experience of the past three years, they are enabled to contract for complete plants under guarantee to accomplish all they claim for them. In addition to the machines already in use, they have just booked the following new orders: Second order for one Jeffrey Electric Mining Machine from the Congo Mining Co. Congo, Ohio. Third order for one Jeffrey Electric Mining Machine from the Redstone Oil, Coal and Coke Co., Grindstone, Pa. Also three orders—First equipment for complete Jeffrey Electric Coal Mining Machine Plants for the Hocking Valley, briefly described as follows:

Two plants, each consisting of boilers, engines, dynamos, and all necessary connections to run four Jeffrey Electric Mining Machines, with a daily tonnage capacity of 800 tons. One plant complete to run six Jeffrey Coal Mining Machines, with a daily tonnage capacity of 1200 tons.

The Jeffrey Manufacturing Co. is also enjoying a flourishing business in their chain specialties. The demand for their new detachable drive chains [see advertisement in this issue] has reached their most sanguine expectations, while the outlook is very bright for a largely increased demand.

Last month we announced the completion of the new boiler shops of Messrs. Thos. Carlin's Sons, the progressive manufacturers of mining machinery, boilers, etc., at Allegheny, Pa. The shops are now in complete working order, and the first boiler was completed in them and shipped to Mr. J. S. Sauters, on the 18th ult.

TABULAR ESTIMATE

SHOWING THE APPROXIMATE QUANTITY, PAST AND FUTURE, PRODUCTION OF COAL IN THE SEVERAL DISTRICTS OF THE NORTHERN ANTHRACITE COAL BASIN OF PENNSYLVANIA.

By William Griffith, Engineer and Geologist, Scranton, Pa.

1	2	3	4	5	6	7	8	9	10
DISTRICTS.	NAMES OF THE COAL BEDS.	DESCRIPTIVE REMARKS.	Average thickness of beds.	Approximate workable area of bed in acres.	Approximate quantity of solid coal originally in place before any was mined, 25 % of contents of all beds deducted for refuse, faults, thin coal, etc., leaves, 1,400 tons per ft. per acre, good coal, 2,240 lbs. per ton.	Approximate area of mine workings to January 1, 1892, in acres.	Equivalent area for bed 1 foot thick.	Approximate number of tons produced to January 1, 1892—800 tons per foot thickness of bed per acre.	Approximate quantity of coal wasted (including culm of washed coal at 20 per cent. of production)—162·7 tons per foot per acre.
Forest City and Carbondale District. From extreme Northeastern end of basin to Powderly Slope, two miles South West of Carbondale Station, D. & H. R. R.	Top Coal	Known as Slope Bed at Forest City.	6·85	6,700	64,253,000	2,010	13,770	11,374,026	2,274,805

EXPLANATION OF TABULAR ESTIMATE.

Showing the Approximate Quantity, Past and Future, Production of Coal in the Several Districts of the Northern Anthracite Coal Basin of Pennsylvania.

Editors "The Colliery Engineer":

SIRS:—I herewith offer for publication an estimate of the approximate quantity and past and future production of coal in the several districts of the Northern Anthracite Coal Basin, more generally known as the Wyoming and Lackawanna Coal Fields.

In making this estimate it was found most convenient to divide the region into districts as shown in Column No. 1 of the table, this will serve to show the distribution of the coal. Column No. 2 gives the local names applied to the various beds in each district, and are arranged with reference to their relative positions in the measures.

Column No. 3 contains short descriptive remarks as to known peculiarities of the individual beds. Column No. 4 contains the average thickness of the individual coal beds in each district and includes all beds that average over two feet thick. While these thin beds are not worked at the present time, they cannot be disregarded in an estimate of this sort, as the time will doubtless come when they will be profitably mined. The items in this column were obtained by taking the average thickness of each bed as found by using all the bore-hole, shaft, and other sections in the different parts of the basin, as published in the atlases of the State Geological Survey of the region.

The number of columnar sections of the measures thus used was 352, about evenly distributed throughout the basin. The totals in this column show the aggregate thickness of coal beds at the deepest point of the measures for each district. The items given in this column includes whatever slate, bone, and other refuse there may be in the beds.

Column No. 5 contains the approximate superficial area of workable coal in each bed, and was obtained from the published maps of the Geological Survey, which very correctly show the outcrops of the lowest coal bed and one other bed that is the most worked in each locality.

The outcrops of all the other beds were sketched approximately upon these maps by the author from his personal knowledge of the geology of the region, aided by the published cross sections and columnar sections. The area of each bed was then computed for each district, deductions were occasionally made from the areas thus found, in order to allow for those areas where certain beds are known to be too thin to be included in the table.

Owing to the prevailing flatness of the measures in this region, no account has been taken of the greater area of coal caused by steeper dips at the margin of the basin, or on the sides of the anticlinals. The actual area of the coal beds will therefore be somewhat in excess of the items given in the table, but this increase of area will doubtless be more than counter-balanced by the loss caused by poor and unminable coal on the outcrops, anticlinals, faults, troubles of various kinds, etc. The totals in this column show the area that would be covered if the beds were spread out side by side upon a level surface.

Column No. 6 contains the approximate quantity of solid coal in the ground before any was mined. The items are obtained by multiplying the thickness of each bed as is given in Column 4 by the items in Column 5, and this product by the factor 1,400, as being the number of tons of pure coal per foot per acre in the average coal bed after deducting 23·4% for the slate, bone, and other refuse, including an allowance for rock, and dirt faults, etc., which always occur in greater or less degree in all large areas.

In order to arrive at an average percentage for the refuse, the author obtained bed sections in various parts of the region from as many coal beds as possible, and from them ascertained the facts shown in table on following page.

The table would seem to show that the refuse material in the average coal bed will amount to 18·7 % of the contents of the bed.

The frequent occurrence of troubles, such as thin and poor coal, various kinds of faults, slips, squeezes, etc., etc., would seem to call for an allowance in addition to those referred to under Column 5, an arbitrary deduction of 4·7% is therefore made on this account. Therefore taking specific gravity of Anthracite coal at 1·5, the weight of good coal in ground per foot thickness of bed per acre would be

Weight of solid coal per foot thick per acre		1,828 tons
Deduct 18·7% for refuse	342 tons.	
Deduct about 4·7% for faults, troubles, &c.	86 tons.	
	428	428 tons.
Good coal in ground per foot thickness of bed per acre		1,400 tons.

The long ton of 2,240 lbs. is used throughout this estimate.

Column No. 7. The items in this column were found in manner similar to No. 5, by measuring the area worked in each bed as shown upon the published Mine Sheets of the State Survey. In doing this the areas were measured full to make approximate allowance for the areas mined over since the date of publication of the maps.

Column No. 8 is found by multiplying items of column 7 by those of column 4.

Column 9. The total approximate production of this coal basin to Jan. 1, 1892, as found from Mine Inspectors Reports and other published statistics is about 383,244,421 tons, and this amount divided by the grand total footings of Column 8 would give 826 tons as the average quantity of coal produced per foot thickness of bed per acre, to Jan. 1, 1892. The items of Column 8 multiplied by the factor 826 will give the items of Column 9.

While the factor 826 tons may fairly represent the average yield for the whole basin in the past, it will not necessarily be correct for the special areas, particularly in the future when more mining is done in deeper parts of the basin.

The conditions under which coal is mined have a direct effect upon the yield per acre, where the conditions are favorable (North of Scranton for instance), light covering over the coal, few surface improvements, little trouble from gas, etc., etc., more tons per acre can be won than in the Wilkes-Barre region where the beds are deep and gassy, surface either much improved or covered by deep gravel deposits filled with water, that will flood the mine if the roof is cracked, thus requiring stronger pillars, better ventilation and more careful mining in every way.

Column 10 is intended to show the approximate quantity of clean coal wasted in mining and preparing the coal for market. (The slate, bone, and other refuse being fully accounted for above under head of Column 6.)

In 1890 and '91 The Clear Spring Coal Company produced 342,523 tons of coal; and 66,532 tons of culm (including all the buckwheat coal) went to the culm pile, *i. e.*, the culm was about 19·7% of the total production, this seems to agree fairly well with the experiments made by the Lehigh and Wilkes-Barre Coal Company as published in Report A, of the Geological Survey of Pennsylvania, page 56, where the average percentage of waste for old style rolls is shown to be 15·7% of quantity charged into the breaker or 19·8% of the coal shipped. And on page 123 another experiment shows the culm to be 21·4% of shipments. The average of these percentages shows the culm to be 20·3% of the production.

Of course in cases where the buckwheat and birdseye are taken out the percentage is much reduced; this is now being done to a large extent: quite a saving is also made by using the more improved machinery. On the other hand all of the pea coal and much of the chestnut formerly went to the culm pile, so that the factor 20 per cent. of the production, or 165·2 tons per foot per acre as used in this column cannot be considered as excessive for the waste in the past.

	No. of bed sections.	Total thickness of beds.	Total thickness of refuse.	Per cent. of refuse.
Wilkes-Barre and Plymouth District	61	593·01 feet	115·1 feet	19·46
Pittston District	28	236·91 "	43·3 "	18·46
Scranton District	33	322·72 "	57·5 "	17·85
Total	122	1152·64 "	21·59 "	18·75

Column 11. By deducting the sum of factors used in Columns 9 and 10 from the factor 1400 we have 408·8 as the percentage of coal per foot per acre now remaining in the ground in the areas that have been mined over, it exists in the form of solid pillars, and coal wasted with the "gob" or mine refuse. While part of this area has been worked out there are still considerable areas where much coal can yet be won by robbing these pillars, but no account has been taken of this item in the table.

By deducting the items of Column 7 from those of Column 5 we obtain the items of Column 12, and using these as a basis we obtain the items of Columns 13 and 14 from it, in same way as Columns 6 and 9 were obtained by using Column 5.

In Column 14 in view of the facts referred to under Column 9, as to the effect of the conditions under which the coal is mined upon the yield per acre, we have thought best to use a larger factor, *i. e.*, 900 tons for the yield per acre for areas North of Scranton where the conditions are more favorable for mining in the future.

For the Scranton and Pittston districts 800 tons per acre is used, and for the lower end of the basin 700 tons, as this is about all that can be obtained under the present conditions, methods of mining, etc.

From the footings of Columns 13 and 14 we see that the result of the estimate is that something over half the solid coal remaining in the ground can be mined.

Column 15 shows the production of the several districts for each year for the past five years, together with the percentage of the total output that each has produced.

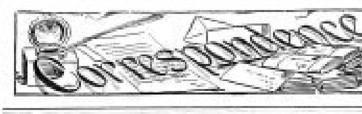
Column 16 shows approximately the probable life of each district at present rate of production, also the percentage of total quantity of coal in the field that each district possesses.

The greatest portion of the mining in the past has been at those points where the coal was thickest, best and most accessible, where the mining could be done at the greatest profit to the operator, and those parts where the beds were thinner have been left for the future, and hence the items in Column 4 which represent the average thickness of beds for the whole district, may be less than the average thickness of same beds for area worked in any particular district, while at the same time they may be more than average of the unworked areas. In this case the quantity of coal we have credited to the unworked areas would overrun because the beds would not be as thick as estimated. In view of this therefore the estimate may be somewhat excessive. On the other hand future developments may prove more and better coal than has been anticipated in portions of these unworked areas.

In addition to this, the experience and methods of mining that have prevailed in the past (and upon which our estimate is based), which have been to say the least very wasteful, may be very much improved in the future, so that larger yields per acre will eventually be obtained from the unmined areas, and the worked and abandoned parts of the region may be partially remined and thus increase the quantity of available coal above our estimate.

WM. GRIFFITH.

Scranton, Pa., April 20, 1892.



This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.

"Watercracks" in Steel.

Editor Colliery Engineer:

SIR:—I would esteem it a favor if some of your correspondents would answer the following question: Is there any remedy for what are called "watercracks" in steel (especially rock drills), tempered in water?

Yours, etc.,
BURLEIGH.

Nanaimo, B. C., March 31st.

Ventilation.

Editor Colliery Engineer:

SIR:—In replying to "H. L. D. W.," of Cincinnati Ohio, in your January issue, I would like to transpose his order of questions, taking *a* as the 300′ at outlet, *b* the 300′ in the middle, and *c* the 300′ at the inlet.

(*a*.) Now for the 6,000′ × 5′ × 8′, we have

$$p = \frac{k\,s\,v^2}{a} = 5·2893 \text{ lbs.}$$ pressure per square foot of area, and for the 300′ × 5′ × 2′, 9·114 lbs. pressure per square foot of area. Then, the total pressure for the 5′ × 8′ × 6,000′ portion = 211·57 lbs., and for the 5′ × 2′ × 300′ = 91·14 lbs.

211·57 + 91·14 = 302·71 lbs. total pressure.

The total pressure at inlet would equal $\frac{302·71}{40}$ = 7·5677 lbs. per sq. ft. The units of work for the 6,000′ part are found by multiplying the pressure by the quantity, or $p\,q$ = 75677 *u*, and for the 300′ part $p\,q$ = 91140 *u*, making a total of 166,817 units, or about 55 H. P.

(*b*). In this case we have three sections, the last section requiring a pressure of 2·6446 lbs., the middle section *alone* requiring 9·114 lbs., but having a total of 105·786 lbs. pressure to overcome at the first section. The pressure at the entrance of the 300′ section equals

$\frac{105·786 + 91·14}{10}$ = 19·6926 lbs., also the 1st 3,000′ takes a pressure of 2·6446 lbs., by adding the separate totals we find the total at inlet to be 302·71 lbs., which equals 7·5677 lbs. per sq. ft. as in case (*a*); but it is different with the power, the units in last section = $p\,q$ = 26,446; for the middle 196,926, and for the first section 75,677, or a total of 299,049 units which equals about 9 H. P.

(*c*). Now in this case we have 300′ at inlet employing 9·114 lbs. pressure per sq. ft., or 91·14 lbs. total pressure, but having the 211·57 lbs. pressure of the 6,000′ section to overcome. This makes a total of 302·71 lbs. for the 10 sq. ft., which equals a pressure of 30·271 lbs. per sq. ft. at inlet, and 5·2893 lbs. at entrance of the 6,000′ × 5′ × 8′. The units of work for each would be 302,710 and 52,893 respectively, or a total of 355,603 units, or 10·7 H. P.

To find the quantity that would be obtained from the above pressure, the whole length being 6,300′ and the area 5′ × 8′, we use the formula

$$Q = \sqrt{\frac{p\ a}{k\ s}} \times a.$$

I am well aware of the apparent anomaly in the power in the three cases, but the more one looks at it the more we find it is only apparent. This shows the folly (not to say wilful waste of power) of having small inlets with long air courses.

Yours, etc.,
J. V.

Punxsutawney, Pa., March 21st.

Mechanics.

Editor Colliery Engineer:

SIR:—Please insert the following in reply to "J. T. G.," of Braidwood, Ill., in your September issue:

On an incline rising 1 in 10, the loads weighing 12,000 pounds and the empties 3,000 pounds, the drums, ropes, and sheaves 5,000 pounds; the friction of the cars equal 1% of their weight, and the friction for drums, ropes, and sheaves $\frac{1}{400}$ of their weight. When they are being let down by a brake, it takes 4 minutes to run 300′, now what is the amount of friction applied by the brake?

The total friction is found to be 275 lbs. as follows:

$12,000 \times \frac{1}{100}$ = 120 lbs., friction of load.

$3,000 \times \frac{1}{100}$ = 30 lbs., friction of empties.

$5,000 \times \frac{1}{400}$ = 125 lbs., friction of drums, ropes, etc.

275 lbs., total friction.

$\sqrt{\frac{30}{16·1}} \times \frac{300}{30}$ = 13·65 seconds theoretical time; and 12,000 − 3,000 = 9,000 lbs. load overbalancing the empty sets.

$\frac{9,000 \times 30}{300}$ = 900 lbs., the power acting vertically that will hold the load on the plane independent of friction.

Also

$\frac{900 \times 13·65}{900 - 275}$ = 19·656 seconds the actual time if the brake were not applied.

The total friction is found thus,

$900 - \left(\frac{900 \times 13·65}{240 \text{ seconds}}\right)$ = 848·8125 lbs. total friction, then

848·8125 − 275 = 573·8125 lbs. friction applied by the brake.

Therefore,

$\frac{900 \times 13·65}{900 - 848·8125}$ = 240 seconds, actual time when the brake is applied.

Yours, etc.,
F. B.

Maccan, N. S., March 25th.

Examination Question.

Editor Colliery Engineer:

SIR:—I submit the following solution in reply to question by "J. W. S.," of Westville, Pictou Co., N. S., in your July, 1891, issue.

"A furnace at the bottom of a shaft 400′ deep produces 15,000 cubic feet of air per minute with 5·2 lbs. pressure per square foot. The temperature in the downcast shaft is 40° F., what is the temperature in the upcast shaft?"

Solution: 5·2 ÷ 400 = ·013 lb., or one cubic foot of air in the upcast weighs ·013 lb. less than one cubic foot of air in the downcast. A cubic foot of air at 40° weighs

$\frac{1·3253 \times 30}{459 + 40}$ = ·079677; then ·079677 − ·013 = ·066677 weight of one cubic foot of air in upcast shaft.

Therefore

$\frac{1·3253 \times 30}{·066677}$ = 596·44 − 459 = 137·44°, the required temperature in the upcast. This result can be proved by reversing the operation.

Yours, etc.,
THOS. J. SIMPSON.

Osceola Mills, Pa., March 28th.

Specific Gravity of Gases.

Editor Colliery Engineer:

SIR:—I submit the following in hopes that it will give "Miner," of Uniontown, Pa., some insight into the specific gravity of gases:

The relative weight is a term used in chemistry whereby it is shown that the specific gravity of a compound gas is not the mean or average weight of the constituent atoms in the molecule, but a weight resulting from the condensation of a group of atoms of hydrogen. For example: Carbon dioxide = CO_2, now here we have three atoms and if no condensation resulted, the molecular weight would be

$$\frac{C + O + O}{3} = \frac{12 + 16 + 16}{3} = 14\tfrac{2}{3}.$$

The true relative weight, however, is

$$\frac{C + O + O}{2} = \frac{12 + 16 + 16}{2} = \frac{44}{2} = 22.$$

From this we get the general law at once simple and and easy to deduce. All the compound gases found in mines have a relative weight, which is found by dividing the sum of the weights of the constituent atoms by two.

To atmospheric air the above law does not apply as air is a mechanical mixture. Nitrogen and oxygen are mixed in the following proportions by weight: Nitrogen, 77; oxygen, 23; and as N = 14 and O = 16, it follows that the specific gravity of air when weighed against hydrogen is

$$\frac{79 \times 14}{100} + \frac{21 \times 16}{100} = 14·42,$$

which means that $\frac{77}{100} \times 14$ added to $\frac{23}{100} \times 16$ will give the specific gravity of air.

We find, then, in mine ventilation we have to deal with five elementary bodies—nitrogen, oxygen, hydrogen, carbon, sulphur, and seven compound gases, viz.: Carbon monoxide, carbon dioxide, hydride of ethyl, methyl hydride, watery vapor, hydrogen sulphide, nitric oxide, and one mechanical mixture, atmospheric air. The specific gravities of gases are found by weighing them in equal volumes against hydrogen, thus H = 1, then carbon monoxide = 14; methyl hydride = 8; hydride of ethyl = 15; watery vapor = 9; carbon dioxide = 22; hydrogen sulphide = 17; nitric oxide = 15; and atmospheric air = 14·42.

Yours, etc.,
WM. STUBBS.

Frugality, Cambria Co., Pa., Apr. 5th.

Ventilation.

Editor Colliery Engineer:

SIR:—Having examined the answer of "T. S. C." to question of "R. R. S.," of Winburne, Pa., in the September, 1891, issue, I am at a loss to see the method by which he attains the results.

"T. S. C." claims that the answer given by "S. U. P." in August issue is too great a quantity, as it would require a pressure of more than 16 lbs. to pass 12,962 cubic feet of air per minute in the question given.

"T. S. C." begins by saying that the question can be answered in several different ways and for which he submits two, but I fail to comprehend the meaning of his formula.

I have several books on ventilation and have carefully searched for the formula in question, but cannot find it.

I took the formula given in Fairley's book where a road of various dimensions can be reduced to a uniform or typical road that will offer the same resistance and took the quantity as found by "S. U. P.," but did not find anything like the pressure, viz., 16 lbs.

I will be obliged to "T. S. C." if he will kindly inform me in what book to find the formula used by him, as it appears that either Mauchline or "S. U. P." must be wrong.

Yours, etc.,
X. Y.

Nanaimo, B. C., Apr. 4th.

Mensuration.

Editor Colliery Engineer:

SIR:—Replying to "L. P. H.," of Avoca, Pa., in the April issue, I beg to submit the following:

The "flat bottomed-kettle" would be in shape a frustum of a cone, and, as such, the formula for finding its contents would be $\frac{a}{3}(B + b + \sqrt{B \times b})$, a, being the altitude, B = the area of large base and b = area of small base. If we let $25\,x$ = B and $9\,x = b$ and substituting the known quantities we have the equation:

$$\frac{12}{3}(25\,x + 9\,x + \sqrt{25\,x \times 9\,x}) = 3{,}666 \text{ cubic inches}$$

which is the number of cubic inches in a score of gallons, less seven, of 282 cubic inches each. $25\,x$ and $9\,x$ are selected because the diameters of the bottom and top are to each other as 5 is to 3, and circles are to each other as the squares of their diameters. The above equation becomes successively

$$\frac{12}{3}(25\,x + 9\,x + \sqrt{225\,x^2}) = 3{,}666$$
$$4\,(25\,x + 9\,x + 15\,x) = 3{,}666$$
$$100\,x + 36\,x + 60\,x = 3{,}666$$
$$196\,x = 3{,}666$$
$$x = 18{\cdot}7$$
$$9\,x = 168{\cdot}3 = \text{area of top in inches.}$$
$$25\,x = 467{\cdot}5 = \text{area of bottom in inches.}$$

As the area of a circle is equal to the diameter squared multiplied by ·7854, if we divide 168·3 and 467·5 by this number we get 214·28 and 595·24 respectively, and then extracting the square root we have 14·6 + inches and 24·4 + inches as the top and the bottom diameters of the kettle.

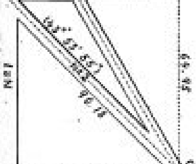
Yours, etc.,
COAL.

Pratt Mines, Ala., April 11th.

Mensuration.

Editor Colliery Engineer:

SIR:—Please publish the following in answer to John Cayar, of Gervias, Ohio: In the sketch No. 1 represents the main gangway of a mine, a breast, A B is opened off from it at right angles and is 25 yards long. From B it runs to C, a distance of 75 yards, and at an angle of 60°. At C it intersects gangway No. 2, now what is the length of No. 2, or from A to C, and what is the angle?



The following rule will answer for all cases of this kind:

R : h :: sine : P or, 64·95
R : h :: cosine : B or, 37·50
B : R :: P : tang., or 43° 53′ 55″, and sine : P :: R : h, or 90·13 yards.

Yours, etc.,
RICHARD LEWIS.

Gasford, Pa., Apr. 15th.

The Co-efficient of Friction.

Editor Colliery Engineer:

SIR:—I think your editorial on "The Co-efficient of Friction," in your April issue, was very timely and to the point. I have no doubt but what the majority of your readers fully agree with you, and thank you for the stand you have taken.

The co-efficient of friction, as formulated by some of the authors, has long been a stumbling block for the average miner to understand and correctly figure out.

Looking at the value of k, as given by the different authors, in the table published by you, we again find the usual disagreement among experts. Some of the figures seem to be founded more on the hair-splitting theory than on actual facts. Naturally we might expect to find considerable difference among authors as to what ought to be the proper co-efficient, on account of the variable and changeable condition in the rubbing surface found in mines. Take our Anthracite mines for an example: From a large roomy gangway, at a comparatively slow velocity, the air current might have to travel behind a brattice, or up behind man-ways, and through small cross-cuts, and finally through a small or partially obstructed return air-way. Even under most favorable conditions, in actual practice there exists no cause or reason why the co-efficient should be carried to the sixth or seventh decimal, except ambiguity or confusion is the aim. It is, of course necessary to make it high enough to cover any ordinary condition, found in actual practice. When the motive power is sought for, it is generally economy, and always desirable, to have ample power. Atkinson's co-efficient, as improved by you, I think is amply sufficient, simple, easily understood; and, until actual experience and demonstration has established a more correct one, ought to be generally used and accepted.

Yours, etc.,
JAMES BOHLIN,

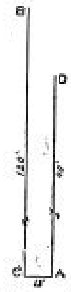
Freeland, Pa., April 23d.

Mensuration and Mathematics.

Editor Colliery Engineer:

SIR:—Will some of your able correspondents kindly answer the following questions:

(1.) Two entries are driven parallel to each other as shown by the diagram, now, wishing to drive from A



to B and from C to D, what would be the distance from A C to where the lines would cross each other?

(2.) A coal barge full of Bituminous coal displaces 6,625 cubic feet of water, how many tons of coal does the barge contain?

Yours, etc.,
R. L.

Gasford, Pa., April 13th.

Pumping.

Editor Colliery Engineer:

SIR:—The following question was asked in the August issue of your journal: "In a shaft 100′ deep, a pump is placed with 5″ suction and 95′ discharge. Will it require more or less power if the pump is placed up the shaft with 20′ suction and 80′ discharge?"

The question has been answered by a number of your correspondents and I think shown and proven in a plain simple manner that the power would be one and the same in both cases. In the March issue C. Walters, of Leisenring No. 1, Pa., explodes the whole theory of pumps by stating that as the 15′ more suction needs no power to bring the water up to the pump, only the power to overcome the extra friction of the extra suction, that the weight of water being less in the discharge pipe would need less power to discharge it and would result in a shorter steam line."

I would like (as, no doubt, would many others of your correspondents) to know how Mr. Walters can lift water 15′ without using any power. It is contrary to the laws of nature, and I would like to see it explained. As the question, as answered by Mr. Walters, would be misleading to some of your readers, I think a reply to it is called for. That water has weight no one will deny, and to talk of raising it without power is wrong. Steam-lines should be shortened where possible without interfering with any other part of the work. In this case the shortening of the steam line 15′ would be a little benefit, if it were not for lengthening the suction pipe, but as it is almost impossible to make a suction pipe of a pump air tight. I think the shortening of the steam line would not compensate for the lengthening of the suction. In the 15′ suction there would be more places for leaks to occur and a very small leak would make quite a difference in the amount of water discharged, and I will stand by my first assertion that the 5′ suction would give best results. Hoping to hear from Mr. Walters I remain,

Yours, etc.,
J. N. K.

Mansfield Valley, Pa., March 17th.

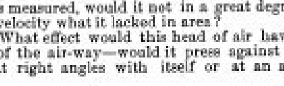
Ventilation.

Editor Colliery Engineer:

SIR:—Please insert the following questions that some of your readers may give their views concerning them:

(1.) A mine is ventilated by exhaust fan; distance from fan to incast is 1500 yards, air measure at incast is 12,000 cubic feet per minute; area, 84 sq. ft. Now what amount of air should be measured at upcast, and if the area was smaller at upcast, where the air was measured, would it not in a great degree make up in velocity what it lacked in area?

(2.) What effect would this head of air have on the walls of the air-way—would it press against the air-way at right angles with itself or at an angle be-



tween 45° and 90° in the direction it is traveling; or would it produce a suction instead of a pressure on the walls of the air-way (see diagram), and would pressure or suction be the same at inlet as at outlet, other things being equal?

(3.) Would it be possible at any time of the year for a hole or holes broken through to surface at any point between the incast and upcast of this mine to become the upcast for the air as long as the fan produced this amount of air, and the air traveled in the mine mouth?

Yours, etc.,
READER.

Mutual, West'd Co., Pa., Mch. 28th.

Ventilation.

Editor Colliery Engineer:

SIR:—I submit the following reply to "Alberto's" question, No. 4, which was published in March number of THE COLLIERY ENGINEER: "The main entry of a mine divides into two entries, each of which extends to the surface. If the pressure in main entry is 4 lbs. per sq. ft., what is the pressure in the two drifts?" As the pressure will vary inversely as the area, it will be necessary to assume the size of the entry, also the two drifts, therefore assuming the size of main entry to be 6′ × 14′ = 84 sq. ft. area, and 6′ × 8′ each for the two drifts, would = 6′ × 8′ × 2 = 96 sq. ft. area for the two roadways, or entries. Then as 96 : 84 :: 4 : x or 3·5 lbs. pressure per sq. ft. of sectional area of the two drifts.

Yours, etc.,
T. K.

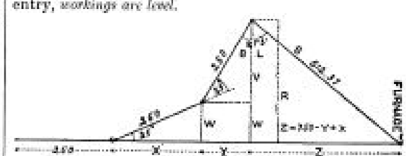
Mount Olive, Ill., April 12th.

Surveying.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to question by Miner, of Elk Garden, W. Va., in the March issue:

A main entry running 1,000′ due East has a furnace at the East end. Through carelessness the entry has been closed; desiring to get back to the furnace we go into the main entry 250′ from the West end and turn to the North 25° and run 250′ then turning 35° still further North, we run 250′ more. Now, I would like to know the degree of bearing from last given point and what the difference of travel would be from mouth of entry, *workings are level.*



In solving the problem we use the following formulæ:

x = 250 cosine 25°	w = 250 sine 25°.
y = 250 cosine 60°	v = 250 sine 60°.
Sine 25° = ·4226	x = 250 × ·9063 = 226·575.
Sine 60° = ·8660	y = 250 × ·500 = 125·000.
Cos. 25° = ·9063	w = 250 × ·4226 = 105·650.
Cos. 60° = ·500	v = 250 × ·8660 = 216·500.

Then

$$z = 750 - (226{\cdot}575 + 125{\cdot}000) = 398{\cdot}425.$$
$$R = w + v = 105{\cdot}650 + 216{\cdot}500 = 322{\cdot}150.$$
$$S = \sqrt{z^2 + R^2} = \sqrt{398{\cdot}425^2 + 322{\cdot}150^2} = 512{\cdot}37.$$

$$\text{Tan. L} = \frac{z}{v} = \frac{398{\cdot}425}{322{\cdot}150}\ 1{\cdot}2368 = 51°\ 3', \text{ nearly,}$$

and 51° 3′ + 30° = 81° 3′. S = v secant 51° 3′ = 322·150 × 1·5908 = 512·37.

The difference in travel will be 250 + 250 + 250 + 512·37 = 1262·37′ − 1000′ = 262·37′, distance on main entry.

Yours, etc.,
W. S G.

Walls, All'y. Co. Pa., March 21st.

Ventilation.

Editor Colliery Engineer:

SIR:—Will you please insert the following plan of a mine so that some of your correspondents may show the best way of ventilating it:

I would like it ventilated without doors being used, and so that both sides of the mine could be worked at the same time. Either No. 1 or No. 2 may be used as the downcast shaft.

Yours, etc.,
STRAGGLER.

Mineral Ridge, Ohio, March 31st.

Crushing Strength of Coal.

Editor Colliery Engineer:

SIR:—Can any of your readers inform me where I can find particulars of any reliable tests on the strength of various qualities of coal to resist crushing or compression? If any of your correspondents would kindly contribute particulars of any tests made by them (describing also the kind of coal), it would, I feel sure, be a great boon if published in the columns of THE COLLIERY ENGINEER.

Yours, etc.,
LONGNECK.

Grape Creek, Ill., Feb. 25th.

Mechanics.

Editor Colliery Engineer :

SIR:—Please insert the following question in your Correspondence Department:

If a mine car weighing 4 tons be suspended by a rope on rails at an angle of 45°, what weight will be on the rails and what weight will be on the rope?

Yours, etc.,
JOHN MOSES.

Jeddo, Luzerne Co., Pa., Apr. 25th.

Ventilation.

Editor Colliery Engineer :

SIR:—I submit the following in reply to question by "Practical Fact," of Plains, Luzerne County, Pa., in your March issue:

Before the fan stopped, the gangway and return was clear from gas. The stopping of the fan allowed the gas to gather in a body which formed like that of a battery against the air which was the obstruction in the way and for said reason the air took the shortest and easiest way to the fan. After headings A, B, C, D, E, F and G, had been bratticed, the pressure of air at point O became greater than that of the gas, consequently the gas was cleared away leaving the air-course and gangway clear for the air to travel through at the same time taking the pressure from the closed headings.

Yours, etc.,
J. E. B.

Glen Carbon, Schuylkill County, March 21st.

Specific Gravity of Gases.

Editor Colliery Engineer :

SIR:—I submit the following rule in answer to "Miner," of Uniontown, Pa., in the April issue:

The specific gravity of a gas is the proportion which exists between its weight and that of an equal volume of distilled water at an equal temperature and pressure. One cubic foot of water at 32° F. and bar. 30″ weighs 62·355 lbs.; one cubic foot of air under the same conditions weighs ·0809749 lb., now if we divide the weight of one cubic foot of air, or of any gas, we will get the specific gravity, thus—·0809749 ÷ 62·355 = ·001298, the specific gravity of air. In the same way computing the weights of one cu. ft. of CO_2, O, and N, we find their specific gravities to be respectively:

·123353 ÷ 62·355 = ·001978 sp. gr. CO_2.
·089255 ÷ 62·355 = ·001431 " " O.
·078416 ÷ 62·355 = ·001257 " " N.

If "Miner" wishes to obtain a simple formula taking air at 1·000 he will find it in Wardle's book, p. 35.

Yours, etc.,
M.

Bevier, Mo., Apr. 15th.

Eleven Miners Drowned.

By a body of water that had collected in old workings breaking through the pillar into the workings of the Lytle Coal Co.'s colliery, near Minersville, Schuylkill Co., Pa., eleven men were drowned on the 21st ult.

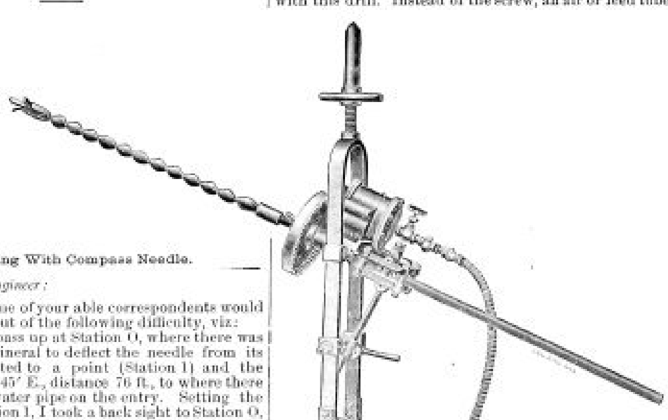
The Lytle Coal Co. were at work opening a colliery at a level lower than that which had been worked years ago, and which had been allowed to fill with water. Considerable of the water in the old workings had been pumped out before work was commenced on the coal lower in the basin. The water that caused the disaster was dammed back by falls, and was not drained off by the pumps.

As a precaution against accident, drill holes were kept in advance of most of the live workings to insure safety. There were no maps of the old workings in existence, and this made the officials extra cautious. But the break occurred at a point where it was least expected and there were no drill holes. It came so suddenly that Thomas Buggy, James Dolbin, John Zerbey, and eight Italians were drowned. The bodies of the drowned men were not recovered for several days, as the amount of water that caused the damage was larger than was at first supposed, and considerable pumping was required before exploring parties could enter. The last body was recovered on April 26th, and the funerals took place on the 27th. Foreman Adams of the colliery was untiring in his efforts to recover the bodies, and with no thought of his own safety, performed heroic work in his efforts to recover the bodies of the unfortunate men. In his work he was ably assisted by a corps of hardy men, always ready to follow where he led. The accident was an entirely unforseen one, as the officials of the colliery had taken every precaution they thought necessary to avert such a disaster.

It was entirely due to the lack of surveys in the old workings, which were operated when the mine surveyor was almost an unknown personage in the Anthracite regions. Had there been even an approximately correct map of the old workings the accident would not have occurred.

Jeffrey Giant Drill.

The accompanying illustration represents the Jeffrey latest improved Power Drill which will be known as their "Giant Drill." The general construction of the frame is the same as the drills heretofore furnished and which are now used largely throughout the coal fields. The Giant Drill, so called on account of the increased power derived from the new pattern of engine used, consists of a double rotary valve engine which in actual service develops great power with a minimum amount of air. This feature is covered by patents and users of the drill will get the benefit of this improvement which will be of great importance. A new, as well as simplified feed arrangement has also been added, making this drill without doubt superior to any power drill yet offered. An air feed can also be used with this drill. Instead of the screw, an air or feed tube



is substituted, being operated by air, the feed is not positive, which allow the auger or drill bit, to advance slowly, when striking an unseen sulphur ball, or hard cutting, thus preventing more or less strain. The manufacturers, The Jeffrey Mfg. Co., of Columbus, Ohio, are to be congratulated on their success which has been achieved with these drills and as a further inducement they now offer these at prices which are about 25 or 30% lower than formerly quoted.

Surveying With Compass Needle.

Editor Colliery Engineer :

SIR:—I wish some of your able correspondents would enable me to get out of the following difficulty, viz:

Setting the compass up at Station O, where there was no iron or other mineral to deflect the needle from its true course, I sighted to a point (Station 1) and the needle read S. 33° 45′ E., distance 76 ft., to where there was some 4-inch water pipe on the entry. Setting the compass up at Station 1, I took a back sight to Station O, and the bearing read N. 39° 30′ W., a difference of 5° 45′ between the foresight and backsight of Station O and 1, I desire to start an entry at Station 1, where the iron pipe is (and which deflected the needle 5° 45′ out of its true course) to go on a true bearing of S. 58° E. Now what I want to know is whether I should add the 5° 45′ to S. 58° E. and start the entry at S. 63° 45′ E. or subtract the 5° 45′, and start the entry S. 52° 15′ E. so as the entry will be going on a true needle bearing of S. 58° E. when it gets away from the influence of the iron pipe.

Yours, etc.,
YOUNG SURVEYOR.

Pomeroy, Ohio, Apr. 20th.

Specific Gravity of Gases.

Editor Colliery Engineer :

SIR:—In answer to "Miner," of Uniontown, Pa., in your April issue, I would refer him to Mauchline's book, p. 10, where he will find the rule he wants. If he hasn't that book, however, it can be found by proportion as follows:

14·4 : 8 :: 1 : ·555, the specific gravity of fire-damp; 14·4 being the atomic weight of air, 8 the atomic weight of CH_4, and one that of H.

Also, the specific gravity is found by dividing the atomic weight of gas by the atomic weight of air, thus for carbonic acid gas—22 ÷ 14·4 = 1·527, specific gravity.

Yours, etc.,
L. P. H.

Avoca, Pa., Apr. 19th.

Mine Inspectors' Examination at Olympia, Wash.

An examination of applicants for State Mine Inspectorships was held at Olympia, Washington, on Jan. 17th. The Board of Examiners was composed of D. T. Davies, Supt. of Carbonado Mines; Morgan Morgan, Supt. of Black Diamond Mines; S. Ronald, Supt. of Roslyn Mines; Oscar Huber, Mining Engineer of Spokane; Mitchell Love, Miner, of Renton; T. Ismay, Miner, of Bucoda, and Wm. Richards, Miner, of Roslyn. There were eight candidates. The two successful applicants were David Edmunds, of Franklin, and Joseph James, of Carbonado. Both of the successful applicants were one time students in the Drifton, Pa. School of Mines.

COLLIERY IMPROVEMENTS.

Colliery Owners, Superintendents, Mining Engineers, Contractors, and others are respectfully requested to inform us as early as possible of all improvements contemplated at their mines. We desire to make this department as complete as possible.—*Editor.*

*** The Lehigh and Wilkes-Barre Coal Company Elmer H. Lawall, General Superintendent, Wilkes-Barre, Pa., will shortly make some important improvements at Lance, No. 11, Colliery. Among the changes will be the erection of one 100 H. P. Dimmick & Smith boiler; the erection of annexes on each side of the breaker, which will increase its capacity from 40 to 75 cars per day; the erection of an additional chestnut and stove coal screen, and the remodeling of the dust fan in the breaker. The shaft will be continued to the Ross seam, a new fan 12 ft. x 35 ft. will be erected, and there will be important changes made in the ventilation of the inside workings.

*** At the collieries of the Silver Brook Coal Company, at Silver Brook, Pa., the following improvements have been made or are in progress under the supervision of Mr. H. C. Zacharias, Superintendent and Engineer of the company:

No. 1 Colliery.—In No. 1 slope from main west gangway, an inside slope has been sunk 30 yards to the first lift, and 90 yds. to the second lift. It is now being sunk to the basin. The self-acting plane has been extended 100 yards. A new slope, called No. 2 Slope, 800 yards southwest of the breaker, has been sunk 140 yards on the No. 6 seam. Two lifts are turned off on the west side, and one on the east.

No. 4 stripping has been opened up, and the removal of the surface for a new stripping on the Mammoth seam is in progress.

A 100 H. P. Dimmick & Smith boiler has been added to the steam plant and extensive repairs and alterations have been made to the breaker, thereby greatly increasing the facilities for preparing the coal.

No. 2 Colliery.—The Slope on the No. 6 seam is now down 240 yards to the basin. The first lift is turned off to the west and the lower lift east and west.

A large area of the Mammoth seam has been uncovered at the stripping started in November, 1890. The new breaker which is in course of erection will be completed in ample time for the fall trade. It is being fully equipped with first-class modern machinery.

A 500 H. P. Babcock & Wilcox boiler, and a pair of 22″ x 36″ hoisting engines with double drums have also been erected.

*** The Peel Splint Coal Company, of Lewiston, West Va., Mr. Z. T. Krieger, General Manager, is laying 3,300 ft. of steel rail around the hill, and in the main entries of the mine. This will result in changes that will increase the capacity of the mine 200 tons per day, and will enable the officials to more economically and expeditiously handle the output.

*** Mr. George Prentis, of Canon City, Col., the Superintendent of the Prentis Coal Mine, is making some radical changes in the methods of mining. He is erecting an air compressor and putting in a number of mining machines.

*** The Leavenworth Coal Company, of Leavenworth, Kansas, Mr. J. E. Carr, General Superintendent, has just completed the erection of a large 25-foot fan, built by the Vulcan Iron Works, of Wilkes-Barre, Pa. This company has also remodeled the shaft head and all cars are handled by machinery operated by a 10 H. P. engine. The machinery is worked by paper friction wheels and rack gear. There are 9 levers, all centering at one point, and arranged to be worked by one man. This machinery was designed by the officials of the company.

*** The Coal City Mining Company, of Coal City, Ala., Mr. Wm. Herbert, Superintendent, is operating at present one slope with an output of 250 tons. The seam is four feet thick, of excellent quality, and makes a coke that is said by foundrymen and furnacemen to be equal to Pocahontas coke. Preparations are now being made to open another slope, and a 100 H. P. Lidgerwood engine is on the ground with two 50 H. P. boilers under construction for use at this new slope. This company intends to increase its output by next fall to 600 tons per day.

*** The H. G. Davis Coal Company, whose office is at Piedmont, West Va., and whose mines are at Thomas, West Va., under the management of Mr. H. G. Buxton, recently completed its second shaft. The main shaft 12′ x 24′ was commenced May 3d, 1891, and the coal was reached at a depth of 179 ft. 9 ins. on September 7th, 1891. The shaft passed through very hard sand rock for almost its entire depth, and it was timbered as the sinking progressed. The sinking of the air shaft, 14′ x 14′, was begun September 14th, 1891, and reached the coal at a depth of 187 ft. on January 21st of this year. Several delays were caused in each shaft by the breaking of pumps. The shafts were sunk to open the Davis seam, which lies 192 ft. below the Thomas seam, which was the only coal heretofore mined by this company, and which was opened by drifts. The coal of the Davis seam has an excellent reputation as a smithing, steam, and coke coal. The output is expected to reach 1500 tons per day by the beginning of next year.

*** The Gallitzin Coal and Coke Company, of Gallitzin, Pa., have lately been putting in a new basket for lowering the coal into the cars without breaking. They also have added an elevator to carry the slack and a car haul operated by rope transmission. This machinery was constructed and installed by the Link Belt Engineering Company, of New York. It handles the coal rapidly and economically.

*** Mr. Jacob Stineman, at South Fork, Cambria county, Pa., contemplates putting in a new rope haulage plant 1500 feet in length in a dip and 1000 feet on the level, also a new 20 foot fan for ventilating.

*** Rapid progress is being made with the new shaft of the Consolidation Coal Company, near Lonaconing, Md. The shaft is known as a "square" shaft, having two sections 8x10 feet each. A Rand compressor engine of three drills capacity is used with the aid of the Ingersoll drill. The winding engine used is reversible, and is fed by two boilers of 85 horse-power each. Mr. R. S. Randolph, the efficient Superintendent of the company, is determined to make this shaft a model of its kind, and to this end is procuring only the most modern machinery.

*** Work on the large haulage plant at Big Soldier Run Mine, Reynoldsville, Pa., has been actively begun. The foundations for the boiler-house and engine house are being laid. The chimney is to be thirteen feet square at base and 100 feet high, and large enough to serve for six 100-horse power boilers. There is also to be erected an iron and steel tipple building 36 feet wide and 120 feet long.

PERSONALS

Mr. A. A. McLeod, President of the Philadelphia & Reading Railroad Company, is to-day perhaps the most prominent business man in America. He is not only the president of the great Reading corporation but is also general manager of its business. His rise to his present position has been phenomenally rapid. He first became connected with the company in November, 1886, having been appointed general manager by Austin Corbin, the then president, who recognized Mr. McLeod's great executive ability. On the resignation of Mr. Corbin as president of the company in 1890, Mr. McLeod was elected his successor, though he still retained the general managership. Under his direction the Reading company has made the most remarkable advances in its history. His foresight, energy and pluck led him to make innovations and extensions that to more conservative men were appalling in their scope, but results have proven the wisdom of his course. In personal appearance he is over six feet tall and splendidly proportioned. He has an erect firm carriage and is a striking figure in any assemblage of men. His features are large and regular, his forehead is broad and high, and his clean cut lips are shaded by a heavy brown mustache.

He wears no jewelry. His taste in personal adornment is exhibited in dark clothing of faultless finish and quiet style, neckwear of subdued colors and always a broad-brimmed beaver hat.

In his personal contact with individuals of all classes he is one of the most affable of men. There is a conspicuous absence of that brusqueness which is affected or becomes second nature, in men who represent great interests and to whom, above all others, time is money. A section foreman whose duties at some period of his life may call him to the president's office receives as much sincere attention and courtesy as does the official representative of a great corporation who may desire to discuss traffic arrangements with the head of the Reading Railroad.

His business habits are very methodical, and he is one of the first to reach the Fourth street offices of the company and the last to leave. Unless called away from the office on official business, he is at his office every day from 9 a. m. till 6 p.m. Naturally, a man having the direction of as much business as he has, must be protected from the interruption of callers desirous of seeing him on trivial matters or with chimerical schemes. Therefore all callers are received by his private secretary, Mr. Frank G. Odenheimer, who is uniformly courteous to all. If the business is of a nature that an interview with Mr. McLeod will expedite it, the interview is readily secured, and the business is rapidly disposed of. While Mr. McLeod is a thorough American by birth and education, his ancestry was Scotch, as is readily shown by his full name Archibald Angus McLeod.

Mr. Peter Sheridan, of Highland, Pa., has accepted the position of mine boss for Coxe Bros. & Co., at Oneida.

The Governor of Ohio has re-appointed Robert M. Hazletine, of Mahoning County, as Chief Inspector of Mines of that State for a term of four years.

Mr. Thomas H. Carey, who has been superintendent of the Woodward Colliery of the D., L. & W. R. R. Co., in Plymouth township since its start, has been placed in charge of the operations of the same company in Hanover township where a breaker still larger than the Woodward is to be erected. Mr. William Beacham, who has had charge of the Dodge Colliery near Bellevue, will succeed Mr. Carey at the Woodward.

Baird Halberstadt, E. M., recently connected with the coal department of the U. S. Census, but now Assistant State Geologist of Pennsylvania, is at work in the Eighth Bituminous district gathering data for a map of the Bituminous regions of the State.

Judge Rice, of Luzerne County, has appointed the following Boards to examine mine foremen in the Third, Fourth and Fifth Districts respectively. They will serve until the first term of Common Pleas Court, 1893:

Third District—S. B. Bennett, operator, West Pittston; Patrick A. Sweeney, miner, Pittston; John F. Evans, miner, Pittston.

Fourth District—Elmer H. Lawall, superintendent, Wilkes-Barre; Thomas Owens, miner, Plymouth; Patrick McGrane, miner, Sugar Notch.

Fifth District—J. C. Haydon, operator, Jeanesville; Michael Mulligan, miner, Upper Lehigh; John Scott, miner, Hazleton.

Mr. John L. Williams, of Shenandoah, Pa., Division Superintendent of the Philadelphia and Reading Coal and Iron Co., has resigned to accept the position of General Superintendent of the Union Coal Co., with headquarters at Shamokin, Pa., vice Mr. Holden Chester, who resigned on account of age, and a desire for relief from his arduous duties. By this change the Philadelphia and Reading Coal and Iron Co. has lost one of its most efficient officials, and the Union Coal Co. has secured a superintendent whose superior as a practical mine manager cannot be found. The writer's aquaintance with Mr. Williams began in 1875, when he occupied the position of Assistant Inside Foreman at Indian Ridge colliery. He was promoted from this position to the foremanship, and from the latter to that of District Superintendent on the death of John Reese, who lost his life with Jonathan Wasley and Frank Willman at Kehley's Run colliery. After serving about four years as District Superintendent of the Shenandoah District. Mr. Williams was appointed Division Superintendent, and had charge of all the Philadelphia and Reading collieries in the Mahanoy and Shenandoah Valleys east of Big Mine Run, 23 in all. Under his direction some of the most important coal developments in the Mahanoy Valley were made, and his mining ability was recognized on all sides. Our acquaintance with Mr. Williams has been a long and an intimate one, and we heartily wish him the same measure of success in his new position as he won in his past.

On the evening of the 30th ult. Mr. Williams was tendered a banquet by his associates among the officials of the Philadelphia and Reading Co., and Inspector Stein, at the Ferguson House, Shenandoah, Pa. The banquet was a very pleasant affair, and at opening District superintendent Elijah Gregory, on behalf of the company assembled, presented Mr. Williams with a beautiful case of drafting instruments in a neatly worded speech which expressed the sentiments of his associates in bidding an official farewell to Mr. Williams. Inspector Stein accepted the gift on behalf of Mr. Williams, and then the entire company joined in the banquet which was prepared by Landlord Hutchinson. At its close the entire company filed past Mr. Williams, shook him by the hand and wished him unbounded success and prosperity in his new field.

Mr. Thomas Mitchell of East Brady, Pa., President of the Diamond Coal Co., died on March 31st, aged 62 years. Mr. Mitchell was a native of England, and emigrated to America in 1854. In 1869 he was appointed General Manager of the Pittsburgh Coal and Mining Company's mines at Catfish, Pa. He discharged the duties of this position for ten years, and then, in company with James B. Stephenson, engaged in mining and shipping coal at Pine Run, near East Brady. After several years work, this mine was exhausted, and in company with his sons he secured coal lands on the Sligo branch of the Allegheny Valley Railroad and opened the Diamond mines. These mines are still in operation, and are now surrounded by other mines opened by parties who followed Mr. Mitchell in this region. During all the years that Mr. Mitchell was engaged in the coal business, he commanded the respect of all who came in contact with him. Honest and upright in all things, and of a kindly nature, he not only won the esteem of his business associates, but had the affection and esteem of his workingmen as well. Some of the latter who had removed to other fields traveled over 100 miles to pay a last tribute of respect and affection to their deceased friend on the day of his interment.

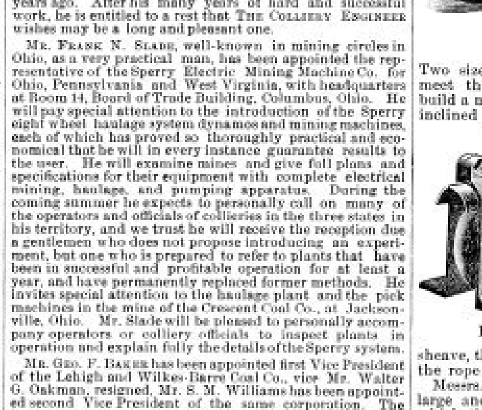
In the retirement of Mr. Holden Chester, of Shamokin, from the superintendency of the Union Coal Co.'s collieries, one of the best known men connected with colliery management in the lower region permanently retires from the business. For many years Mr. Chester was the superintendent of the Mineral Railroad and Mining Co.'s collieries, and when the late Hon. Wm. L. Scott leased from that corporation several of its largest mines purchased large tracts of anthracite coal lands and formed the Union Coal Co., he made Mr. Chester his general superintendent. Up to the time of his death he had unbounded confidence in Mr. Chester's ability, and when the latter spoke of retiring from active duty several years ago, Mr. Scott personally requested him to remain with the Union Co. until he could find an equally competent successor. Had it not been for this Mr. Chester would have retired from active work several years ago. After his many years of hard and successful work, he is entitled to a rest that The Colliery Engineer wishes may be a long and pleasant one.

Mr. Frank N. Slade, well-known in mining circles in Ohio, as a very practical man, has been appointed the representative of the Sperry Electric Mining Machine Co. for Ohio, Pennsylvania and West Virginia, with headquarters at Room 14, Board of Trade Building, Columbus, Ohio. He will pay special attention to the introduction of the Sperry eight wheel haulage system dynamos and mining machines, each of which has proved so thoroughly practical and economical that he will in every instance guarantee results to the user. He will examine mines and give full plans and specifications for their equipment with complete electrical mining, haulage, and pumping apparatus. During the coming summer he expects to personally call on many of the operators and officials of collieries in the three states in his territory, and we trust he will receive the reception due a gentlemen who does not propose introducing an experiment, but one who is prepared to refer to plants that have been in successful and profitable operation for at least a year, and have permanently replaced former methods. He invites special attention to the haulage plant and the pick machines in the mine of the Crescent Coal Co., at Jacksonville, Ohio. Mr. Slade will be pleased to personally accompany operators or colliery officials to inspect plants in operation and explain fully the details of the Sperry system.

Mr. Geo. F. Baker has been appointed first Vice President of the Lehigh and Wilkes-Barre Coal Co., vice Mr. Walter G. Oakman, resigned. Mr. S. M. Williams has been appointed second Vice President of the same corporation. The circulars announcing these appointments also states that Genl. Supt. E. H. Lawall will report direct to, and receive instructions from President Maxwell, and that the General Auditor and Purchasing Agent will report to, and receive instructions from second Vice President Oakman.

Friction Drums and Guide Sheaves.

Messrs. Thos. Carlin's Sons, of Allegheny, Pa., who have for years made a specialty of double friction drum power hoists, as used for tail rope system for operating derricks, and other works where power is obtainable either through sprocket chain or belting, herewith



illustrate their drums that have proved so successful wherever used. A driving pulley or other means of

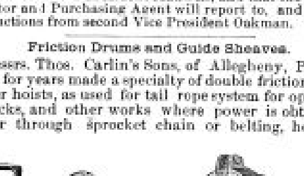


Fig. 1.

transmitting power is furnished with each hoist. Each drum may be fitted with foot breaks as shown, and cut heads or winches may be placed on the far end of the drum shaft, for use in some locations where it is desired to drag cars on side tracks.

When fitted for tail rope haulage, the several levers may be combined so that the operator may have perfect control of the machine by a hand and foot lever.

As will be seen in the cut, the gearing runs constantly, but the drums operate only when the friction levers shown in the front are moved. It is a very strong machine and takes up but little floor space.

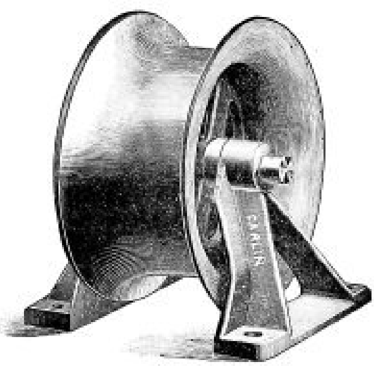

Fig. 2.

Two sizes are made and drums are constructed to meet the requirements. Messrs. Carlin's Sons also build a machine of the same general design for use on inclined planes, etc.

Fig. 3.

The pulleys shown by the three cuts, show their several designs of guide sheaves for use with wire rope haulage. It will be seen by reference to Fig. 1 that the vertical guide sheaves have a neat iron base plate, which can be bolted to the cross-ties. They are made in two sizes. The carrier sheaves (Fig. 2) with stands have chilled bearings and are very neat and strong. Fig. 3 shows a tail rope carrier sheave, the frame of which makes a guard that keeps the rope from coming out of the groove.

Messrs. Carlin's Sons have recently issued a very large and complete catalogue of their specialties, in which they illustrate and describe in detail all their products. It is a very complete work, and can be secured by actual purchasers on application.

Nothing Succeeds Like Success.

The invention of a piece of machinery is one thing. Its successful introduction is another. When an invention is such that it economizes labor and makes it possible to do more work with less cost, its introduction is comparatively easy. All that is needed is a good machine, and the faculty of making its merits known to those who will be benefited by its use.

The Cannelton Supply Co. of Cannelton, Beaver Co., Penna., have a good and cheap machine in the Grim Patent Coal Drill, and have brought it to the attention of the miners and operators in all parts of America through the medium of an advertisement in the columns of The Colliery Engineer during the past year. Mr. Heilman, the manager of the company, informs us that they have been very successful in introducing it into every coal field in America, and among the recent prominent purchasers who are using it with success are:

The Coahuila Coal Co. of Mexico, 16 sets, and the Winifrede Coal and Coke Co. of West Va. Messrs. Wolf, Lane & Co. of Pittsburgh, who represent the company in the Pittsburgh region disposed of 52 sets in March alone. The Short-Frick Mercantile Co., of Dillonvale, Ohio, who also handle these drills have in a comparatively short time disposed of over $900 worth of them.

They are largely used in the Anthracite regions and are particularly in favor in the Shamokin region. They are adapted to all kinds of coal, and need only a trial to ensure their permanent adoption. The following letter from one of the most prominent colliery officials in Pennsylvania, shows the favor in which the Grim drill is held:

Bell, Lewis & Yates Coal Mining Co.
Reynoldsville, Pa., Feb. 12th, 1892.

Cannelton Supply Co.
Cannelton, Pa.

Gentlemen :—

I am in receipt of your favor and will reply that at our mines at both DuBois and this place, we are using your drills and they have given us very good satisfaction We are not now in need of any more, but when we shall be in the market we will undoubtedly call on you as heretofore.

Yours truly,
S. B. Elliott, Gen'l Manager.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED 1881, INCORPORATED 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
ALEX. DICK, MINING ENGINEER, ASSISTANT EDITOR.
THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed

THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Scranton, Pa.

Cable Address—"Retsof, Scranton."

THE METROPOLITAN PRESS AND THE COAL COMBINE.

THE enterprise of the more prominent American daily newspapers, as a rule, is such that it excites the wonder and admiration of all intelligent readers. But there are subjects on which their writers generally display ignorance that under the circumstances is almost criminal. One of these subjects is coal.

The recent great union of coal roads was a matter that in the importance of its results, entitled it to the most careful investigation on the part of news writers before opinions regarding its effect were expressed. In regard to the capital invested, and the people directly affected, it was more important in many ways, to the general American public than any of the political changes south of the Rio Grande, or on the continent of Europe.

But, the subject of coal and coal mining has always been one on which the metropolitan news writers have as a rule displayed either amazing stupidity or a sensationalism that is only equaled by the literature distributed by dime museums or the peripatetic circus. Those unfamiliar with the technicalities of coal mining accept their false statements as gospel truths, while those familiar with the subject are impressed with the idea that if a newspaper will make such absurd and erroneous statements on one subject, it must also be unreliable on others.

The statements that are daily published attributing to the officials and stockholders of the several companies, a desire to corner the Anthracite coal market and force prices to a point that will be burdensome and that will practically drive consumers to the use of Bituminous coal, are ridiculous because it is unreasonable to suppose that those with capital invested in an industry will deliberately ruin it.

The Anthracite coal business for a number of years past has been such that except in a few isolated cases the cost of production was fully equal to or exceeded the price the coal brought on cars under the breaker. The great cost of Anthracite mining plants and the expenses connected with the mining and preparation of the coal, including the necessary drainage, ventilation, etc., are not understood by the metropolitan news writers, simply because they have never taken the trouble to inquire into details. The coal is limited in its supply, and when once taken from the mine is gone forever. A new crop cannot be raised the following year as with vegetable productions. This is another phase of the subject never taken into consideration.

Another point to be considered is the law of supply and demand. When the demand is not equal to the supply in any other branch of business, the supply is curtailed, and there is no reason why this rule should not be enforced regarding coal as other productions.

For years the men employed at the Anthracite collieries have been working but part time and at wages that are not such as they should receive. This was due to the low price paid for coal under the breakers. The operators can not afford to pay higher wages and the workingmen have gone on without resorting to strikes, which they knew could not benefit their condition.

The new state of affairs, it is hoped will remedy these conditions. Coal will either be mined at prices that will ensure a fair profit to the operator and fair wages to the miner, or it will not be mined at all.

It cannot be claimed that Anthracite is a necessity as breadstuffs are, for if it becomes too expensive, the cheaper Bituminous coal can and will take its place. The men at the head of the new deal understand this and they have too much hard business sense to advance prices enough to discourage consumption. Before jumping at conclusions it would be well for the New York dailies and their followers among the provincial journals to send conservative intelligent men into the Anthracite region to study the existing conditions and the policy of the corporations and operators interested. If they do this, and then base their editorial utterances on the facts gleaned, they will, if honest, commend rather than condemn a policy that is rational and equitable, and one that is designed to bring about a condition of affairs in the Anthracite region that will prove beneficial, not only to the capital invested in the coal business, but to every workingman and business man dependent upon the industry.

ANOTHER USE FOR COKE BYE-PRODUCTS.*

IN the production of coke by the crude method of the old oven, whereby the only product is coke, there is an enormous waste of valuable fuel under the name of bye-products.

The tar and tar oils, which are the result of coke manufacture, differ from the tar products of the gas works, but such difference as exists is not of material importance in some respects. It is perhaps inferior as a source from which the creosote oils can be made which seem best fitted for use in the preservation of railroad ties. But apart from this question of creosote, or of artificial manures there is the growing importance of tar as a fuel.

Under the head of liquid fuel we may include every combustible substance which will flow through pipes of an inch or two inches diameter when warmed, and in this category come practically all the bye-products of the distillation of Bituminous coal. There are of course certain constituents of all such products which have a comparatively low temperature of volatilization and it is well that such substances should be eliminated, as they may readily be, prior to the employment of the tar as a fuel, but this done there appears no good reason for doubting the entire safety of liquid fuels for the purposes of the steamship or of the railroad. Needless to say common caution would point to the use of properly devised tanks for their reception, whether in the tender of the locomotive or the bunker space of the steamship, and there are those who hold it essential that under no circumstances should the feed of liquid fuel to the furnace be in the slightest degree aided by gravity. This is, perhaps, a fair and proper precaution to exercise as a safeguard against the possible breakage of the pipe connections and the sudden escape upon the floor of the stokehold of a quantity of the fuel before it could be shut off at some point nearer to the tanks themselves.

The convenience of a gravity flow is not so great but that such a precaution may not be cheerfully accepted and it may be pointed out that in the locomotive also, the arrangement of the oil tanks can be such that the flow need not be assisted by gravity. For some years there have been at work in Russia, near the oil fields, many locomotives which use petroleum as their sole fuel.

The earliest experiments in Russia with petroleum fuel were made in 1874, but the fuel was abandoned on account of cost at that time but has since been adopted, as the fuel of the Tsaribein Railway.

As compared with Bituminous coal, petroleum refuse showed, according to the locomotive superintendent an advantage of fifty-six per cent. in weight, and sixty-six per cent. in cost, and when carried in bulk the loading and unloading of any liquid is so easy that there appears good reason to suppose that the use of petroleum refuse will extend. But petroleum refuse is not the sole liquid fuel by any means.

Apart from the tar produced from coal in the process of manufacture of illuminating gas, there is a tar which is saved from blast furnaces, and a tar from coke ovens. Blast furnace tar, produced by cooling the gases from blast furnaces, is stated to possess the following properties and composition by Watson Smith.

The example analyzed had a specific gravity of ·954 and was distilled to dryness with the following result:

	Percentage of Products	Specific Gravity.
Volatilized below 446° F.	Water 30·6 by volume	1·007
	Oil 2·9 by volume	·889
Volatilized at 446°—572°	7·0 by volume	·971
Volatilized at 572° till oils solidify	18·0 by volume	·994
Soft Paraffin scale	16·7 by volume	·987
Coke	21·5 by weight	
Loss	5·5 by weight	

As a fuel therefore something like seventy per cent of this tar is combustible.

The tar from Jameson coke ovens is of very similar composition, and we may probably take it that the water present in the crude tar would all pass off with the first distillates, leaving behind an anhydrous liquid, free from the more volatile constituents which can be better utilized, and eminently suitable for use as a liquid fuel.

This, it appears, is generally, if not invariably, thrown away in America, and some interest may be aroused as to the latest English practice with liquid fuel At the outset it may be stated that England does not present a specially favorable field for the employment of liquid fuels.

The ties used on English railroads are half square timbers, usually of Baltic Fir, and they are usually heavily treated with creosote. There is thus a large demand for the tar of the gas works, which not many years ago was a nuisance, and it is converted variously into aniline dyes, artificial manures, and creosote for ties, and pitch for paving purposes.

Coal, too, is plentiful, and it is unlikely therefore that liquid fuel can oust coal. Nevertheless on the Great Eastern Railway the locomotive superintendent has evolved a system of liquid fuel combustion which possesses considerable merit, for it has involved no departure from the normal style of coal burning furnace, which can prejudicially affect the capacity for burning coal alone.

The arrangement consists of a pair of steam actuated injectors, fitted at the rear of the firebox, under the foot plate, about twenty inches apart and ten inches above the grate level. Their nozzles are placed centrally in two five-inch holes cut through from outside to inside of the back of the firebox, the holes being tubed from box to casing, through the water space. Each nozzle has a double opening, one directly forward, the other toward the middle space of the firebox.

Round each nozzle is a ring pierced for several small steam jets, which induce air currents into the firebox round the injector nozzles.

The action of the injectors is to finely spray the liquid fuel, brought to them by pipes from a tank at the rear of the tender, and distribute it in the furnace, any which is not consumed falling to the grate or settling upon the brickwork of the smoke arch, which at once volatilizes it.

The grate is thinly covered with a fire made up of coal and broken chalk, its object being to serve as a lighter of the oil, and preserver of temperature during stoppages, as well as to intensify and ensure a more perfect combustion, sufficient air being allowed through the grate to maintain this light fire and assist to burn the oil likewise, but more air being provided by the air injection jets of the two fuel injectors, by which latter indeed the correct air supply is maintained at the point when smoke is just formed in occasional light puffs.

The preservation of a bed of actual fuel has the advantage that lighting up can be just the same as in any other engine, and the oil fuel need not be used till the engine takes its turn with a train.

Any failure in the supply of oil can make no difference, for coal can at once be used instead without the least inconvenience. This is an advantage which is unattainable where a special brick furnace is built for oil burning, as is done on the Russian line using petroleum.

The latest engine fitted with liquid fuel on the Great Eastern Railway is one of a class of ten similar express engines, and, as compared with the other nine engines doing the same round of duty, the oil burner has used about one-third the weight of coal per mile, and about as much oil as coal in weight. Her total fuel is thus about two-thirds by weight what it would be if all coal. The liquid practically gives an efficiency of double its weight of coal. The writer has had runs on this engine when burning mixtures of plain gas tar and creosote residuals, warmed up, in the tank which is placed at the rear of the tender, to a liquidity sufficient to cause it to flow freely through the injector pipes, and to destroy its viscosity so that it would spray finely from the nozzles. Its behavior in the furnace is satisfactory, filling the firebox with white flame, while the air rings admitted of the most delicate adjustment of the supply of air to effect perfect combustion without air excess. Steam was made most freely.

A discussion took place in the English papers on this locomotive. It was urged that the combined system of solid and liquid fuel was not so economical as the all, liquid furnace. On the other hand it was urged that the ability to use either or both fuels at a moment's notice and to make the change instanter was an advantage not to be lightly despised. Where the firebox is filled with cellular brickwork, this cannot of course be done and there can, after all, be no refractory material as a covering for the bars and as an incandescent bed for ensuring volatilization of any oil which may fall, superior to a thin fire of coked coal, clinkers, and chalk lumps, as used in Holden's system on the G. E. Railway. The elasticity of the system commends it where a locomotive may run through a district in which alternations of coal or liquid fuel occur.

In England, for example, gas tar can be picked up at a country town at a distance from any tar distillery works for a price less by the carriage than it can be had where there is a creosote works, and where liquid is cheaper it may be used in a compound furnace just so long as it can be had in sufficient quantity. The reduction in the labor of the fireman is very marked, and the cleanliness when burning oil is equally noticeable.

With such an immense field open for the consumption of all the tar which can be produced there should be no throwing such a valuable article to waste to the blackening of the atmosphere and injury of vegetation. Its saving is called for, to redeem American coke making from the stigma of extravagance. The coke industry cannot afford to throw away such valuable bye-products.

THE NORTHERN ANTHRACITE COAL FIELD.

ON another page we publish a tabular estimate showing the approximate quantity, and the past and probable future production of coal in the several districts of the Northern Anthracite coal field, prepared by Mr. Wm. Griffith, engineer and geologist, late of the geological Survey of Pennsylvania.

This table is accompanied by an explanatory letter from Mr. Griffith explaining the methods whereby he arrives at his deductions, and we think all readers will agree in the opinion that his figures are as nearly correct as it is possible to make them. The compilation of this table entailed on Mr. Griffith an immense amount of research and hard work. He was, however, specially fitted for the undertaking by his experience on the Geological Survey and his practical acquaintance with the geology of the region. The table, will, on inspection, be found very interesting, and the interest will not end with its first examination. It contains a vast amount of information concerning the great Northern coal field, arranged in the most convenient form, and for years to come it will no doubt be used as a work of reference and as a basis for calculations.

A careful study of the table reveals the following interesting generalities:

It shows that in the past nearly sixty per cent. of the coal originally in the ground has been won—this includes shipments and local consumption.

Mr. Griffith thinks the future production cannot well be expected to much exceed fifty-three per cent. of the coal remaining in the ground, but this may be increased somewhat by improvements in the methods of mining, but as most of the coal remaining is at the lower end of the field, where the measures are deep and gaseous, some radical change in methods will be necessary to materially increase the percentage stated.

The large yield of sixty per cent. in the past, as shown by the table, may be partially accounted for by the fact that the coal has been mined from the margin of the field and points where it is not so deep and the surface of little value, so that more coal per acre could be taken out.

According to Mr. Griffith's deductions the several minor divisions of the field will, at the present rate of production, last the following lengths of time:

District.	Time of exhaustion excluding thin seams not now worked.	Time of exhaustion including thin seams not now worked.
Forest City and Carbondale	70 years	
Jermyn	14 "	19 years
Archbald	21 "	86 "
Peckville and Olyphant	75 "	140 "
Scranton	53 "	61 "
Pittston	80 "	83 "
Wilkes-Barre and Plymouth	127 "	134 "
Nanticoke and lower end	121 "	138 "

Of course, as the northern districts are exhausted the production will be greatly increased in the lower end of the basin. A large percentage of the coal north of Scranton is in thin beds that have not yet been worked to any extent, and in this portion of the field more robbing can be done, as the beds are not deep, and the surface is not very valuable. This statement makes plain the relations existing between the figures in the above table.

In the following table is shown the proportion of the whole quantity of coal still unworked by districts and the percentage of the 53% of the whole quantity (that may yet be mined), which will probably be produced in each district.

District.	Percentage of coal remaining in the ground.	Percentage of 53% of coal that may be mined.
Forest City and Carbondale	2·0	3·5
Jermyn	0·7	1·1
Archbald	0·6	0·9
Peckville and Olyphant	4·5	8·6
Scranton	16·0	16·0
Pittston	18·0	14·0
Wilkes-Barre and Plymouth	47·0	42·0
Nanticoke and lower end	16·0	14·0

Of all the coal remaining in the ground, including pillars in the mines, the Wyoming Valley has about 70 per cent. and it has produced about 54 per cent. of all the coal produced from the entire Northern Field. The Lackawanna Valley has 30 per cent. of the coal remaining in the ground, and has produced 46 per cent. of the total production. The past production divided up by districts, gives each district the following percentage:

Forest City and Carbondale, 6%; Jermyn, 3%; Archbald, 2%; Peckville and Olyphant, 4%; Scranton, 31%; Pittston, 16%; Wilkes-Barre and Plymouth, 32%; Nanticoke and lower end, 6%.

Of all the solid coal in the unworked areas, about 20% is contained in seams that have not been worked to any extent in the different districts.

The greatest thickness of the measures is at Wilkes-Barre, where they have at the deepest point, fourteen beds, aggregating 97·6 ft. in thickness. The Archbald and Carbondale districts have the least thickness, the former having two beds with a total thickness of eleven feet, and the latter three beds with a total thickness of seventeen feet.

To give an idea of the magnitude of the amount of prepared coal still to be produced from this field (2,374,194,600 tons) it is necessary to use something beside figures. This amount would fill an ordinary 60 feet wide city avenue, 60 feet deep, or level with the top of an ordinary fifth story window, for a distance of 5,000 miles.

WHAT IS A "MINER?"

THE Anthracite Mine Law of Pennsylvania (1891) states (Art. 8, Sec. 4) "Certificates of qualification as mine foremen and assistant mine foreman shall be granted by the Secretary of Internal Affairs to every applicant who may be reported by the examiners, as heretofore provided, as having passed a satisfactory examination *and as having given satisfactory evidence of at least five (5) years practical experience as a miner.*"

What constitutes a "miner," however, is not defined and the real meaning of the word is the subject of some dispute.

It seems that some candidates on presenting themselves for examination have been refused the right to sit because they could not give satisfactory evidence of having *mined coal* for five years. Is this right?

When we speak of any craftsman, we speak of a man who is competent in all branches of his trade, and who is especially competent in the more important and dangerous branches. It is very rarely, however, that we find in any trade a man who is an all-round, first-class workman. In large industries it is well known that the greatest amount of work can be got out of a certain number of men by apportioning a particular piece of work to each, and we must be content therefore to consider any man an artisan who has a good knowledge of the most important branches of his trade.

In reading the law under question we must consider the object which it is intended to accomplish. It is called "*An act to provide for the health and safety of persons employed in and about the Anthracite coal mines of Pennsylvania, and for the protection and preservation of property connected therewith.*"

The intention of the section of the law under consideration is to provide competent foremen, and the workman who knows most about all the work in mines will make the best foreman, as the more he knows the better able is he to protect life and property.

We do not think five years coal hewing is a sufficient training in this respect, and personally we would rather trust ourselves underground with a man of five years general experience, than in the care of a man who has done nothing but hew coal for the same period.

According to law, any man who has labored underground two years can receive a certificate that he is a miner, and if a miner is to mean only a coal hewer, then, after working other five years, perhaps in a single chamber, with never a thought only to secure so many cars of coal a day, and with no experience in timbering, tracklaying, bratticing, door building, or any other branch of the work except cutting coal, he can present himself at an examination and be allowed to sit while the man who has had experience at all the work but digging, and who for years has had charge of the doors, and brattices, and timbering, which supply pure air and safe travel to the digger, is refused the right to sit.

The term "miner," as used in this section of the act, must certainly mean a workman in the mines who has had five years of general experience in the work underground and who understands the practical details of every branch of the underground work well enough to qualify him to be a competent foreman.

Whether the candidate possesses these qualifications which will constitute him a "miner," and qualify him to stand for examination is a matter to be decided in each individual case by the Board of Examiners.

THE COLUMBIAN EXPOSITION AND THE MINING INDUSTRY.

CONSIDERABLE misapprehension exists, both in this country and abroad, as to the mines and mining exhibit which is to be made at the Exposition. At World's Fairs, heretofore, the mineral and allied exhibits have been shown in the manufacturers' building, or in annexes to other structures occupied by exhibits having but remote relation to anything of the mineral description. Many press notices and comments indicate that the impression prevails widely that such is to be the case at the Exposition of 1893. But that is far from being true. "Mines and Mining" has been made a separate and distinct "Department" of the Classification of Exhibits, and will have the exclusive use of one of the finest and largest of the Exposition buildings. The mines and mining building measures 350 by 700 feet, has a total floor space of almost 9 acres, and cost $265,000. The fact is that, at the World's Columbian Exposition, for the first time in the history of such enterprises, the mining industry and products are accorded the recognition which their exceedingly great importance to the wealth and prosperity of all civilized nations really demands. Mr. Skiff, Chief of the Department, says that it is already assured that in the Mines and Mining Building will be gathered in 1893 incomparably the largest array and most complete and most instructive evidence of the mineral wealth and progress of the mining industry ever collected or attempted.

With the mining industry so well taken care of, there is every reason to suppose that enterprising manufacturers of mining machinery will endeavor to make such displays of their products as will show the high standard to which American ingenuity and skill have brought the construction of all kinds of mining appliances.

During a recent visit to Chicago, the writer spent a pleasant and profitable hour with Mr. Skiff, and afterwards visited the exposition grounds and buildings. Everything connected with the exposition is on an elaborate and stupendous scale, and the manufacturer of mining machinery who fails to avail himself of the opportunity to show his products to the mining officials and engineers of the world will miss a great opportunity.

Comparitively few persons have any idea of the high grade and powerful machinery used in coal mining. The terms, engines, fans, pumps, etc., as applied to coal mines are to them merely the names applied to rough small pieces of mechanism of most primitive construction. For them to see the character of the machinery used will be an education. In fact so general is the idea that almost any kind of an engine will do for use at a colliery, that it can best be illustrated by the following incident:

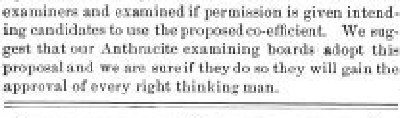
A representative of this journal recently called at the works of a prominent firm manufacturing machinery for metalliferous mines in one of the large cities and endeavored to secure from them a contract for advertising. He was courteously received by a young man in charge, who made the absurd statement that their works "manufactured no hoisting machinery suitable for coal mines. They made only large direct-acting hoisting engines." There was no use in trying to show him his error. He knew all about it. If a man holding as high a position as he does in such works is so ignorant, what must be the ignorance of the general public on the subject.

A first class display of coal mining machinery will effect a double purpose. It will show the mining world that American manufacturers lead those of all other nations in the production of serviceable, convenient and economical mining machinery, and it will show them that both directly and indirectly the coal they consume is only mined and marketed by the expenditure of large outlays of money and exercise of engineering skill.

The manufacturers of mining machinery suitable for coal mines have not been as active in their arrangements for exhibiting their products as have others, and it is time they took the matter up. The expense of a good display will be found a most profitable investment.

THE CO-EFFICIENT OF FRICTION.

IN our correspondence columns we publish a letter from a subscriber commending our editorial on the above subject in the April issue. The co-efficient we proposed (·02 the pressure for a velocity of 1,000 feet per minute) is so much more easily used than Atkinson's, and the difference in the result of calculations will be so little that we fail to see any reason why it should not be adopted. The annual examinations for mine foremen in the Anthracite regoins are about to be held and in such examinations every minute is valuable to candidates who are not adepts in writing, and if their thorough knowledge of formulæ can be demonstrated without long calculations such as Atkinson's figures entail, surely it will be a convenience to both examiners and examined if permission is given intending candidates to use the proposed co-efficient. We suggest that our Anthracite examining boards adopt this proposal and we are sure if they do so they will gain the approval of every right thinking man.



The Anthracite Trade.

The Anthracite trade opens this month in excellent condition. The accumulations of coal have been reduced to a minimum at all points, and the output from the mines has been kept rigidly down to the requirement of the markets. On the first of the month the increased prices went into effect, and the output for this month has been placed at 2,750,000 tons. By placing the output at this amount the new prices will be maintained. These new prices are as follows:

Stove coal, \$4.15; chestnut, \$3.90; egg, \$3.75; broken, \$3.65. These are tide-water rates f. o. b., and are for a ton of 2240 lbs.

Unbusinesslike competition and excessive production has ceased. Anthracite coal will either be sold at a reasonable profit to the producer, or not mined. The advance in prices will not only enable a profit to be made on the capital invested in mining, but will also result in better wages to the workingmen who naturally share in the advance of the sliding scale system of payment at the collieries in the Schuylkill region, and it is but natural for the wages of the miners in the other regions to be placed on the same relative figures. Navigation on the great lakes has opened and western shipments have begun.

Unfilled orders for coal at old prices have been cancelled, and a determined stand for better prices is being made. All the coal that can be sold will be mined and there will be no excessive charge made for it. The prices will be fixed at figures that will result in reasonable profits, and in reasonable wages to the miners. The only parties who will object to this, are the sensational writers on the New York dailies, who endeavor to stir up dissension and trouble by unwarranted attacks on the "Coal Barons" which are inspired either by dense ignorance, or ulterior motives.

The Bituminous Trade.

Since the making of the larger contracts early last month the Bituminous trade in New York and Philadelphia has settled down to ordinary business. There is a fairly good demand from those who held off in the expectation of lower prices during the contract season. The advance in the price of Anthracite has had a stiffening effect on Bituminous coal, and shippers are anxious to get coal to tide. Conservative dealers do not think this effect will be a permanent one, as the Anthracite advance is not large enough to effect a material change from hard to soft coal by consumers.

The supply in all the larger southern markets is large, and business for the operators shipping there is naturally dull. Business at Chicago is active and coal is in excellent demand. The railroads are placing their contracts, and competition for them is brisk. There is considerable uncertainty regarding the prospects for labor troubles in Northern Illinois, and users of coal from that section are laying in supplies. The Indiana miners and those of the Pittsburgh region have signed their respective scales, and peace between operators and workingmen in these fields is assured.

The Coke Trade.

The coke trade is in rather an unsatisfactory condition and production is being curtailed. The larger operators in the Connellsville region have shut down a large number of ovens, so that now only about two-thirds of the total number in the region are in operation. The idea of the operators being to work a portion of the ovens full time rather than all of them part time. Prices are quoted at the same figures as have prevailed for many months, though they are cut by some of the smaller operators. The larger operators controlling about nine-tenths of the output of the region are, however, firmly holding to the quotations.

The Explosion at McAlester, Indian Territory.

In previous issues we gave in detail an account of the explosion at the Osage Coal Mining Co.'s shaft No. 11, at Krebs, near McAlester, Indian Territory. At the request of Mr. R. M. McDowell, the General Manager of the company, Messrs. Walton Rutledge, Inspector of Mines, Fourth District of Illinois, C. C. Woodson, State Mine Inspector of Missouri, and Jno. T. Stewart, State Inspector of Coal Mines, of Kansas, made an investigation and inquiry into the cause of the explosion. Their report to Mr. McDowell has just been issued and corroborates the accounts published in our columns. It also contains as an appendix some recommendations regarding the future working of the mine which we print in full, as they are of a nature that may prove beneficial to other mines working coal of a similar nature.

The recommendations were as follows:

"We would recommend that this system of working the coal in Mine No. 11 be changed, as the coal is of a highly Bituminous nature, very dusty, and gives off small quantities of fire-damp. Powder should be very carefully and judiciously used; no shots to be fired unless properly undercut in rooms; in entries the coal to be sheared on one side and properly undercut; no holes to be drilled ahead of the cutting; no entry or room or other workmen allowed to fire shots, except the properly appointed shotfirers, and all men to be out of the mine except those engaged in firing shots; no more than enough powder to be in the mine at any one time except for one day's use, and the powder to be kept in proper air-tight powder cans, and the cans to be kept in a close, tight-locked box, said box to be at least sixty yards from the working face; and a sufficient interval must be given between the firing of each shot, to allow for the smoke to pass away and the subsiding of the coal-dust.

"At the intake on the slope, on account of the stoppings being blown out, we could not get a proper measurement of the ventilating air current. We measured in returns, and found the total quantity to be 23,135 cubic feet of air per minute. A Crawford & M'Crimmon fan, fifteen feet in diameter, four feet wide, making ninety revolutions per minute, is used for the ventilation. The volume of air herein described, in our opinion, is not sufficient for the number of men employed and extent of the workings; but it should be mentioned that the large falls not yet cleared from the slope or main intake form a serious obstruction to the current, and make it impossible for us to judge closely the quantity of air passing previous to the explosion.

"The fan shaft No. 7 and the escape shaft are located too far from the center of the workings, causing unnecessary friction of the air currents. As the escape shaft is so far from the main workings, sign boards ought to be posted up at each angle or turn, indicating the road to the escapement shaft. We would also recommend that the mine should be ventilated by split currents of air; overcasts should be put in, giving each set of working entries a separate split or current of air not more than fifty men to work in one split, as we consider it very dangerous in a dry or dusty mine, giving off fire-damp, to have the air passing around in one continuous current. The air is now split in Mine, 11 at the bottom of the slope, passing through the workings in two currents.

"We would also recommend a proper system of sprinkling, by introducing a system of pipes on the slope, engine plane, and entries, the water to be introduced into the intake air current in a finely divided spray.

"All mines in this seam of coal have been exclusively worked on the room and pillar plan since the time operations were begun, twenty years ago, except centerly for a short time, in Mine No. 8, now abandoned.

"In our opinion Mine No. 11 could be more economically worked, the coal produced at a less cost, a more efficient ventilation produced, and the mine kept in a safer condition, by Longwall system of working, the condition of the roof and bottom being very suitable for the same. Such an explosion as that at Mine 11 would be impossible under the Longwall system of working, as little or no powder would be used.

"The company have introduced this plan into their new mine, No. 12, in a different seam, which gives evidence of working very satisfactorily wherever the Longwall work is given a chance; but the miners are so wedded to the use of powder and so disinclined to mining or undercutting that every obstacle has been thrown in the way."

WALTON RUTLEDGE,
State Inspector of Mines, Fourth District, Illinois

C. C. WOODSON,
State Mine Inspector of Missouri.

JOHN T. STEWART,
State Inspector of Coal Mines, Scammon, Kansas.

Recovery of the Bodies of The Hill Farm Mine Victims.

The bodies of twenty-two of the thirty-one miners entombed in the Hill Farm Mine at Dunbar, on June 16, 1890, were recovered on March 23, after nearly two years of unceasing work and the expenditure of an immense amount of capital. The men whose bodies were found had been suffocated, and their death was a sudden and comparatively painless one. The coroner's jury that held an inquest on the first six bodies recovered, rendered the following verdict, which meets the approval of every person conversant with the facts connected with the unfortunate accident and the untiring work of Gen'l. Supt. Frank A. Hill and his assistants in their efforts to recover the bodies:

We, the jury, find that these six bodies came to their death by suffocation from smoke caused by the turning of a brattice cloth. And we further say that the Dunbar Furnace Company deserve great credit for the interest and expense they have shown in recovering the bodies, and also Frank A. Hill, General Manager, Superintendent Robert Lang, and other officials of the company are deserving of great credit for their perseverance in recovering the bodies.

BOOK REVIEW.

PROCEEDINGS OF THE ENGINEERING ASSOCIATION OF N S. W. FIVE VOLUMES 1885-90. We have just received a copy of the above transactions from the secretary, Mr. Henry V. Ahrbecker M. I. Mech. E. They contain papers read by members and the discussions thereon and cover the field of Mechanical, Marine, and Mine Engineering. They are well gotten up, well illustrated and printed and are a valuable addition to the library of any engineer.

REPORTS AND STATISTICS OF THE MINING DEPARTMENT OF VICTORIA (AUSTRALIA) FOR THE QUARTER ENDED 30TH SEPT., 1891. COMPILED AND ARRANGED BY THE SECRETARY FOR MINES.

It is a difficult matter to dress up a batch of statistics in a form that will be interesting, but Mr. A. W. Howitt the Victorian Secretary for Mines seems to make such a task successful. The above quarterly report which we have just received is the best Government report that we have seen. Besides the usual particulars of production of ore, number of men employed, etc., there are mineralogical reports and assays, notes on boring operations, with numerous diagrams of sections and a well illustrated article is given on Lake Karng, and another on the country lying between north and south Mirboo.

ANTHRACITE COAL STATISTICS.

Statement of shipments of Anthracite coal for month of March, 1892, compared with the corresponding period last year. Compiled from the returns furnished by the Mine Operators.

	MARCH. 1892.	MARCH, 1891.	DIFFERENCE.		FOR YEAR 1892.	FOR YEAR 1891.	DIFFERENCE.	
From Wyoming Region, - -	1,622,938·15	1,300,240·03	Inc.	322,698·12	4,709,386·19	4,219,737·19	Inc.	549,649·00
From Lehigh Region, - - -	433,016·06	399,381·11	Inc.	33,634·15	1,318,596·06	1,273,529·01	Inc.	45,067·04
From Schuylkill Region, - -	1,016,894·18	815,838·05	Inc.	201,056·13	3,011,705·17	2,538,355·15	Inc.	473,350·02
Total - - - - - - -	3,072,849·19	2,515,459·19	Inc.	557,390·00	9,039,689·01	8,031,622·15	Inc.	1,008,066·06

The stock of coal on hand at tide-water shipping points, March 31, 1892, was 821,023 tons; on February 29, 1892, 885,653 tons; decrease, 64,630 tons.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since Our Last Issue.

Keystone & King Mining and Milling Co.,	Carter, Mont.
Chester Mining Co.,	Missoula, Mont.
Zenith Iron Co.,	Duluth, Minn.
Brush Heap Mining Co.,	Kingston, N. M.
Fire Center Gold Mining Co.,	Milwaukee, Wis.
Pennsylvania Zinc and Iron Co.,	Roanoke, Va.
Richmond Mica Co.,	Richmond, Va.
Hamilton, Lowe & Co.,	Chicago, Ill.
Oxford Mining Co.,	Chicago, Ill.
Montana Silver Mining Co. of Chicago,	Chicago, Ill.
Seymour Concentrator Co.,	Chicago, Ill.
The Carroll County Zinc Mining Co.,	Logansport, Ind.
The Sterling Iron and Railway Co.,	Warwick, N. Y.
Beaver White River Stone and Marble Co.,	Eureka Springs, Ark.
The Grand City Coal Co.,	Chicago, Ill.
Silver Plume Consolidated Mining Co., of Nebraska and Colorado,	Lincoln, Neb.
The Douglass Lava Co.,	Colorado Springs, Colo.
The Extension Gold Mining and Milling Co.,	Denver, Colo.
The Crown Point Mining and Milling Co.,	Creede, Colo.
The Nelson Tunnell Mining Co.,	Creede, Colo.
The Cripple Creek Mining and Milling Co.,	Fremont, Colo.
Vermont Red Slate Co.,	Fair Haven, Vt.
Iowa Fuel Co.,	Oskaloosa, Iowa.
Charlerol Coal Co.,	Charlerol, Pa.
Madison Gas Coal Co.,	Greensburg, Pa.
Northern Light Iron Co.,	Duluth, Minn.
The Jefferson Mining Co.,	Moreland, Colo.
The Tabor Mines and Mills Co.,	Denver, Colo.
The Solar Fuel Co.,	Denver, Colo.
The Mineral Hill Mining and Tunnel Co.,	Fremont, Colo.
Evans Mining, Milling, and Smelting Co.,	Baltimore, Md.
The Heirs of Philippe Francois Renault Title Co.,	Jersey City, N. J.
The Calectin Co.,	New York City, N. Y.
Libertyville Clay and Gravel Co.,	Libertyville, Ill.
The Vermillion Sandstone Co.,	Danville, Ill.
The Peerless Coal Co.,	Calvert, Texas.
Monte Cristo Development Co.,	Everett, Wash.
The Wannicut Lake Mining Co.,	Spokane, Wash.
The Eastern Consolidated Mining Co.,	Missoula, Mont.
Illinois Mining & Investment Co.,	Helena, Mont.
The Peerless Cement Plaster Co.,	Saline, Kan.
The Miners Union Association,	Creede, Colo.
The Paystone Mining and Milling Co.,	Aspen Colo.
The Murdie Mining and Milling Co.,	Village of Chaney, Colo.
Caskill Gravel Mining Co.,	Marysville, Cal.
Cottonwood Milling and Mining Co.,	Fort Bidwell, Cal.
Mexican Zaragosa and Hidalgo Gold and Silver Mining Co.,	San Francisco, Cal.
Don Carlos Gold Mining Co.,	Santa Cruz, Cal.
Blue Mountain Oil and Mineral Co.,	Waveland, Ark.
Nebava Iron Mining Co.,	Duluth, Minn.
The Polaris Mining & Milling Co.,	Dillon, Mont.
The Champion Empire Mining Co.,	Aspen, Colo.
The Summit Mining and Milling Co.,	Colorado Springs, Colo.
The Nellie Sandborn Mining Co.,	Pueblo, Colo.
The American Lithograph Stone Co.,	St. Louis, Mo.
The Adair Coal Mining Co.,	Fort Worth, Texas.
The Vermont Quarry Co.,	Montpelier, Vt.
Salmon River Placer Mining Co.,	Salmon City, Idaho.
The Farmers Mutual Gas Company of Jackson,	Jackson, Ind.
Swan Lake Iron Mining Company of Minneapolis,	Minneapolis, Minn.
The Carnegie Mining Co.,	Duluth, Minn.
Chicago and Assiniboia Railroad Co.,	Clinton, Iowa.
The Aztec Onyx Co.,	Albuquerque, N. M.
Excelsior Red Stone Co.,	Hancock, Mich.
Denny Clay Co.,	Seattle, Wash.
The Franklin Mining Co.,	Pueblo, Colo.
Hamar Zinc and Lead Mining Co. of New Jersey,	Jersey City, N. J.
Mosley Zinc Company,	Plainfield, N. J.
The Sandia Mining and Smelting Co.,	Hoboken, N. J.
Aurora Iron Co.,	Duluth, Minn.
Idaho Springs Mining and Development Co.,	Denver, Colo.
The Gregory Consolidated Mining Co.,	Denver, Colo.
The Alamo Mining Co.,	Colorado Springs, Colo.
The Addie E. Mining and Milling Co.,	Colorado Springs, Colo.
The Coronado Gold Mining Co.,	Pueblo, Colo.
The C. and I. C. Gold and Silver Mining Co.,	Denver, Colo.
The Hindoo Mining Co.,	Pueblo, Colo.
The Squaw Gulch Gold Mining Co.,	Colorado Springs, Colo.
The New Zealand Mining Co.,	Denver, Colo.
The Pneumatic Ore Milling and Mining Co.,	Denver, Colo.
Rolfe Coal and Coke Co.,	Rolfe, W. Va.
Big Four Wilmington Coal Co.,	Chicago, Ill.
Cambria Coal Mining Co.,	Williamsport, Pa.
The Climax Oil and Gas Co.,	Woodsfield, Ohio.
Morning Mining Co.,	Mullan, Idaho.
The Beatric Consolidated Mining Co.,	Colorado Springs, Colo.
The Louise Mining Co.,	Denver, Colo.
The Nogal & Bonito Mining & Milling Co.,	St. Louis, Mo.
The Wittenmeier Stone Co.,	Columbus, Ohio.
Bessemer Iron Mining and Manufacturing Co.,	La Fayette, Texas.
Eagle Iron Co.,	Spring Valley, Wis.
Pacific Coast Prospecting & Developing Co.,	Springfield, Ore.
The Belmont Oil & Gas Co.,	Wheeling, W. Va.
Angeleno Oil & Mining Co.,	Los Angeles, Cal.
Forest Grove Stone Co.,	Forest Grove, Ore.
The Bright Light Mining Co.	Portland, Ore.
The Imperial Mountain Iron Mining Co.,	St. Paul, Minn.
The Brown Bonnell Iron Co.,	Youngstown, Ohio.
The El Dorado Gold Mining Co.,	Chicago, Ill.
The Foley Mining Co.,	St. Cloud, Minn.
Sedalia Mining & Prospecting Co.,	Sedalia, Mo.

Single Connection Sight Feed Lubricator.

This lubricator has been devised to meet the demand for a low priced cup, suitable for small engines and steam pumps. They are simple and very effective. The oil reservoir and arms are cast all in one piece, so there are no joints to leak or rack loose. A very desirable and convenient feature of this cup is in the mode of attachment. The stop valve N is so made as to be attachable to a vertical or horizontal steam pipe or directly to the steam chest as may be desired, by

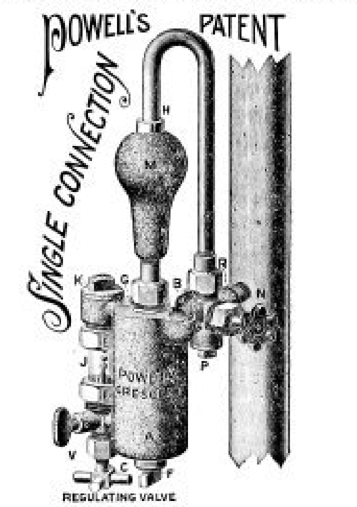

FIG. 1.

simply transposing the position of the screw nipple R and plug P.

Fig. 1 shows side connection and Fig. 2 shows bottom connection when it is desired to attach the lubricator to a vertical pipe, an ordinary short pipe nipple, as shown in Fig. 1, should be used. If it is desired to attach to a horizontal pipe or steam chest, the plug P, and nipple R, should be removed and changed places as show in Fig. 2. Should the nipple R be too short,

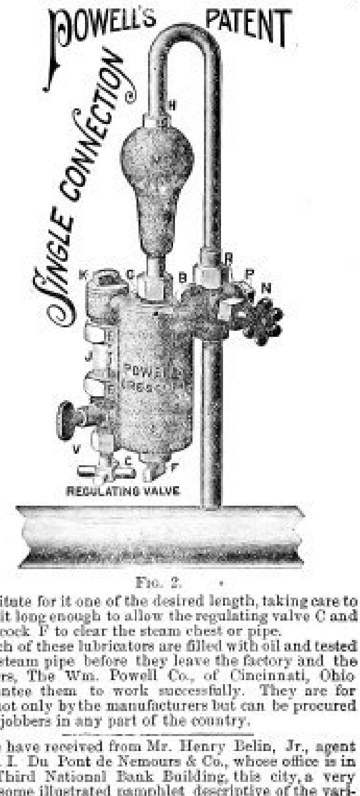

FIG. 2.

substitute for it one of the desired length, taking care to have it long enough to allow the regulating valve C and vent-cock F to clear the steam chest or pipe.

Each of these lubricators are filled with oil and tested on a steam pipe before they leave the factory and the makers, The Wm. Powell Co., of Cincinnati, Ohio guarantee them to work successfully. They are for sale not only by the manufacturers but can be procured from jobbers in any part of the country.

We have received from Mr. Henry Belin, Jr., agent for E. I. Du Pont de Nemours & Co., whose office is in the Third National Bank Building, this city, a very handsome illustrated pamphlet descriptive of the various types of explosives manufactured by the Du Ponts. Besides being a beautiful specimen of typographical art, it contains among other interesting data a table showing at a glance the periods during which the game laws are not in force in the different States and Territories throughout the Union, and at which time sportsmen are at liberty to go in pursuit of game.

LEGAL INTELLIGENCE.

Lehigh & Wilkes-Barre Coal Co. vs. Delaware & Hudson Canal Co.—Miners—Equity—Flooding—Pressure on Pillars—Fire. A fire occurred in Deft's Mine which threatened to destroy both Deft's Mine and those of the adjoining mine owners. To prevent the injury the mine was flooded. The Plaintiff asked the Court for an injunction alleging that the barrier pillar was not strong enough to withstand the pressure of the water. On a motion for a preliminary injunction, the Common Pleas of Luzerne County held that the preliminary injunction should be refused.

Opinion delivered January 11, 1892.—Rice, Presiding Judge. The plaintiff is the lessee of a colliery known as the Hollenback mine, and the defendant is the lessee of an adjoining colliery known as the Conyngham mine. In each there is a large quantity of unmined coal, and each is connected with other mines. The two mines are separated by a barrier pillar of solid coal, which, according to the plaintiff's affidavits, has a minimum thickness of fifty feet. The vein of coal as mined is seven or eight feet in thickness. About a year ago a fire occurred in the Conyngham mine, whereupon the defendant company turned water into the mine and filled the same to a height of two hundred feet above shaft level. The plaintiff alleges that the effect of turning in the water was to bring on a squeeze or crush of the barrier pillar and to endanger the Hollenback and all the connected mines, as well as the lives and safety of persons employed therein. The plaintiff's witnesses, including the mine inspector of the district, testify that when the water reached a height of two hundred and thirty feet it came through the pillar with considerable force, the coal was cracking off the pillar, and the signs that the pillar was weakening were unmistakable. On the other hand, the defendant's engineer, who was present at the same examination, testifies that the cracking of the pillar and percolation of water do not prove pressure from the column of water on the other side, that the same often happens without any danger or undue pressure, and that the cracking was not of a character to indicate a squeeze. We shall not undertake to decide between these witnesses upon this question of opinion, but it is a significant fact, tending to corroborate the testimony of the plaintiff's witnesses, that when the water was at a height of one hundred feet the pillar showed no signs of weakness and was apparently safe, and that these signs, which the plaintiff's witnesses say were unmistakable, did not appear until afterwards.

At all events, there was so strong probability that these manifestations were due to the pressure as to make it necessary, in the exercise of ordinary prudence, to strengthen the pillar. The method adopted is thus described by the plaintiff's superintendent: "A borehole was put down by one company to connect with the return air-way, which is parallel with said pillar, and said air-way and the adjacent breasts have been partially filled with culm, which has the affect of re-enforcing and strengthening the pillar to such an extent that the mine inspector is now willing that our men, who have been idle in that mine for three months, shall return to work provided no more water is put in the Conyngham mine." It is claimed that while the barrier pillar as re-enforced is sufficient to resist the increased pressure which will be caused by raising the water to any considerably greater height, and therefore the plaintiff prays for an injunction.

The defendant claims: (*a*) that in re-enforcing the pillar it was possible for the plaintiff company to have so placed timbers as to put the resisting strength of the barrier beyond all question; (*b*) that the present barrier will successfully withstand any pressure of water that will be brought against the same. The mine inspector, although not going the same length, says: "My opinion as to the weakness of the barrier pillar . . . was based on the fact that of the coal cracking off the pillar, and yet I learn that under similar circumstances in a mine at Harleigh, notwithstanding the cracking of the barrier pillar, the parties continued the filling of water to a height of two hundred feet additional, and the pillar successfully withstood the pressure. In that case the vein, as mined, was about thirty feet thick, while here it is only seven or eight feet thick, which is an advantage in favor of the defendant's mine. I learn ten feet thick held the water at Kohinoor mine."

In the disposition of this motion we are to consider, first, the probability of injury to the plaintiff's property consequent upon raising the water in the Conyngham mine to any greater height than it now is; second, the consequences to the defendant if it should be enjoined.

That great damages, which could not well be measured and compensated in money, would ensue to the plaintiff if this barrier pillar should give way, cannot well be doubted. Work would have to be suspended in the Hollenback, and probably in the connecting mines, a very large number of men would be thrown out of employment, the ventilation would be disturbed, and the mines would be filled with explosive gases, and the gangways and air-ways with *debris*. But it is equally true that the only practicable way of putting out the fire in the defendant's mine is by flooding it in the manner proposed, and that if the fire is permitted to go on it will prove ruinous to the Conyngham mine, and may prove destructive to adjoining owners. The mine inspector says: "It is to the interest of the plaintiff company and all the neighboring owners to have this fire extinguished." This is a fact which scarcely needs proof. We have, then, on the one hand, an anticipated injury which may occur, but which is not certain to occur if the defendant is not enjoined, and, on the other hand, an injury which will certainly occur if the injunction is granted. It will be observed also that the act to be enjoined is not a trespass, nor a nuisance *per se*, but is a lawful use of the defendant's property, and is necessary to prevent destruction and injury to adjoining properties. A man may not use his own so as to injure another's property. But the question here is not whether the defendant could defend an action at law in flooding the plaintiff's mines upon the ground that it was necessary to the preservation of its own property, but whether the fact of its act will cause injury to the plaintiff's property is established with such certainty that a court of equity would be justified, under all the circumstances, in enjoining it. In cases of doubt as to the plaintiff's right, or the imminence of the danger, the uniform rule is for the court to withhold its hand, especially where the injury which would result from granting the injunction is greater than that which would result from refusing it: Richards' Ap., 57 Pa. 105; Gray *vs.* Ohio & Penna. R. R. Co., 1 Gr. 412; Harkinson's Ap., 78 Pa. 196-204; Dilworth's Ap., 91 Pa. 247.

Anticipations of danger which may never occur, apprehensions merely speculative, eventual, and contingent, where the grounds on which they rest are denied, rarely warrant interference by injunction: Rhodes *vs.* Dunbar, 57 Pa. 274—287—289; Spring Brook Railway Co. *vs.* Bryan 4 Luz. Leg. Reg. 117; New Boston Coal & Mining Co. *vs.* Pottsville Water Co., 54 Pa., 164; Huckenstine's Ap., 70 Pa. 102—187.

Appreciating fully the seriousness of the dilemma in which these parties find themselves, and not by any means wishing to be understood as making light of the plaintiff's apprehensions, we are, nevertheless, compelled to say that in view of the certain injury which would ensue if the injunction were granted, and the doubt raised by the defendant's affidavits as to the necessity for the exercise of this extraordinary power we would not be justified in interfering at this time. Therefore the motion for preliminary injunction is denied.

Who Owns the Culm Piles?—Some days ago, one of the staff of The Colliery Engineer interviewed Charles L. Hawley, Esq., of this city, concerning a matter of much interest to many of our readers. In answer to the question, "Who owns the culm piles?" Mr. Hawley said:

One of the greatest of the changes which have taken place in the coal business during the past few years is in the treatment of culm and the value placed upon it.

Millions of tons of it are piled up near the various breakers over the whole Anthracite coal region—at as late a time as five years ago the lessee of coal lands did his best to get his lessor to allow him to burden as much as possible of his, the lessor's, land with what was then supposed to be valueless waste, or culm, and he thought himself shrewd when he piled upon such land every year thousands of tons of it containing coal which is now being delivered at houses in this city for two dollars per ton—at least one instance has been brought to my notice in which the very man who threw it away, with the mental ejaculation "good riddance to bad rubbish" recently tried to buy from his lessor the right to screen it out at a substantial per ton royalty.

When these culm piles were built—excuse the term—the lessors, lessees, and public generally considered them, not only of no value but an actual incumbrance on the land; but now that they have been shown to have a value in the market, conflicting claims to them are likely to be made and the courts will, no doubt, be called upon in many cases to decide upon the respective rights of lessors and lessees claiming limited or absolute ownership thereof.

In very many cases the lessors sold to the lessees "all the merchantable coal" under certain lands and gave to their lessees the right to deposit culm on the surface of a certain part of said lands described in the lease. For years all parties to the lease treated the culm like anything in the world but "merchantable coal" and are now estopped from claiming differently. In these cases the coal in the culm pile, as well as the pile itself, as a whole, belongs to the lessors who own the land on which it is; the lessees by their conduct having waived their right, (if they ever had such right *after throwing the culm away*, which I very much doubt) to screen out the good coal in the culm, even upon paying to their lessors. The same per ton royalties called for in the lease.

In such cases the terms of the lease must be interpreted with reference to the common understanding at the time the lease was made; and the thing farthest from the minds of the parties to the lease was the final screening over a small mountain of apparently worthless refuse. It was thrown aside as waste—all parties agreed upon that way of treating it and now they have to stand by it.

This view of the case seems to have been sustained by the courts of our State: In Erwin's case, an owner of lands in Berks County (Pennsylvania) in 1877 leased to another for a per ton royalty the right to mine and dispose of the iron ore in said lands. The refuse resulting from the mining of such ore was afterwards found to contain, not only iron but valuable ochre. In 1887 our Supreme Court sustained a lower court in holding that the lease was made by the parties to it not upon "future possibilities but upon the obvious facts of everyday life," and that the lessees should be enjoined from obtaining the ochre from the refuse.

Years ago the parties to a coal lease did not believe that the lessors were selling what was then considered "waste" to the lessees as "merchantable coal." Had the lessors sued the lessees for royalty on the "merchantable coal" in the dump, would the lessees have fought the case? The question answers itself. While the Berks County case does not precisely cover the point, it does go far enough to establish that when the lessees threw away the refuse they lost their dominion over it.

This position is further sustained by a Lehigh County case (Doster vs. Zinc Co)., decided last year, in which the court say: "However general the terms may be in which an agreement is conceived, it only comprehends those things in respect to which it appears that the contracting parties proposed to contract and not others they never thought of."

One must not be misled by the usual clause, giving the lessee the right to pile the refuse on his lessor's land into the belief that the lessee is thereby given an estate in the land covered by the dump and the possession of the same for the purposes other than the depositing, (for example the screening) of the culm. The clause is much the same as if the lessor had said to the lessee "Mine all you can and put *what you don't want* on my land." The lessor simply agrees that his land may be burdened by the waste. Under a lease of *all the coal* with a royalty to be paid on all coal passing over a certain mesh the lessee would no doubt have the right to prepare and sell, without payment of royalty thereon, all coal passing through such mesh. But to avail himself of such right he must prepare and sell the same without first storing it as waste for years, on the land of his lessor and to his injury. The minds of the parties to the lease when they made it did not unite in such interpretation of its terms.

Lunkenheimer's Glass Body Oil Pump.

Our illustration below shows one of Lunkenheimer's Glass Body Oil Pumps, and is a very important adjunct to an engine. This is intended as an auxiliary to the sight feed lubricator, and is in fact so necessary that no engine should be without one. With this pump any amount of oil can be supplied to the cylinder at any time.

The advantages of this can readily be seen when starting up the engine. Or suppose an accident happen to the sight feed lubricator in the breaking of a glass tube. This would cause great annoyance, but all this can be obviated by having one of Lunkenheimer's Glass Body Oil Pumps on the steam chest or cylinder. These pumps are simple and practical in construction, durable, efficient and very ornamental. They have been adapted by the leading engine builders in the United States, and are highly endorsed by them and thousands of other users. They are strictly first-class and warranted; made in two sizes, holding one-third and one pint respectively, and furnished highly finished either in brass or nickel plated. The glass body shows the stage of oil. It will pay you to investigate this useful article, as it can save its cost many times over in a year. Can be supplied by any dealer in brass goods or by The Lunkenheimer Brass Manufacturing Co., Cincinnati, Ohio, U. S. A. Our 1892 catalogue of superior steam specialties, valves, lubricators, glass oil and grease cups, etc., will interest you. Write for one. See our advertisement on another page.

ATLANTIC CITY.

And the Reading's Royal Route.

The popularity of Atlantic City long since reached National proportions, and it continues to grow from year to year. The approaching season promises to be the greatest ever known at this, the greatest of all seaside resorts. The Reading Railroad, whose superbly magnificent line between Philadelphia and Atlantic City has become famous throughout the country as the "Royal Route to the Sea," will continue to be the principal and favorite means of getting to and from the City by the Sea. The Reading's superiority in equipment is generally conceded. Its chief advantage consists in the fact that it has the only double track line of railroad to Atlantic City. The importance of this cannot be overestimated. Not only does it insure the absolute safety of passengers, but it admits of quicker and more reliable transit. The Reading line is also several miles shorter than any other road to Atlantic City, and it runs almost as straight as the crow flies. The great "Seventy-five Minute Flyers" are the most talked-of trains in America. For beauty, elegance, and speed they are literally beyond rivalry and those of our readers who visit Atlantic City should not fail to experience the delight of a ride on one of these matchless trains. The summer schedule will comprise a larger number of fast express trains than has ever heretofore been run on any line. Trains will start at such frequent intervals that one can scarcely fail to catch a "Flyer" at whatever time he may desire to go. The "Royal Route's" Philadelphia stations are at Chestnut and South Street wharves, and all Ticket Offices on the Reading System have through tickets and baggage checks for Atlantic City.

Mr. George Wise, of Jeddo, Pa., the general agent for Beagle's Patent Mine Hames, which have through their superiority over other hames, replaced all other styles in the more prominent collieries in every American coal field, writes us as follows: "The hame and harness trade is tip top, and my advertisement in The Colliery Engineer is to blame for it."

Our shoulders are broad enough to carry all the *blame*, but it is but fair to state that some of it is due to the merits of the goods and Mr. Wise's straightforward business methods.

EASY LESSONS FOR BEGINNERS

IN THE STUDY OF THE

ART OF MINING

AND THE

SCIENCES RELATED TO IT.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the theory of mining and to learn how to answer the questions in ventilation, mine surveying, and mechanics which are asked at the examinations for mine manager's and mine foreman's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine manager's and mine foreman's certificates and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and the calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

The capital letter V consists of a capital loop, the same as is employed in making the letter U, and a compound curve extending upwards two-thirds of the full height of the letter, joined by a turn at the base line. This capital is written correctly in the first letter at the left of Fig. 43. In the second letter from the left the

FIG. 43.

compound curve retraces the capital loop making an angular turning at the base. The third letter is imperfectly made, in that the capital loop is contracted and the turn at base too wide. The fourth law of penmanship is violated in writing the fourth letter from the left, namely, all curves should be elliptical.

In Fig. 44 the first letter W satisfies the requirements of the four laws of penmanship and is pleasing to the eye. Its development consists of a capital loop, a right curve which is joined at the base by a sharp angular turn to the bottom of the loop, and a slight left curve which is joined at the base with an angular turn to another left curve which extends upwards two-thirds of

FIG. 44.

the height of the letter. The last left curve turns a little to the right. The second letter is a deformity arising out of the imperfect development of the curves near the base line. In the third letter the capital loop is carelessly made, and is out of proportion to the rest of the letter. The turns at the base are too wide, and the second law of penmanship broken in that the strokes are not proportional in distance. The fourth letter shows a common mistake in writing the capital loop, viz., that of making its general shape round instead of oval. The curves are on a wrong inclination, being vertical instead of slanting.

The capital letter X is shown as it should be written in the first letter, counting from the left of Fig. 45.

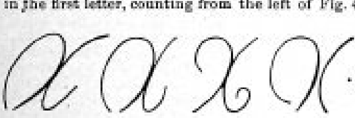

FIG. 45.

It consists of a capital loop, a left curve which touches the loop at one-half its height, and a right curve which is one-third of the height of the letter. In letter 2 the loop is a little too circular and on the wrong inclination. The third letter shows the loop incomplete, and as a consequence offends the eye. In finishing the letter an extra curve is made which spoils the looks of the letter and prevents its union with the following letter in writing a word. In letter 4 the capital loop and left curve do not come together. This is an error which should be guarded against, as it destroys the symmetry of the letter. It is also terminated with a straight line instead of a curve.

METHODS OF MINING.

Shaft Sinking—Tunneling—Systems of Working Coal and Metals—Timbering in Mines.

46. Is this a good form?

It is the commonest and is very strong. The joints must be nicely cut and no spikes used. All the plates must be perfectly level and the posts plumb.

47. Is it not expensive?

It is not hard to make and is very quickly set.

48. Is it used for large shafts too?

Yes, those of three or four compartments are timbered in this style.

49. How are the compartments made?

At every ten or twelve feet buntons, or cross-pieces, are laid, and to them the partition planks are nailed, or else the cage guides are spiked to them.

50. How many compartments should a shaft have?

Always one for a ladder-way, and one for the pump pipes and steam pipes, besides as many hoist-ways as the mine requires.

51. Why are they laid side by side and not in a group?

FIG. 14.

It has been found that a shaft is stronger with the compartments laid as in Fig. 14, instead of as in Fig. 15.

52. Is the round shaft better than the oblong?

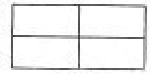

FIG. 15

In general, the round shaft is stronger than the oblong, but it is not so convenient to divide it up into compartments. There is some waste room. There is another reason to account for the round shaft. Many of them have been sunk through wet, or very soft ground and, as we shall see, the method of sinking produces a round shaft which can not cheaply be lined with wood.

53. Is there any other method of lining with wood than what you gave in question 45?

Yes. In firm rock a small shaft may be lined with three-inch plank on edge. Each plank is cut like the pattern shown in Fig. 16 with a shoulder at each end. The left hand cross-plate is not placed. Another common method is that shown in Fig. 17, in which the same kind of a shoulder is cut as in the planks in Fig. 16 but

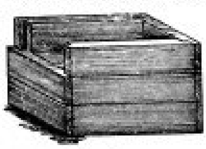

FIG. 16.

they are wider. In Fig. 16 the shoulders are only one-half the thickness of the plank. In Fig. 17 they are as wide as the width of the plank. Besides the planks are laid on their broad side, not on their edge. The two methods last mentioned require sawn and dressed lumber. The first will do with hewn logs.

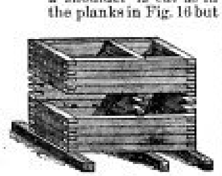

FIG. 17.

54. Are these methods of timbering strong enough for shafts through soft rock?

For rock not crumbling, or swelling, this latter form of timbering with four or six inch scantling is quite strong enough. If the ground requires stronger support, it would be better to use iron or masonry built up in sections.

55. How is a round shaft lined with masonry?

The shaft is timbered rather strongly, and when it is down far enough the masonry is built upwards. At every thirty or fifty feet a strong set of timbers is set into the walls for a foundation, and from this the bricks are built up like a round chimney-wall to the next upper set.

56. How is an iron lined shaft put down?

About in the same way as with masonry. The iron lining is in sheets flanged so as to fit together around the temporary timbers, and also to be fitted together up to the surface.

57. Can not the iron lining be put in as the shaft goes down just as we do in timbering a shaft with wood?

Yes, if the iron tubing is hung from the surface until the foundation has been prepared for it. Then the tubing is lowered to rest on the foundation of stulls.

58 Is there any other method of lowering the iron tubing, or of sinking the shaft?

Yes; a process known as Kind-Chandron bores the shaft down into moderately hard rock without men going down into it at all. The tools are like the oil well rigs, but the drill is thirteen feet across and bores a shaft thirteen feet diameter and quite fast, too. Then, if the shaft should strike soft running ground like water or sand, the tubing is lowered and an arrangement is added below by which the bottom of the tubing is closed completely, preventing the tubing from sinking or the water from rising. A stop-cock in it can be opened if desired and that would let the water out from below and thus permit the tubing to sink. This scheme works very beautifully.

59. Is there any different method of sinking a shaft?

Yes, the late General Henry Pleasants, of Pottsville, Pa., at the time Chief Engineer of the P. & R. C. & I. Co., at the sinking of Ellangowan shaft had diamond drill holes put down holes two inches in diameter, 400 feet deep. These were about 36 inches apart and as many were drilled as would cover the entire area of the shaft. Then the holes were filled with sand, all except for three or four feet deep. They were fired off, all together, by electricity and dualine. After clearing away the broken rock another three-foot section was cleaned out of each hole and fired. So on all the way down.

60. What are the methods of timbering and supporting the roof or the hanging wall?

One way is to leave portions of the vein untouched, as pillars. Every shaft, slope, entry, air-way, or gallery should have pillars of the vein matter on each side, so as to protect these haulage ways against a crush of the roof. The size of them should increase as the gangway increases in importance. Rooms have pillars on either side for protection, which are larger as the mine is deeper. They should be large for a firm roof, because then the weight on the roof, instead of breaking it, falls upon the pillars, so the pillars receive both the weight above them and that on the roof too. With a strong roof the rooms may be wide; if the roof is weak the rooms must be narrow.

61. What are panel pillars?

They are especially large pillars left in the mine to enclose a large area of the workings. A panel is a section of the mine surrounded by panel pillars. Each panel has a set of rooms or stopes which are ventilated separately from the others.

62. What is the advantage of this panel pillar?

It is so strong that if anything happens in a panel, the panel pillar prevents the accident from spreading too far.

63. How else may the roof be supported?

You may timber it up. For a vein of ordinary thickness the ordinary post and cap, or collar will do. But the post is not very strong, so it must not be expected to support very much of the roof. So the posts must be near together. It is safer to have a number of them near together than to have only a few large posts. In working Longwall the miner should keep at least three rows of posts behind him, and not over three feet apart nor over six feet from the face, unless the roof is very good.

64. May these props be used in thick veins too?

They are not advisable. Ordinarily thick veins are worked in slices between the partings (see Question 55 Geology); or else they are worked in slices about six feet high just as if they were veins of that thickness. Then other roof may be propped up temporarily and the props removed afterwards, before beginning the next slice to it. But this is a dangerous plan. When timbering is to be used the plan is what is called the Nevada system. A gang of men work a face six feet high by six wide, and as soon as they have advanced six feet they build up a set of timbers, cut by machine, that fit together like the edges of a box. There are four pieces laid on the floor, making a square; four posts rest at the corners and on them a square of four pieces is laid. This makes one square set. Imagine, now, the men going ahead another six feet. They then lay three sills down on the floor in the same direction as the others. Then put up two posts at the far corners.

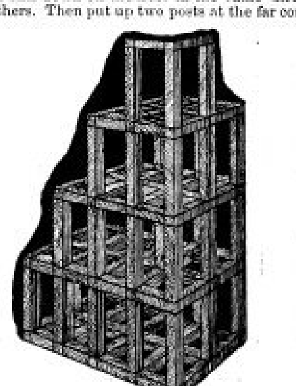

FIG. 18.

On top of the two they rest a cross sill, and finally they place one on each side, resting on one of the last posts and one of the posts of the first set. They proceed building up a honey-comb square set behind them. Then other gangs start on each side and also on top, each building his set onto the first sets. Soon the room will look like Fig. 18 where the men are supposed to be mining to the right, left and ahead.

65. Is this a good method?

Yes, but it is expensive. Think of the amount of timbering to be done! It must be cut faultlessly perfect and fitted well. They have machines for cutting the pieces all exactly alike, so there is no play at the joints. If each joint should have, say, one-fourth inch play you can see that if the roof begins to squeeze or slide, that in a few sets the pieces will slip out of place and then the whole timbering is destroyed. Or if a post or sill breaks for some reason or other, those standing receive more than their proportion of the pressure and the weakest of them is liable to break, then the next weakest, and in a few minutes the whole room is in ruins. A room I know of, ninety feet high, was timbered in this way. When the foreman noticed a broken sill he ordered the men all out, and in ten minutes the crushing had progressed so rapidly as to bury the entire mass.

66. Is the entire vein mined out in this way?

The richest parts are taken out and the space supported by timbers. The iron mines of Lake Superior are worked in this way, and the Comstock silver mines of Nevada. So also the flat lead mines of Colorado are timbered.

67. For what kind of ground is the square set used?

For thick veins of soft ore.

[TO BE CONTINUED.]

POWER IN MINING.

The Elementary Principles of Mechanics—Steam—Boilers—Engines—The Machinery Employed in Mines.

50. Can you write out a simple relation for the second motion engine?

Let W be the weight of cage, car, and rope.
P be the pressure on the crank pin.
c be the length of the crank arm.
d be the diameter of the drum.
y be the diameter of the friction band, or spur wheel.
x be the diameter of the pinion wheel.
R be the pressure between the teeth or friction surfaces,

then $W\,d = R\,y$,
and $P\,c = \frac{1}{2}\,R\,x$

from which we get, $W = \dfrac{2\,P\,c\,y}{x\,d}$.

Try this on the example in Question 45.

51. How would this apply on a direct-acting engine? You know that in a direct acting engine the crank pin is on a wheel that is on the same shaft with the drum. Then, in that case, there is no pinion or geared wheel, so that y and x are each zero, and they drop out of the formula given in Question 50.

52. According to the formula, then, one can not hoist a very large load unless one makes the drum smaller than the friction band, or makes the crank arm larger than the pinion wheel?

That is true.

53. Has not the connecting rod some effect upon the power of the engine?

Yes, it makes the power of the engine vary because it is so short (and it would not pay to make it long because the machinery would have to be so big). The explanation for that is very difficult. At any rate, when the crank is at its dead points, that is, when the piston is at one end of the cylinder, all the power of the steam imaginable could not turn the drum. When the crank is the least bit up from the dead point then the steam power has a leverage so it can turn the drum,

FIG. 9.

In Fig. 9, the leverage of the steam is the distance A B. If the piston moves as shown by the arrow, the distance A B becomes larger until it is equal to the length of the crank arm. Then it becomes small again

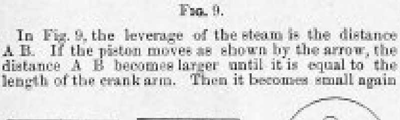

FIG. 10.

to the other dead point, and so on around. That is the reason why the engineer will not let his engine stop at the dead point. For when he tries to start it again it will not start with a very big load. The best place to stop it is at a quarter from the dead point.

54. How may I know the length of the lever arm, A B?

When you know the angle of the crank you can easily enough find A B, because A B is the sine of the angle times the length of the crank. It will be as easy, however, instead of finding A B to calculate the rotational force operating on the crank and multiplying by the length of the crank arm. I give here an average case of connecting rod 5½ times as long as the crank. For

Angle of Crank. Forward.	Angle of Crank. Return.	Position of Piston.	Rotational Force.
0°	360°	0·000	0·202
20°	340°	0·035	0·393
40°	320°	0·13	0·713
60°	300°	0·278	0·914
79° 48'	280° 12'	0·45	1·000
84° 48'	275° 12'	0·50	0·992
90°	270°	0·54	0·972
120°	240°	0·785	0·764
150°	210°	0·946	0·418
180°	180°	1·000	0·000

any other ratio you will need a different table. This is the average case for hoisters. At 0° the crank is at its inner dead point, then moves on the forward stroke to outer dead point at 180°. Thence it returns to 360° or 0°. If the rotational force be multiplied by the steam pressure and by the area of the cylinder also by the length of the crank (or half stroke) you have the movement of the engine power which operates to turn the drum and move the load.

55. Suppose the engine does stop at a dead center, it could not hoist a load?

If the engine is at dead center it could not start a load at all, so the engine would have to be backed up or else assisted.

56. Is that the reason why two cylinders are used?

By using a "duplex" engine—that is two steam cylinders—with the cranks set at right angles to each other there is never any fear but what one of the crank arms is off from dead center.

57. Is there any other advantage with a duplex engine?

In a duplex engine one cylinder is placed on each end of the drum or pinion shaft, and the drum turns smoother with less twisting on the axle.

58. Could not a drum be used for two ropes, one lowering while the other is hoisting?

Yes and if they are keyed to one shaft, each helps the other. Imagine in Fig. 11 the rope A to be hoisting and the rope B as lowering. Hanging from B is a short rope, cage, and car, or a bucket, at the surface. The rope A extends all the way down the shaft and at the bottom has another cage, and car, or bucket hanging from it. The rope and the weight is trying to turn the drum right-handed while the rope and weight A is endeavoring to turn the drum left handed. Each has a lever arm of the same length so we have the weight of two cages and cars, or of the buckets balancing one another and the engine has to start only the long rope A and the ore or coal in the car. As the coal comes up on A, the rope B is going down. The weight of the rope A is constantly growing less while the rope B is lengthening out as it reaches the bottom. When the two cages pass each other, half way down, the rope, cage, and car of A balances the rope, cage, and car of B, and the engine need only be powerful enough to raise the ore. After that the rope B more than balances the rope A, until just before they are landed the weight of the rope A is very small and that of the whole rope B may even balance the weight of the coal.

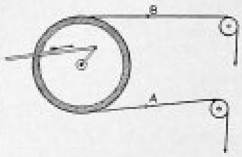

FIG. 11.

59. That ought to be a very good idea?

Yes, it is. Remember, however, I am neglecting friction; of that, I will speak later. But there is a still better plan for saving power than by using double rope on one drum. By the way, what I have explained assumes that the ropes pass off and on the same drum or different drums feathered on the same shaft. If the lowering drum is thrown out of gear while the hoisting drum is geared to the engine, you gain nothing then for the effort of the lowering rope and cage is all spent upon the brake which the engineer has thrown on.

60. Are many drums arranged so they turn on the shaft?

Not many, though it is a convenient plan. If the drum was fixed to the crank shaft you could not lower the rope B without, at least, running the engine. So in such a hoister, the engine must be reversible so as to turn right handed or left handed. Some of them use steam always, even for lowering, whether there are two ropes or only one. The Lidgerwood reversible link motion is one of this variety.

61. What was the method you mentioned as still better than the one described in Question 59?

By a tail-rope system. Imagine, in Fig. 12, A and B to be cages under each is an old rope, too weak to be safe for hoisting passing around a sheave at the bottom. Now, no matter where the cages are, you see that each top sheave has hanging from it a cage, a car and a full length of rope. These always balance while the engine has only to hoist a load of ore. This form of counterbalance or counterpoise works very well if the shaft is clear enough to allow of it.

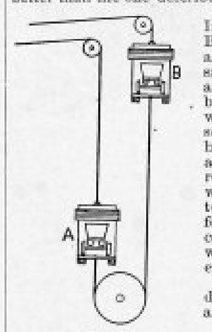

FIG. 12.

62. These all require double rope. Is there any arrangement for single rope?

Yes the double rope requires often a larger shaft than the mine has, so for a single rope there are two forms of counterbalance. One uses a cylindrical drum which we have just been considering, and the rope A is still the hoisting rope. Instead of lowering rope B, Fig. 13, there is a heavy chain so-proportioned with weights as to balance fairly well. It hangs down in a small shaft and when the cage on A is at the bottom, the whole weight of the chain is balancing the cage, rope and car. As the load comes up the chain lowers until it strikes the bottom of the shallow shaft, and coils up there just as fast as the rope A becomes shorter and lighter, until when the load is landed only a little chain is hanging from the drum, by a length of rope. This is used in Australia and in Germany.

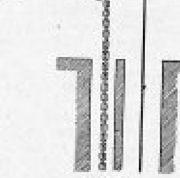

FIG. 13.

[TO BE CONTINUED.]

GEOLOGY

In its Relation to Coal, Iron, Oil, Gas, and Ores.

47. Have these faults anything to do with the cleat of coal?

Not at all. By the name of "cleat" we mean the joints in the coal. All rocks have joints and split along them giving smooth surfaces. Slate cleaves into thin slabs and building stones have also that tendency. But besides breaking into slabs, many stones break across them into blocks more or less like a cube. The joints, along which the stones naturally break are called cleavage joints or "cleats." These joints are natural to every material. Even volcanic rocks, as we shall soon see, have cleavage planes. (See page 287, July, 1891, issue of THE COLLIERY ENGINEER).

48. Are the cleats the same distance apart in all coals?

No. The soft coals have the cleats nearer together than in the hard coals. But for a particular coal they are the same distance apart. Sometimes they are in such directions as to give a cubical shape to the coal. At other times, the cleats are at an angle.

49. What is the cause of cleats?

It is the natural condition of the coal just as the "mundic," "iron," or "pyrites" in the coal always occur as a cube.

50. Are cleats of any help to the miner?

Yes, indeed. The coal breaks off easily at these joints and so the lever will cut under as far as a cleat and then let the coal fall. To make this possible, it often happens that direction of the cleat fixes the direction of the working faces. So the rooms are turned off from the gangways so that their faces shall be with cleat. Mines working by the "pillar and stall" method can take advantage of the cleat in this way. Those working Longwall can not always. In Anthracite, the cleat is not an important enough matter to determine the direction of the working faces. The coal seams are generally too steep there.

51. How does the coal look on the cleat?

Smooth and shiny.

52. Can you explain the methods of mining as you mentioned them?

I leave that to another time.

53. Is the coal often crushed badly by these folds, bends, and faults?

Oh yes. In the hollows of the sharp bends there is a great deal of finely broken coal. The quality of the coal is very much injured and the loss by waste is often very high from this cause.

54. May it be that the "dirt faults" and "rock faults" are caused by grinding of the strata on each other?

Yes, the name of dirt fault is often applied to places where the coal has been badly broken up. Sometimes though the term like that of rock fault or slate fault is used to express the idea that the coal has thinned out and is replaced by dirt, rock, or slate.

55. What are "partings?"

They are seams of clay or slate found in the coal beds that divide the coal into several layers. Rarely is a coal bed without them. They occupy on an average one-seventh of the entire thickness of the bed. These partings are mud deposits that show the bottoms of the ancient marshes had been raised or that the currents flowing through them had changed in direction or speed.

56. What is the amount of coal yet remaining in the U. S.?

That is hard to say. But the Census Bureau estimates 250,000 square miles of coal beds of all varieties and thicknesses. Assuming 5 feet as the average thickness of the coal and an average of 1000 tons of coal that can be recovered from every acre of coal bed of one foot thickness, we have,

$250,000 \times 640 \times 5 \times 1000 = 800,000,000,000$ tons as the total amount of coal.

57. How long will that last?

Last year there was sold and used 128,000,000 long tons. At that rate there is supply for 6250 years. But population is increasing and the demand increases likewise. From the past experience, it has been found that the consumption doubles every 16 years. On this basis, in 190 years all the coal will have been burned up unless other sources of power and of heat are meanwhile discovered or else more economy shown in the burning of fuel.

58. Am I to understand that all coals are made of the same vegetable decay?

We believe so, that club mosses, ferns and trees like our ground pine furnished the most of the mineral coal of the Carboniferous age.

59. How about the cannel coal?

That is a compact smooth-breaking coal which will light with a match just as a candle would. It is formed of the finer grained marsh weeds.

60. I can not understand how so much coal could be formed from one marsh. For the peat and wood must have lost much of its oxygen and of its weight in being compressed to coal?

Yes, so it has, wood actually loses three-fifths of its weight in being altered to Bituminous coal, and three fourths of it is lost in being changed to Anthracite. Besides this, the decayed matter is compressed and loses in bulk. So that, altogether, it took about 5 feet of vegetable marsh to make one foot of Bituminous coal and 8 feet to produce one foot of Anthracite.

61. How thick is the coal?

Coal occurs in marshes very thin at the edges and thick in the middle. In some places a single bed is as thick as 40 feet (one in Colorado is 90 feet thick) but a pure seam is seldom over eight feet. Any thing over that is a compound seam, in which the streaks are separated by thin partings.

62. How many coal seams are there in a district?

In Pottsville, Pennsylvania, there are 113 feet of coal seams; and in the U. S. the largest number of seams, one above the other is 42. In Wales there are 100, of which 70 are worked. In Nova Scotia there are 81 workable seams.

63. Did you say that these different seams were caused by the ocean overflowing the land several times?

Yes. The forests and swamps were covered by sediments and became hidden from view. The marshes sunk during the disturbances that followed. Then the ocean flowed over it and brought more mud. The peat bog compressed and coal began to form there under the clays. After a rest during which more mud and sand was deposited, more disturbances occurred. Some ground went up, some fell. Forests began to grow and more ferns flourished to form marshes. After these had decayed, another sinking is supposed to have taken place, and another mass of peat was buried to afterwards form coal. This must have been repeated as many times as there are seams of coal. Sometimes salt water covered the marsh, sometimes it was fresh water.

64. How long did all this take?

I have seen estimates making it over a million years.

65. How is that measured?

An ordinary forest will make about 2000 pounds of organic matter per acre, each year. This is 200,000 pounds in a century. One hundred tons compressed to be as heavy as coal will make 2420 cubic feet. If these are spread over an acre of 43560 square feet surface, they will form a layer only two-thirds of an inch thick. But in the formation of coal four-fifths of the material escapes as gas, oil, or water and only one-fifth remains in it, therefore it must take 500 years, instead of 100, to make a layer of coal two-thirds of an inch thick. For a coal seam of the standard size, four feet, it must therefore have required 72 times 500 years to make it, or 36,000 years. But some coal regions have over 100 feet of coal. To form the coal alone would therefore require about 900,000 years. Think of it! and we are using it up as fast as we can, and have perhaps enough for the sixth generation beyond our own.

66. What is meant by an ore?

An ore is an accumulation of mineral in such quantity and of such a quality as to pay for mining.

67. What is a mineral?

A mineral is the compound of a metal in chemical union with a non-metallic substance, as sulphur, carbonic-acid (the choke-damp of mines), etc.

68. Will you give some examples?

Iron and sulphur make a mineral called pyrites; lead and sulphur give a mineral known as galena; iron with oxygen makes a very common iron mineral, and silver with arsenic and sulphur is often seen. And when a big bed of any of these minerals is found it is mined for the ore of iron, of lead, or of silver.

69. Is pyrites a common ore of iron?

No. Pyrites is the commonest occurrence of iron in the earth, but it is mined not for iron manufacture but for the sulphur in it. Hence it is not an iron ore. It does not pay to roast off the sulphur and make iron of it when there is so much of a better ore to be had.

[TO BE CONTINUED.]

ANALYSES OF COAL, ORES, ETC.

Instructions in Sampling and in Making Analyses to Ascertain the Quality and Value of Coal, Ores, &c., &c.

The accompanying table gives briefly the results of analyses of some of the varieties of coal:

	Locality.	Sulphur	Fixed Carbon.	Water and Volatile Matter.	Ash.
Plumbago..........	Penn.		94·30	0·60	5·06
Anthracite..........	Rhode Island	0·26	85·84	*10·30	3·60
"	Mauch Chunk	0·50	90·1	6·6	3·3
"	Lehigh	1·00	87·5	7·5	4·0
Bituminous..........	Indiana	·75	75·	21·	4·
"	Penn.		75.4	16·4	8·2
"	Va.	1·1	58·9	30·5	8·6
"	Ohio.	0·7	53·2	43·8	2·3
Fat "	Penn.	·3	49·8	42·7	7·
"	Mo.	1·8	50·7	33·8	14·1
"	Ill.	1·	45·5	43.5	1·0
Lignite..........		1·2	27·1	60·0*	11·6

* 33 per cent. is water.

Determination of Sulphur.—The Sulphur exists in the coal in organic combination, partly in iron pyrites and perhaps as sulphate. So that properly, the sulphur should be reported separately.

Take 30 grains of the pulverized coal and mix it with 30 grains of calcined magnesia and 15 grains of carbonate of soda. Heat in a platinum crucible for an hour, or until the mass melts without boiling. Then lift crucible and all off and let them cool. Place in a glass beaker, or better, in a porcelain dish, and treat them with water and bromine (about ten grains). Filter through a glass funnel. (The filter papers can be had already cut to different round sizes. One of these is folded once across to form a half circle, then the paper is crimped by beginning as shown at A, Fig. 3 and folding A on B then doubling both of them back under. Now bend C and take all three as shown, to form the next crimp and so on till the operation is complete and the paper looks like Fig. 4. Now open the paper out and place it in the glass funnel, wet it a little with clean water and you have a very rapid filter. Looking into the funnel it is like Fig. 5.)

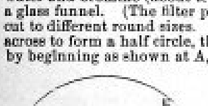

Fig. 3.

Fig. 4.

The portion which has filtered through into a glass beaker is slowly treated to some hydrochloric (muriatic) acid as long as any bubbling of carbonic acid is shown. Now place the beaker on a wire cloth or asbestos cloth, boil off the bromine, add some chloride of barium. A white precipitate forms; this contains the sulphur. Filter this through a funnel as before, dry the paper and its contents slowly, burn off the paper and let the contents fall into a small watch glass or place paper and contents in a platinum crucible and burn off the paper. Weigh and find out how much the precipitate weighs. Multiply that weight by 13·73 per cent. and you have the weight of the sulphur. For example, 30 grains of coal gave us a precipitate which weighed 2·4 grains. Now $2{\cdot}4 \times 13{\cdot}73 \div 100 = 0{\cdot}329$ grain of sulphur. That corresponds to 1·09 per cent. of the coal. As pyrites has 53·33 per cent. of sulphur in it, there was 2·06 per cent. of pyrites, probably.

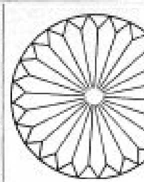

Fig. 5.

Calorific Effect of Coal.—This is measured in a variety of ways. But if you read under Geology of this series questions 116 to 125, you will find a discussion of this matter. The simplest heat measurer is the thermometer. But it only measures the degree of heat, not the amount of heat. For example, a small stove fire may show the thermometer to read 2000° F. inside of it, and so will that in a very large stove. But the small one cannot heat as large a room as the big stove, because it does not contain as much heat. True, the amount of heat does depend upon the temperature of the body, but also upon the mass of that body.

The standard unit of heat is that amount of heat which is necessary to raise one pound of water 1° Fahrenheit. A hot substance, therefore which raised 100 pounds of water 1° F. or 1 pound of water 100° F. has given out 100 heat units. Now it is the number of heat units which coal will give out that we want to know in order to ascertain the calorific—or heat making—value of fuel. This I have explained under questions 116 to 125 in Geology, basing the calculations on the ultimate analysis of the coal. (This latter form of analysis differs from that previously described, in that it requires very elaborate apparatus and aims to convert all the carbon into carbonic acid, weighing the amount produced and collected in a tube. It also converts all the hydrogen into water and weighs that. Then there are 40·7 per cent. of carbon in the carbonic acid 11·1 per cent. of hydrogen in the water. The method described was an approximate analysis which serves for most purposes). See also page 18, of August, 1891, number.

Besides desiring to know the number of heat units, it is equally as important to ascertain the evaporative value of a fuel when placed under a boiler. This may be ascertained quite well by the use of an appliance shown in Fig. 6. This consists of a glass cylinder which will hold 29·01 grains of water (or a multiple of that quantity) up to a certain mark, A. A perforated copper stand, B, has a socket, C, and a copper cylinder D, having springs as shown.

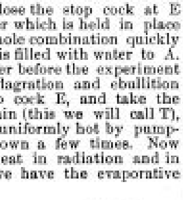

Fig. 6.

The copper cylinder is charged with 30 grains of the pulverized coal, 80 grains of nitre and 240 grains of chlorate of potash. *Do not grind these after mixing.* This mixture is packed gently in the copper cylinder in and around a cotton fuse that is saturated with nitre. Ignite the fuse, close the stop cock at E and put on the copper cylinder which is held in place by the springs. Place the whole combination quickly into the glass cylinder which is filled with water to A. The temperature, *t*, of the water before the experiment is noted. As soon as the deflagration and ebullition has ceased in D, open the stop cock E, and take the temperature off the water again (this we will call T), making sure that the water is uniformly hot by pumping the combination up and down a few times. Now allowing 10 per cent. loss of heat in radiation and in warming up the apparatus, we have the evaporative power of the fuel.

Assume as an example,

t, before the test is	62·1° F.
T, after " " "	73·2 F.
Then the rise of temperature is	11·1°
Loss by radiation	1·11
Result	12·21°.

The ratios and proportions are so taken that the rise in temperature corresponds to the number of pounds of water evaporated by one pound of the fuel under test. From this we learn that one pound of fuel would evaporate, under favorable conditions 12·21 pounds of water. The fuel value of coal does not depend only upon the percentage of combustible matter nor is it exactly proportional to it. A deduction must be made for stoking and the removal of ash. It is because of the increased difficulty of firing that smalls sell at less price than lump, rather than because of the excess of production over the demand for small sizes. In any event, however, consumers are not so careful to ascertain the heating value of the coals as one might expect. If a certain fuel is advertised as a strong steam coal, it is accepted irrespective of its chemical impurities.

[TO BE CONTINUED.]

SURFACE APPLIANCES.

The Preparation of Coal and Ores for Market.

43. Is that the way you control the jigs, too?

Yes, the less water used the cleaner will be the coal in the trough or the jig.

44. Why not do that then?

The trouble is that if you use little water, only a little coal is washed out clean, and the operation is too slow. It would not pay to make such perfectly clean coal as to make the output small. So that the general plan is to work as fast as you dare without producing too bad a coal. So the jig pistons are run fast, and the troughs or sluices are set steep to give a big output of rather clean coal rather than to get a small turnout of very clean material.

45. Are these sluices much used?

You will see them in some coal washing plants in Kentucky, Indiana, West Virginia, and England. They are used in cleaning iron ores, and for washing iron sand out of clay. They are also common for washing dirt and gravel from gold.

46. How are they used for gold?

The cleats are fast to the trough and mercury is placed behind them (gold mines call the cleats, riffles). As the ore is washed down the sluices, the gold settles at the bottom and rolls in behind the cleats where the mercury catches it and holds the precious metal.

47. Are these cheap to work?

Yes, that is their advantage. They will wash only very small coal, and use much more water than jigs. They are not as good washers as some of the jigs.

48. Are they no better for ores?

They work quite satisfactory where there is a great difference between the weights of the material to be saved and that of the waste; so that for ores, or gold washing they work quite well.

49. Can coal be cleaned by any other forms of machines?

Yes, there are the Osterspey Siphon and other conical washers and also bumping tables. These will clean coal nicely and other varieties of these machines used upon ores too.

50. How does the Osterspey Siphon work?

If you notice in Figure 3 you will find a tank having two partitions reaching nearly to the bottom and forming three compartments. Water pours down the central compartment and rises in the other two. In the right hand one, the automatic balance is connected with the lever, rod, and plug of the left hand compartment. The coal and other stuff to be washed enters the left hand compartment and tends to fall down to the bottom but it meets a current of water rising in it. The pyrites is heavy enough to fall against the upward current, but the coal can not. So the pyrites settle in the hopper at the bottom while the coal is washed out at the top. The material is fed constantly so as to make it a continuous machine.

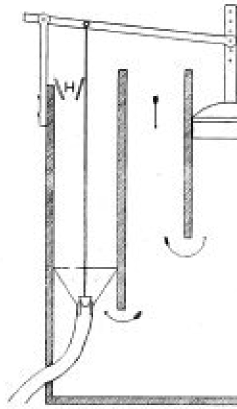

Fig. 3.

51. But the pyrites and slate which accumulate in the hopper will soon choke it up so that the water can not get through?

True, when the water can not get through the right hand compartment comes into play for the water tries to get out there. It raises the balance I mentioned before and that raises the plug which opens the bottom of the hopper and lets the pyrites escape through the tube.

52. Why is this called a siphon washer?

It does not act like a siphon at all and there is no accounting for the name. However, it works well.

53. Does this machine clean the coal well enough without repeating it?

Generally two or three or four of these machines are placed side by side so that the overflow from one washer goes to the next, and so on. This gives a very good quality of coal at the end. Jigs are also arranged the same way so that the overflow from B, Fig. 1, goes to other similar machines alongside of, and slightly below it. By this plan, without any great difficulty, the material gets three or four cleanings.

54. How many times may the coal be cleaned by machines?

Just as along as there is any impurity mixed with the coal, but there comes a time when it does not pay to treat the material more; because the value of the coal after that is not enough greater to pay for the time lost and cost of handling. The cheaper the mineral the sooner that comes. For example: It does not pay to wash coal more than in one class of machines, that is on jig, on sluice, or in an Osterspey; lead and zinc ore are usually treated two, sometimes three times. But silver and gold ores are treated on a variety of machines, over and over again, as I will explain.

55. Is there any other form of coal dresser?

Yes, one which I have not seen frequently here. A form of table that is inclined and about 10 feet long by 3 or 4 feet wide. The material to be separated is delivered at the upper part of the table and tends to flow down it. But the table is hung from rafters overhead and is bumped at the end and the result is that the slate and pyrites actually climb up to the top and fall off into a chute while the coal makes off at the bottom. This goes on continuously.

56. Why should these separate?

Lay a nickel coin on the table, then with your nail catch the table cloth and stretch the threads of the cloth. If you suddenly let go, the cloth will move under the coin which will be stationary. By repeating this you will find that the coin actually moves toward your hand. Now that is what takes place on the bumping table. Under ordinary conditions the coal, pyrites, and all would wash down the table. But it is struck at the end by a wiper A, Fig. 4, striking the block B. A is in continual revolution so it strikes B about 30 times a

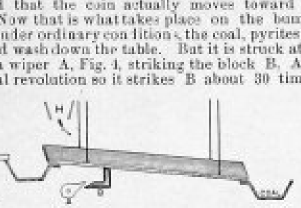

FIG. 4.

minute. So the table is jarrred or "bumped" 30 times a minute. Now all the stuff resting on the table would behave just like the nickel coin on the table cloth, if it were not for the water, which washes the material down hill. One force tries to wash every thing down and another to help every thing up. Between the two, you can arrange the supply of water so as just *not* to wash the slate and pyrites down. As you vary the water supply so you vary the cleanness of the coal. With little water you will have very clean, but only a little coal, With much water you get a bigger output, but there may be some impurities mixed with it.

57. Then this is automatic?

Yes, unless these machines work automatically without constant watching, they would be of no value.

58. How much can these machines treat in a day?

That depends upon how clean the coal is to be made. Of course you do not try to clean coal any better than is necessary for a sale. But a jig will handle about 30 tons of coal a day; a sluice has about 20 tons capacity; while the siphon washer (Q. 50) can treat 40 tons. A table will handle 30 tons without trouble.

59. Do these machines take much power to run?

No, I should say that a jig or table can be run with about ½ a horse power.

60. Are they expensive?

The cost is not high, $300 will set up a large table or jig. Of course for a big plant a number of these will be required, so that the cost runs up, as I said to many thousands.

61. Are there any other means of treating coal that you have not described?

Not that I am aware of.

62. How is it with ores?

They are treated in much the same way.

63. What is the first step?

The ore must be broken just as the coal was. The material however is much harder and therefore requires very powerful machinery to break it.

64. What is in the ore?

Quartz, limestone, pyrites, galena, blende, and silver mineral.

65. What is an ore?

Anything that has a mineral in it enough in quantity and pure enough in quality to pay for mining.

66. Then coal is an ore?

Yes, though some of it is very poor. While other coal is so far away from railroad as will not yet pay to mine. Often, clay of good quality may be an ore.

67. Please define minerals and those you mention in Q. 64.

See questions under Geology, in June and July issues for an explanation of the different minerals in ores.

68. Please explain the kind of breaker used to crush metallic ores?

The ore falls between the rough jaws of the crusher One jaw is fixed while the other swings from the top. An eccentric forces the lower movable end against the lower end of the fixed jaw. The rock which falls between the two is crushed to about walnut size and smaller. I cannot conceive any rock that cannot be broken by this machine.

69. Then it does not work like the steamboat rolls?

No, those rolls will do for coal, but not for quartz.

70. Is that all the breaking the ore gets?

No, the broken stuff slides down the chute to a pair of rolls—just like those for coal, only they have no teeth. These rolls turn constantly in opposite directions to one another and are so set that they break the ore very fine—to one-half inch or less.

[TO BE CONTINUED.]

VENTILATION IN MINES.

Including a Description of the Gases Met With in Mines and the Atmospherical Conditions Necessary to Be Known to Understand the Laws of Ventilation.

26. What effect has the falling of the barometer upon the ventilation of the mine?

The pressure outside being so much less, air is sucked up, just like the water, only faster, because air is lighter.

27. How does it effect the gas in the goaf?

In the same way. It "sucks" the gas into the gob roads or air-ways because a partial vacuum is produced by the escape of mine air, at the surface, and the gas rushes out to help fill the space abandoned by the mine air.

28. Is that the principle of the fan exhaust?

Yes, the fan revolves very rapidly and produces a vacuum into which the air rushes to fill because at the downcast shaft the atmosphere is forcing air through the mine and up the return way.

29. Is that what produces the current?

Yes, the downcast is like the arm N, of Fig. 3. Upon it the weight of the atmosphere added to the air in the intake is pressing on one side trying to balance the weight in the arm M. But just as fast as air enters the mine, an equal amount goes out of it at the upcast and the current is circulating.

30. The U tube in Fig. 3 looks like the water-gauge we use.

So it is, just the same. The air of the intake forces N down and M up, the latter being connected with the upcast. The height M N measures the difference of pressures in the two shafts. If the fan makes a vacuum so that the barometer reads in the fan way 29 inches of mercury while the barometer outdoors reads 30 inches, the mine air weighs only $\frac{29}{30}$ of the atmosphere.

31. How much does the water-gauge read?

In an easy mine to ventilate, the gauge pressure is not over ¾ inch—that is the difference between the levels of the water in the two arms is about ¾ inch. A mine which is large and has long, or narrow, entries and air-ways requires a pressure equal to a 4-inch difference in level.

32. What is the pressure corresponding to the water-gauge readings mentioned?

You may remember that the atmosphere weighs 14·7 pounds for a pressure of 34 feet, or 408 inches of water column. Then for the gauge readings mentioned we have 0·027 pounds and 0·144 pounds, because

$$408 : \tfrac{3}{4} :: 14{\cdot}7 : 0{\cdot}027$$
$$408 : 4 :: 14{\cdot}7 : 0{\cdot}144$$

33. What is meant then by saying the pressure is 10 pounds in speaking of mine ventilation?

The figures I gave are for each square inch, but mining men prefer to figure in feet. So as there are 144 square inches in every square foot, it follows that the pressure per square foot of area, produced by the atmosphere is $14{\cdot}7 \times 144 = 2086$ pounds.

Those given above are 3·9 pounds and 20·7 pounds. The 10 pounds you refer to mean that the difference in the water column levels is such as to correspond to 10 pounds weight per square foot or 0·07 pounds per square inch.

34. How may I best calculate the pressure?

The formula we use is $p = 5{\cdot}184\ g$. In this p is the pressure in pounds per square foot; 5·184 is the weight of a column of water 1 inch high and 1 foot across while g is the difference in level of the water columns.

35. What is the pressure when the gauge reads 2 inches in my Anthracite mine?

The pressure is 10·4 pounds per square foot.

36. Would this be true in the light air of Colorado, too?

Yes, the pressure would be the same anywhere.

37. Of what use is it to know the gauge pressure?

It measures the force necessary to drive a current of air through the mine. One arm of the tube projects through a door into the intake current and the other arm is on the other side of the partition in the return air-way. If there is any difference in the levels of N and M, Fig. 3, then that measures the difference in the pressures of the incoming and outgoing air. It measures therefore the loss of pressure by reason of the "drag" or friction of the air in passing through the airways. To overcome the friction, greater force must be given to the current in proportion as the gauge reading is great.

38. Then the gauge only indicates the drag of the air, not the amount of air?

That is so. It does not follow that because a mine has a high gauge reading of, say 4 inches, that it is receiving any more air than one working with a ¾-inch gauge.

39. How is the required pressure obtained?

You can get it by an exhaust fan, a blowing fan, or by the furnace?

40. Which is the best?

Generally speaking, an exhaust fan is preferred because it is cheap to run, and always reliable. The blowing fans are used to ventilate the faces of breasts working on a steep pitch. The furnace is dangerous, consumes more coal than the steam engine running a fan and is not as good as a fan for mines of moderate depth.

41. But there are more furnaces than fans used?

Yes, but fans are being acknowledged better and nearly all new mines are putting in fans instead of furnaces. A good fan and engine is cheaper than a furnace for a mine not deeper than 4,000 feet. Below that, a furnace may be more efficient. Hence, the utility of the furnace is confined to very deep shafts.

42. Are they not good ventilators?

Yes, furnaces are fairly good, but they are limited in capacity because they can burn only a certain fixed quantity of fuel and the temperature to which they can raise the air is therefore limited.

43. How is the difference in pressure produced?

Do you remember, how in Question 23 I explained the suction with a tube? Well, an exhaust fan does the same thing. If it turns very fast it draws the air out which the atmosphere tries to replace. If the fan could be worked air-tight like the plunger of a pump, a very strong suction could be produced, but this is out of question.

44. What is the idea with the furnace?

To produce a volume of air, at the bottom of the upcast, hotter than the air in the intake. The hotter a gas is, the lighter it becomes. So as the light, hot gas rises the atmosphere drives cold air down the other shafts.

45. How may we know the effects of the fan?

By the water-gauge and by our knowledge of the weight of a gas. A gas increases in weight as its pressure increases. You remember that the weight of the gas in Scranton is greater than that in Colorado, because the pressure under which it is is also greater, Fig. 1. Again the weight of a gas decreases as its temperature increases. So the weight of a cubic foot of gas is equal to

$$W = \frac{1{\cdot}3253\ B}{459 + t}$$

In this B is the number of inches of mercury of the barometer and t, the number of degrees Fahrenheit of the thermometer. From this we can calculate all conditions of ventilation.

46. Our mine is 600 feet deep and the furnace gives us gas 150° Fahrenheit, how am I to know the weight of the gas?

At the sea level the barometer stands at 30 inches of mercury, so one cubic foot of gas will weigh

$$39{\cdot}759 \div 609 = 0{\cdot}0653 \text{ pounds.}$$

If the temperature of the air outside is 60° F., then one pound of it weighs 0·0766 pounds. Every cubic foot of air in the downcast weighs 0·0766 pounds while each cubic foot of the upcast weighs 0·0653 pounds. Each shaft is 600 feet deep. Now, a column of air 600 feet high and one square foot of base weighs 600 times 0·0653 (= 39·18 pounds) in the upcast, and 600 times 0·0766 (= 45·96 pounds) in the downcast. Then one side weighs more, for every square foot, than the other by 6·78 pounds. And just as the columns of water in Fig. 2 changed because of the pressure on one side so here, if you imagine the water at the higher side to run over at the top just as air does. The ventilating pressure of that furnace is therefore 6·78 pounds, or 1·30 inches of gauge (see Question 34).

[TO BE CONTINUED.]

First Class Mine Cars.

There is no equipment of a colliery that requires more care and better work in construction than the mine cars. They are subject to the severest usage, and to be of most service they must not only be constructed of substantial materials, but they must also be so made as to run with a minimum amount of friction.

The Star Manufacturing Company, of New Lexington, Ohio, recognized these facts when they started in business, and the result has been that to accommodate their steadily growing trade they have largely increased their works, and at the same time introduced such machinery and system that they are able to turn out first-class cars at very low prices. They are prepared to build mine cars of any shape or size, and use in their construction nothing but the best Muck bar iron and seasoned timber.

Every portion of the car is made so as to secure the greatest strength and convenience in handling. When brakes are required they are arranged so that they are most efficient and convenient.

Their wheels and axles are deservedly popular wherever used, and their points of excellence are as follows: They are made of the best grade of charcoal iron, carefully selected for the purpose. The wheels are cast in chills that give them an exceptionally deep chill. The oiling device is simple and economical, and makes an easy running wheel. The wheels are made either self-oiling or plain and sample sets are sent on approval. They are all bored out in the hub, true to fit the spindle, before they leave the factory, and are carefully inspected so that none but perfect wheels are shipped.

Wheels, axles or car irons, of any size or description, are sold separately whenever it is desired to construct the cars at the mine.

The facilities of the factory are such that orders can be filled at short notice, and we advise our readers to write them for their special circular describing their mine cars. One of the features of this establishment is a blank form which they cheerfully send to mine owners or superintendents. These blanks are so printed that the superintendent can readily fill them out so as to describe exactly the size and character of car desired, and prompt estimates will be made from them when returned to the shops. Or, if the gauge of track, size of wheel, height of car, height of coal, and capacity of car is given, they will cheerfully give their ideas of the size of car and irons adapted to the same, based on their past experience. As stated before, the Star Manufacturing Company's shops are located at New Lexington, Ohio.

Anti-mony Rubber.

In the present age of diffused knowledge it is surprising how little is known about India Rubber although the consumption of that article runs into the millions per annum and many companies with millions of dollars capital, are daily manufacturing and putting it before the public. Buyers keep on purchasing and using rubber that don't last half as long as it would if intelligently ordered. A case in point is Drill hose, so largely used in mines. In a late edition of that bright trade paper, The Rubber *World*, we read: "We think that the very best rubber which in the present state of knowledge upon the subject, it is possible to manufacture is what is known as 'Anti-mony Rubber.'" Now, how many of our subscribers know what Anti-mony Rubber is, or why it is better than sulphur cured rubber? In fact, how many of them know the different terms by which the trade distinguishes between Sulphur cured and Anti-monial cured Rubber? And yet for purposes where Rubber is constantly subjected to steam-heat there is probably double the life in the Anti-mony (or Mineralized) Rubber, than there is in the Sulphur (or Vulcanized) Rubber.

Again it is a well established fact that Mineralized Rubber will withstand the action of earth oils far longer than Vulcanized and yet what engineer takes this into consideration in ordering? It is not a case of price. Quality for quality, we believe that the Mineralized is as cheap as the Vulcanized, although probably the former is not susceptible of being adulterated to the extent that the latter will bear.

These remarks are communicated by the Mineralized Rubber Co., whose advertisement will be found in our columns and who, despite their name, supply both Vulcanized and Mineralized Rubber, and who will gladly reply to any further enquiries that may be addressed to them at their offices in Cliff St., New York.

USEFUL INFORMATION

The Columbus of History.—How his Character appears under the Search-Light of Modern Investigation.

The Columbus of history is one of its least pleasing characters. He was evidently a searover and a buccaneer. He sold his services to Rene of Anjou, or Charles of France indifferently. A rude uneducated seaman, he joined in the barbarous sea-fight off St. Vincent, and aided in the massacre of honest traders and useful men. Time somewhat softened his harsher traits, but his early impulses never left him. He became familiar with the slave-trade in Portugal, and introduced it to the New World. He treated the natives of the new land with pitiless severity. He threw them into chains, cut off their hands and feet, or sold them as cannibals to misery and death. He probably invented the fiction of the Caribs only to destroy them. Las Casas thought that the judgments of Heaven had fallen upon the merciless discoverer. In almost every trait of moral excellence Columbus seems equally wanting. To the Spanish settlers in Hispaniola he was a hated tyrant, a cruel usurper. He threw Moxica over the walls of his fort with his own hands, and spurned him as he fell. His victims, hung by the neck, shocked the humanity of Bobadilla. It was believed that Columbus and his brothers planned a new empire in the Indies, and hoped to throw off the yoke of Spain; in later years Columbus engaged in a treasonable correspondence with Genoa. His ingratitude to the Pinzons, his betrayal of Beatrix Enriquez, his falsehoods, his fierce bursts of rage, his avarice, his revenge, his wild ambition, his pious frauds, his fanatical faith, can never be forgotten; they may be forgiven. Harsh, fierce, severe, the features of Columbus look down upon us over the flight of four centuries, the symbol of his cruel age.

Columbus found the natives of America full of the passion for gold. The glittering particles had for them an irresistible attraction, as to so many of what are called the educated races. They searched in the rivers and sands for gold, and when they had found it hung it in their ears and noses. Sometimes the more highly cultivated beat it into plates, which they fastened around their necks. It was their chief and almost only ornament, almost their only dress they used, too, paint, feathers, and strings of pearls. The universality of this strange passion for the ductile metal in civilized and savage man is without an explanation; it is natural. We are told that there are ants that heap together glittering particles of precious or colored stones; it is their instinct. In Columbus the passion raged with a violence seldom known. He dreamed of golden palaces, heaps of treasure, and mines teeming with endless wealth. His cry was everywhere for gold. Every moment, in his fierce avarice, he would fancy himself on the brink of boundless opulence; he was always about to seize the treasures of the East painted by Marco Polo and Manderville. "Gold," he wrote to the king and queen, "is the most valuable thing in the world; it rescues souls from purgatory and restores them to the joys of paradise."

It was something of his early pirate life that stirred him in his plans of discovery. He was always a buccaneer. He was always a slave trader. He selected the port of Navidad because it seemed a convenient harbor for slave-ships. He made slaves wherever he went. In his fierce avarice, when he found the naked Indians had little gold, he proposed to sell them, and thus establish a wide source of profit. Gold he must make by some means. He urged upon the king and queen his infamous project. They seemed at first to disapprove, and afterward countenanced it. They could scarcely fail to see that hunting the helpless natives through the islands and the continent to sell them into slavery was not a Christlike trade. They gently rebuked the discoverer, but soon after we find them lending him their approval. "Let him be informed," they wrote, "of what has transpired respecting the cannibals that came to Spain. He has done well," etc. Soon every Spaniard who sailed to America became a slave-trader. Ojeda and Americus Vespucius filled their ships with "cannibals," and the brothers of Columbus followed the example of the admiral. A boundless horror settled upon the new-discovered lands. Las Casas thought the sickness and pains that fell upon Columbus a judgment for the woes he had inflicted upon the helpless Indians.—*From "The Mystery of Columbus," by Eugene Lawrence, in Harper's Magazine for April.*

Ocean Depths.

The eight or nine mile depths in mid-ocean, declared very probable by Maury, are not found by later actual investigation, according to the *Engineering News*. A depth of five to six miles is very exceptional and the average appear to be about 2,500 fathoms for the waters of the globe. The greatest depth yet found is 4,575 fathoms (5¼ miles) south of the Ladrones, and 4,561 fathoms north of Porto Rico, near St. Thomas. The deepest sounding, then, in the North Atlantic is 4,561 fathoms, and in the South Atlantic bottom is always found at a less depth. The Mediterranean gives 2,150 fathoms as a maximum to date, and the deepest known water in the Indian Ocean is 3,199 fathoms. The polar basin seems to grow shallower as the North Pole is approached, and bottom was found at 72 fathoms in the most northern sounding made. These soundings, so far as made, also disprove the theory that the ocean bottom is a counterpart of the dry land in its irregularity of surface. It has its peaks and deep gorges, but as a rule, the surface lies in very gentle undulations, without abrupt or steep slopes.

The Problem of the Age.

"The labor problem" remarked a political philosopher from Western New York, "not only puzzles the student of economics in your big cities, but it tries the soul of the agricultural bosses. I own some large farming tracts in the Northwest and West and understand pretty thoroughly the conditions that prevail there, as well as in the interior of our own State. There are hungry hordes of unemployed men and women in every large city in the land. I am assured that there are thirty thousand unemployed in the city of Chicago alone, and probably as many here in New York. The same holds good proportionately in other cities. Not the same persons all the time, perhaps, but an average—some working to-day and some to-morrow, for a few weeks or a few months, another set being idle while these have work, and so on. When we consider the still greater number who labor at a recompense so slender that it serves merely to keep soul and body together, who live practically in perpetual bondage to their daily necessities this view is appalling. As a matter of cold fact there is employment to-day for every able-bodied man and woman in the United States—remunerative employment.

LABORERS WANTED.

"There is more territory and are more interests suffering to-day for want of laborers than there is territory overcrowded or are interests oversupplied. There are vast sections of this country where it is actually impossible to obtain help, male or female, and where that is we have arrested development. I know it to be a fact that within twelve hours of Chicago enough help cannot be obtained to carry on farming operations. There are no farm hands to be had, although homes and good pay are offered on yearly contracts.

"There are no house servants to be hired for love or money, and the well-to-do are obliged to do their own washing and other housework. The absence of help is as marked in all the small Western towns as in the country. I believe there is some kind of employment and a home for every man, woman and child in this country who can do anything.

"The trouble is just where the trouble is with contracts—the question of exchange. People are freezing to death within a few hours of coal regions; other people are starving here while corn is being burned for fuel in Kansas. Our grain rots in the shock for want of help to garner it, and thirty thousand hungry mouths and idle hands are within a day's travel of us.

THE RUSH FOR THE CITY.

"The high daily wages of manufacturing centers drains the country of young men, and once there they will never return. Their children would rather live in garrets in the city than go on a farm and plough and plant and do housework. The real labor problem is to equalize things, to draw off the surplus from the congested points and spread it on the deficient spots. If the so-called labor leaders and humanitarians could work earnestly together to that end the labor problem might be solved. I do not say it could be accomplished without the co-operation of labor, for it couldn't. You can't take an unemployed man or woman off the streets of a city and compel him to accept work and a home. You can't make him stay if you get him. If you could do that the question could be settled. It rests with the labor world. The employers of labor don't want it settled. The sharper the competition the cheaper they get their work done."—*New York Herald.*

"Records for One Mile."

Of the various methods which man has found or invented to get himself over the ground as rapidly as possible, railroad travel is the fastest. The following table gives the fastest time for one mile of the leading methods:

Railroad Train	49 sec.
Ice Yacht	1 min. 10 sec.
Running Horse	1 min. 35 sec.
Torpedo Boat	1 min. 50 sec.
Pacing Horse	2 min. 4 sec.
Trotting Horse	2 min. 8 ¾ sec.
Steam Launch	2 min. 12 ¼ sec.
Skating	2 min. 12 ⅗ sec.
Bicycle	2 min. 15 sec.
Ocean steamship	2 min. 40 sec.
Foot Running	4 min. 12 ¾ sec.
Four-oared shell	4 min. 51 sec.
Single sculls	5 min. 1 sec.
Eight-oared shell	5 min. 4 ⅘ sec.
Walking	6 min. 55 sec.
Swimming	12 min. ½ sec.

Training the Memory.

A splendid way to improve the memory is to begin by treating it as if it were another person, and then charging it upon penalty of a severe upbraiding, to keep until wanted the information, fact, date, name, or whatever is to be remembered. By this course you unconsciously do two things—you sort out things worth while to know, and you impress them upon the memory in such a way as to cause it to grasp and keep them.

The latter is a most important thing to do. Half of one's forgetfulness comes from failure to properly grasp what it is that you are to remember. It is said of Thomas B. Reed, the famous member of Congress from Maine who was Speaker of the House of Representatives for two years, that he considered it a great hardship to have to tell a man the same thing twice.

You ought never to cause any one such hardship.—*From Harper's Young People.*

MECHANICAL NOTES

Precious Metals.

Many of the elementary metals are more valuable than gold. To speak of them as being mined is, however, hardly precise. They are extracted by tedious and expensive processes in chemical laboratories in infinitesimal quantities. The following is a recently prepared list of the elements whose market value exceeds that of gold, the price of the latter being $299.72 per pound, avoirdupois:

	Value Per Lb.		*Value Per Lb.*
Vanadium	$4,792.40	Indium	$1,522.08
Rubidium	3,261.60	Ruthenium	1,304.64
Calcium	2,446.20	Columbium	1,250.28
Lantalum	2,446.20	Rhodium	1,032.84
Cerium	2,446.20	Barium	924.12
Lithium (wire)	2,935.44	Thallium	788.20
Lithium (globules)	2,224.76	Osmium	652.32
Erbium	1,671.57	Palladium	498.30
Didymum	1,630.08	Iridium	466.30
Strontium	1,576.44	Uranium	434.88

These are not nominal values, as many of the elements are used in the arts. Vanadium, for instance, is employed in the production of analine black. It requires some twenty-five distinct chemical operations to extract vanadium from sandstone.—*New York Herald.*

A Great Pumping Engine.

An engine for pumping, which is said to be the largest ever built in this country, will soon be placed in position at the Spring Garden Water Works near Girard Avenue bridge, Schuylkill River. It has just been completed by the Southwark Foundry and Machine Company, at Fifth Street and Washington Avenue, this city. A daily journal says of it:

The mammoth engine, which is of the twin compound condensing type, will have a capacity of 20,000,000 gallons per twenty-four hours delivered against a head of 250 feet above the water in the fore-bay, through a rising main of 48 inches diameter and 14,000 feet length. The order for it was placed with the company about a year ago, and it has required ten or eleven months to make the patterns and build it. Considerable time and care were devoted to the study of the designs, it being the purpose to meet as completely as possible the special conditions of space alloted for the pump at the Spring Garden Works, the work to be performed, the convenience of operating, and the durability of the details of the engine.

The entire pump weighs 950,000 pounds. It will occupy a floor space of 40 by 30 feet and is 35 feet in height. Two massive bed plates, single castings, weighing 80,000 pounds each, will support the steam and water cylinders and also carry the bearings for the beam shaft, crank shaft, fly wheel, and steam cylinders.

The pump is supplied with two high-pressure steam cylinders of 3 feet 8 inches diameter each and two lower pressure steam cylinders, each 7 feet 4 inches in diameter.

The water cylinders are placed horizontally with valves moving in a vertical direction. The fly wheel, 20 feet in diameter and weighing 90,000 pounds, is carried by the main shaft. A triangular walking beam is employed for transmitting the power to the pump. The two pump plungers are of the double-acting pattern, each 37 inches in diameter.—*Philadelphia Manufacturer.*

How a Thermometer is Made.

The making of a thermometer may be either a delicate scientific operation, or one of the simplest tasks of the skilled mechanic, according to the sort of thermometer made. With the extremely sensitive and minutely accurate instruments designed for scientific uses great care is taken, and they are kept in stock for months, sometimes for years, to be compared and recompared with instruments that are known to be trustworthy.

But so much time can not be spent over the comparatively cheap thermometers in common use, and these are made rapidly, though always carefully. The method of manufacture has been so systematized within a few years that the very cheapest thermometer should not vary more than a fraction of a degree from the correct point.

Whether the thermometer is to be charged with mercury or alcohol; whether it is to be mounted in a frame of wood, pressed tin, or brass, the process is substantially the same. Mercury is used for scientific instruments, but most makers prefer alcohol, because it is much cheaper. The alcohol is colored red with an aniline dye which does not fade.

The thermometer-maker buys his glass tubes in long strips from the glass factories. The glass-blower on the premises cuts these tubes to the proper lengths, and with his gas-jet and blow-pipe makes the bulb on the lower end. The bulbs are then filled with colored alcohol, and the tubes stand for twenty-four hours.

On the following day another workman holds each bulb in turn over a gas-jet until the colored fluid, by its expansion, entirely fills the tube. It then goes back into the hands of the glass-blower. He closes the upper end, and turns the tip backward to make the little glass hook which will help keep the tube in place in the frame.

The tubes now rest until some hundreds of them, perhaps thousands, are ready. Then the process of gauging begins. There are no marks whatever upon the tube, nothing to show the temperature of the atmosphere, and the first guide-mark to be made is the freezing point, 32 degrees Fahrenheit. This is found by plunging the bulbs into melting snow. No other thermometer is needed here for a guide, for melting snow gives invariably the exact freezing point. This is an unfailing test for any thermometer whose accuracy may be suspected. But melting snow is not always to be had, and a little machine resembling a sausage grinder is brought into use. This machine shaves a block of ice into fleecy, snow-like particles, which answer the purpose as well as snow.

When the bulbs have been long enough in the melting snow a workman takes them one by one from their icy bath, seizing each one so that his thumb-nail marks the exact spot to which the fluid has fallen. Here he makes a scarcely perceptible mark upon the glass with a fine file, and goes on the next.

The tubes, with the freezing point marked upon each, now go into the hands of another workman, who plunges them, bulb downward, into a vessel filled with water kept constantly at 64 degrees. A standard thermometer attached to the inside of this vessel shows that the temperature of the water is correct. Another tiny file-scratch is put at 64.

Then a third workman plunges the bulbs into another vessel of water, kept constantly at 96. This is marked like the others, and the tube is now supplied with these guide-marks, each 32 degrees from the next. A small tab is then attached to each tube on which its number is written—for owing to unavoidable variations in the bore of the tube each one varies slightly from the others.

With its individuality thus established the tube now goes into the hands of a marker, who fits its bulb and hook into the frame it is to occupy, and makes slight scratches on the frame, corresponding to 32, 64, and 96 degree marks on the tube. The frame is given a number corresponding with the number of the tube and the tube is laid away in a rack amid thousands of others.

The frame whether it be wood, tin, or brass, goes to the gauging room, where it is laid on a steeply-sloping table, exactly in the position marked for a thermometer of that size. The 32, 64, and 96 degree marks must correspond with the marks upon the table; if they do not the error in marking is instantly detected, and the frame is sent back for correction.

A long, straight bar of wood or metal extends diagonally across the table, from the lower right-hand corner to the upper left-hand corner. On the right this works upon a pivot, and on the left it rests in a ratchet, which lets it ascend or descend only one notch at a time. That notch marks the exact distance of two degrees. With the three scratches already made for basis the marker could hardly make a mistake in the degrees if he tried.

The marks made upon the frame or case are all made by hand with a geometric pen and India ink if the frame is of wood, and with steel dies if it is of metal.

The tube bearing the corresponding number is next attached to the frame, and the thermometer is ready for the market without further testing. Some makers use only two guide marks; but the best makers use three.

In the process of manufacture the ordinary thermometer goes through the hands of nineteen workmen, half of whom are often girls and women.

Some of the larger concerns in and near New York produce several hundred thousand instruments annually, and on every one of them the purchaser may see, if he looks closely, the tiny file scratch on the glass at 32, 64, and 96 degree marks—or somewhere near them, as different makers use different points.—*William Drysdale, in Philadelphia Inquirer.*

HOW TO LIVE

Civilization as a Cause of Disease.

Dr. Wm. Cushing, in a lecture recently, maintained that to live in accord with the present civilization it is impossible to conform to the laws of health; hence civilization and health are not cordial in their relations, the chief aim of study in the past has been to cure disease that has taken such fearful hold of civilization; the study of the future will be to prevent disease. The best means to that end will be to properly educate the people.

One of the greatest sources of evil in civilization is the use of stimulants; it has indeed come to be regarded as necessary. As a scientific fact, however, stimulants are not necessary.

No beverage in use is so hurtful as tea, particularly to women. It excites and shocks the nervous system and results finally in prostration. The tannin in tea is a poison that only serves to impede all the natural functions. Coffee is much less hurtful because it interferes less with nutrition.

ALCOHOL HURTFUL.

Alcohol is bad in its concentrated form and the primary cause of a great many disorders. In its lighter forms it is less hurtful, and in some forms even beneficial if properly used. As it exists in malt and light wines it is an aid to nutrition and prevents the waste of tissue. The study of civilization should then be to learn the proper use of alcohol.

Tobacco has no redeeming qualities; it is bad from beginning to end, and absolutely no good comes from its use. It impairs to a greater or less extent all the senses; but its chief evil is its hurtful influence on the heart and brain. It is particularly injurious when taken into the immature system. If people are determined to use it, the effect would be much less hurtful by waiting till after they are 21 years old.

Overeating is a dreadful vice of civilization. It takes into the system an excess of material that cannot be thrown off, and the inevitable consequence is the turning of that into poison, the chief agency of disease. People eat too much meat, too many varieties of food and too much trash, which moves in genteel society under the alias of "pastries." Meat once a day is usually enough for any one, and there is no better specimen of health than the ruddy German, who is glad to get it twice a week. Too much food results in fatty degeneration.

EATING TOO FAST.

An evil hardly less hurtful than overeating is fast eating. This, too, is one of the pernicious products of civilization. People not only eat too fast, but they live too fast, and the extra energy they expend is taken off the end of life.

The fast living of civilization causes riot among all the natural functions. The nervous system becomes irritated and weakened till it can no longer resist fatigue. Then disease takes hold.

Contagious diseases are peculiar to civilization. Consumption, scarlet fever, typhoid fever, cholera, smallpox and others, all contagious, are rare among the aborigines. They are in the great majority of cases the result of drinking impure water.

The cure of all this is the education of the people. Every school in the land should have one or more competent teachers of hygiene. For every dollar spent in building schools, a like amount should be spent in providing proper means for physical training.

Night Air and Malaria.

"Ever since I can remember, I've heard changes rung on the necessity for sitting in doors at night, especially in malarial districts. To walk about much in the evening was deadly. To sit on the porch or door step was to take one's life in one's hands, while riding or driving were only permitted as matters of necessity, and the team generally went home against time, in order to get us in out of the night air.

"Now, the physician comes in here and attends a patient suffering from a malarial disease, and after divers and sundry other directions, tells us, that, whatever we do, we must not shut fresh air out of the sick-room even at night, but must have the windows so arranged that the ventilation will be as nearly perfect as possible.

"Now, this is a malarial locality, at all events it is considered so, and the patient contracted whatever disease there may be just here. If you will tell me what difference there is between breathing night air indoors, and night air out of doors, it will relieve my mind of great anxiety. We would no more think of spending the night, or any portion of it, in the hammock on the porch than we would of seeking suicide in any other direction, and yet here is this medical authority insisting that we bring indoors the very elements that we are supposed to stay in the house in order to avoid.

"Now, don't understand that I am quarrelling with anybody's notion on the importance of fresh air, for I am not, but I am trying to make up my mind why so much is said against spending a little time out of doors in the evening, and so much in favor of bringing the same atmosphere into the house. For my part, I think that a great deal of the danger from night air comes from the fact that people go out without sufficient wrappings. I think that I could spend half of my evenings on the piazza, and not receive the slightest injury, if I protected myself in a proper way, but I should wear a cloak as thick as the one I use in midwinter, and should keep a hood or light shawl over my head all of the time. I once spent a season in one of the worst malarial districts I ever knew. It was confidently predicted by every one who knew me, that I would have malaria-fever, because I insisted on sitting out on the porch of evenings, but I always put on a jacket, and then wrapped myself in a mackintosh with a hood pulled over so as to cover all but my face. I didn't catch cold, nor did I have an ache or a pain either that season or the next. Almost every one around there had ague and chills and fever and aches of all sorts, but I assure you that the sick ones were those who went out without wrappings, and always declared: "Oh, it won't hurt me to go out a little while; I never take cold;" but they took the consequences of their imprudence, and some of them paid for their folly with their lives. This and similar experiences have fully satisfied me that it is less what you do than the way you do it, which preserves the health; therefore, I am going to obey the doctor's orders and open the windows, but they will not be the windows of the sick-room. I shall let in the air to the other rooms first, and ventilate entirely in what you might call a secondary fashion. I shall also take the precaution to put an extra blanket over the sufferer, or, what is often better, a very thick linen sheet, which is a more complete protection under such circumstances than the heaviest blanket."—*New York Ledger.*

The Balance Sheet in Life.

It is said that the world gets value received for all of its acts and doings, and that the law of compensation is so accurately adjusted that the balance sheet tallies to the millionth part of a fraction.

It might be interesting to note the operations of this law as regards drunkenness and other excesses. There is a Scripture text which seems to bear directly upon this subject: "Because sentence against an evil work is not executed speedily, therefore the heart of the sons of men is fully set in them to do evil." To put off the day of accounting, to be fully persuaded in their own minds that because it has not appeared to come it never will, is the line of reasoning which the self-indulgent sinner adopts, and feeling secure on this ground, he gives himself up to license of all sort, and actually revels in wrong doing.

So much for the present evil. The law of compensation does not appear as yet; but it is leavening this lump of defiance, and sooner or later will have its perfect work. Some day there is a pain in the head, an "all gone" feeling that destroys ambition and puts hope out of joint; or there is a slight attack of dizziness, some symptoms of apoplexy, or a scarcely perceptible feeling of numbness over one side or in the hand or foot. The law is beginning its work. But some way proceedings seem to be stayed; the reconstructive powers of nature rally a little, and enable the victim to pull himself together and to go on again, often with more recklessness and less reason than ever before. Of course, nature finally rebels, and the result is either a mental wreck or a physical burden.

And the real reason for all of this breaking down is never given to the public, if, indeed, it is not carefully concealed by the physician, even from the patient himself. He is often called the best doctor who humors the patient's whims, and, wise man that he is, he allows a certain amount of dissipation, on the theory that a too sudden breaking off is not wise. In this way the victim's conscience is lulled to rest, and he is "kept comfortable," the friends say, when in reality he is still clinging with the feeble grasp of a dying man to the few vices which his circumstances and surroundings will permit. But the doctor is building better than he knows, and is helping to finish the work by permitting these indulgences. The struggle cannot last long, and soon nature feels that she has had enough of such a destroyer of her handiwork, and quietly drops him, as not worth looking after any longer. Better men than he are ready and anxious to fill his place in the world, and nature has vindicated her great and unchangeable laws.

Well would it be for the sons of men if they gave heed to these warnings. But they go about, blinded by ignorance and an overwhelming desire to prove all things which are evil. And this is the way in which lives are wrecked and hearthstones are made desolate.

"Because sentence against an evil work, is not executed speedily, therefore the heart of the sons of men is fully set in them to do evil."—*New York Ledger.*

SCIENTIFIC ADVANCEMENT

Astronomical Advance.

No department of science has made greater progress in late years than has astronomy, and the discoveries brought about by the aid of photography may yet compel a revision of the existing theories in regard to the solar and stellar systems. Reference has already been made in these columns to the investigations into the variations in the light of Algol, which the Arabs call the Demon Star, and to the discovery that these variations are due to a huge, dark body revolving around Algol, which at regular intervals comes into the line of sight between the latter star and the earth, and thus partially eclipses the Demon Star.

Certain irregularities in the motions of these two bodies have given rise to the suggestion that possibly their erratic movements may be due to the presence of another star in their immediate neighborhood; and Mr. S. C. Chandler, of Boston, has, after careful calculations, come to the conclusion that such a star actually exists, and that it is far more massive than either Algol or its companion. Mr. Chandler goes even farther, and says that there are several other stars known to astronomers to be variable which evidently have one more dark companions like those of Algol; and if this speculation should prove to be true it would simply be additional evidence of the great number and variety of material objects that undoubtedly exist in the stellar system.

The announcement made last month of the appearance of a new star in a constellation in the Milky Way has also attracted the attention of astronomers. New stars have heretofore been supposed to be stars of the ordinary kind, suddenly subjected to some process which has driven them into a condition of fervent heat; but new facts obtained by the use of the spectroscope have suggested that the former theories need to be entirely recast. In a memoir on this subject, presented recently to the Royal Society, Mr. G. Norman Lockyer, the great English astronomer, declared that one by one "the facts have been established that the solar system may, at a former stage of its history, have been a swarm of meteorites; that the spectra of nebulæ and of a certain class of stars remarkable for the appearance of bright lines in their spectra are similar to a degree hitherto undreamt of; and finally, that in a nebula so-called stars may vary their brilliancy with unimagined rapidity, and that even such stars as the Pleiades may in all probability be only the bright centers of a nebulous assemblage, a meeting-place of meteoritic streams."

During the last twenty years astronomers have been at work on new stars with the spectroscope, and it has been discovered that the quality of the light emitted by the stars is intimately related to comets and nebulæ. It has also been discovered that by heating a meteorite in a vacuum tube a bright light may be produced in the spectrum which disappears when the temperature is increased. It was also found that this line of light was coincident in position with the one observed in new stars, in nebulæ, and in faint comets; and the conclusion has, therefore, been reached that the appearance of a new star is due to the collision of two meteor swarms of different densities.

The amazing progress of science is strongly illustrated by these discoveries. In his lonely tower the astronomer scans the heavens, with his instruments, weighs and measures the flaming masses that are whirling through space billions of miles away, recognizes the colors which they give out as easily as those which come from the flame of his spirit lamp, and describes the composition of a flaming sun as readily as can the geologist the constituent parts of the rock which he is chipping with his hammer. Each fresh discovery, too, adds to the mystery of the heavens, and causes the finite mind to stand amazed at the complexity of the laws which rule the universe.—*Philadelphia Record.*

Sun Spots and the Aurora Borealis.

Observers of the sun's face have for centuries noticed at times dark spots on it. Now we know from the accumulated observations that the extent and number of these spots vary. Sometimes we can see very few, or even none at all, and sometimes we can see a great many, some of which are visible to the naked eye when protected by a colored or smoked glass. Such a spotted region is now (February 18th) passing out of sight on the southwestern limb of the sun; but a second group of spots is finely visible on the northern hemisphere, stretching in a long line from the eastern edge to the center of the sun. But what has the sun to do with the aurora? Simply this: It has been shown that when we have the greatest number of sun spots, then we have the most frequent and most gorgeous displays of the aurora. When there is a great storm on the sun-producing spots, then we feel at once on our little earth a disturbance of electrical conditions. The display of the aurora on February 13th is regarded as an accompaniment of the solar disturbances which have produced the tremendous spotted regions mentioned.

The average time from when the spotted area on the sun is greatest to the next maximum is a little over eleven years. The last spot maximum occured in 1883-4, a year or two behind the average time, and we seem now to be approaching a maximum in 1892-3. We may therefore fairly conclude that during this year we shall be favored with numerous and brilliant aurora.—*Professor John K. Rees, in Harper's Young People.*

ELECTRICAL PROGRESS

Electrical Action of the Human Body.

In the course of a series of lectures delivered by Prof. McKendrick before the Royal Institution of London, the speaker showed some interesting experiments to demonstrate that there was in reality a distinct electrical action of the human body. He showed the effect of animal electrical currents by means of a very sensitive galvanometer. Current from animals such as the torpedo fish had long been known, he said, but it was much disputed whether there was such a thing as an electric current from man. This man-current he demonstrated by putting his hands into a three-quarter per cent. solution of common salt contained in two flat vulcanite dishes. The effect upon the galvanometer was greater as the number of fingers inserted was increased, and was greatest when the muscles of the arm were contracted. There were no fewer than 50 species of animals that were living electric batteries, the speaker declared, although only five or six were generally known.

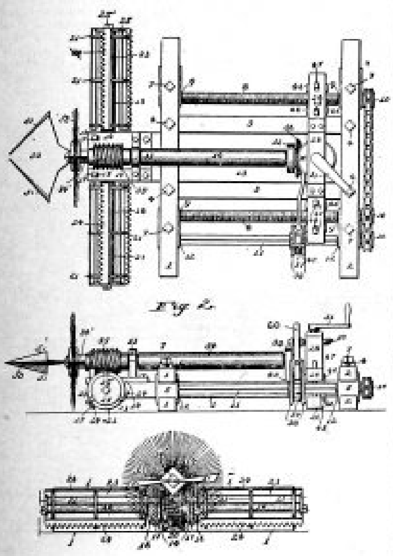
Is Electricity a Manufactured Article?

If electricity is a manufactured article, so is the atmospheric air we breathe, and the one is quite as much open to taxation as the other. Atmospheric air is utilized in many ways. Take one, for example, viz.—blast furnaces. The air which surrounds this globe of ours, and without which active natural life (animal or vegetable) cannot exist, is drawn by the blast engine into its cylinders, and there compressed and forced out through the tuyeres into the furnace with the force required to raise its contents to melting heat; it undergoes no chemical or other change; it is not manufactured by a combination of other elements; it is certainly a combination of gases, but that combination is not the result of human agency, and it is free to all creation; consequently cannot by any laws or possible course of reasoning be brought under the head of a manufactured article.

In its utilization for the above-mentioned and for hundreds of other purposes, it undergoes no change of any description, and cannot be placed in the same category as gas. Electricity is an element similar to atmospheric air. Every one who knows anything about electricity knows that it pervades everything in the universe, in a positive or negative state, and by disturbing the equilibrium which if left to itself maintains, certain effects are produced. Electrical machines of whatever description, do not manufacture the electric fluid. They are merely suitable forms of machines for collecting, or *generating* (though it is a question whether the latter is a strictly correct term) the electric fluid which already exists; just as the blowing cylinder of the blast engine draws in and compresses the air, so the dynamo draws off from the surrounding earth its supply of electricity, which by careful insulation is utilized as required in its efforts to return to its normal condition. Blast is conveyed by pipes from the blowing cylinder, and air vessels (when they are used) to the furnaces or to whatever other use the compressed air is to be applied. The electric current is conveyed by insulated wires and cables to whatever use it is to be applied, but man did not make the air or the electric fluid but he does make the gas, because by a mechanical process he produces it from a substance—coal—which undergoes a change and yields other products besides gas. Neither the atmospheric air or the electric fluid undergo any change in their constituents by utilizing the energy collected, and stored in the appliances and apparatus in use at electric lighting stations, or at the blast furnaces of iron companies, and the latter could not reasonably be taxed for the supply of air drawn from nature any more than the electric fluid can be taxed which is also drawn from nature. Water works companies do not manufacture the water which they supply to the public, but all three industries derive pecuniary profit from the supply of these articles to the public, with which articles they are supplied by nature, and consequently to determine the point mooted in your article it is for legislators to decide whether setting aside the nature and description of article (atmospheric air, electricity, or water), the industry itself as a profit-producing business taken from the same aspect as any other profit-producing business in which capital is invested, is or is not liable to taxation on the profits of the concern; if it is not taxed the chances are the public will not be supplied a whit cheaper, and if it is taxed the public will indirectly pay the tariff.—*W. D. Baylis in Discovery.*

ORE MINING MACHINE.

No. 471,434. James C. Robertson, Glen Campbell, Penna. *Patented March 22, 1892.* A large triangular drill head 50 is mounted on the end of the drill shaft 34, which is rotated by hand by means of the crank 31, and the bevel gears 30 and 33. The drill shaft carries a large brush 52, to clear away the borings made by the drill head 50. It also carries a worm 35, which drives a worm wheel 20 (seen in the front end view) and the cutter shaft 18. This shaft has several flanges or discs 21 which are notched to receive and hold three cutter bars 24. These cutters are notched on their edges as shown, and they serve to tear out the ore that is loosened by the drill. The cutter shaft and the drill shaft are mounted on a sliding plate 13, which slides between the front end bars 1, and the side bars 3. A cross head composed of two transverse bars 26 is attached to 13 and guides it, and also carries the driving gears and crank. It is provided with two nuts, made in halves, which engage



the screws 8. These feed screws are journaled in suitable boxes in the front and rear frames 1 and 2, and are turned by a chain and sprocket wheels 10. The third sprocket is carried on the end of the square shaft 31, which is rotated by a ratchet 37 and a pawl carried on a lever 60. This lever is vibrated by a pitman attached to a crank pin on the face of the gear 36 and the throw of the lever is varied by connecting the pitman at different points, for which purpose the lever is provided with several holes. In operation the frames 1 and 2 are securely fastened in place by jack screws or bars, and the crank is rotated until the drill and cutters are driven as far forward as the crosshead will carry them. Then the keys 47, on each side of the feed nuts, are drawn out allowing the nuts to open. Next the frame is moved forward by bars or handspikes, until the rear bars 2 encounter the crosshead; the feed nuts are closed, and the machine is ready for another advance.

GAS APPARATUS.

No. 469,574. James R. Kendall, Terre Haute, Ind. *Patented February 23, 1892.* The shell or casing A, is made of wrought iron plate, and is lined with fire-brick *a*, as is its cover T, which has in it the valve T^1 closed by the hinge E.

The apparatus has within it three chambers B, C, and D, of which B and C are heating and decomposing chambers, and D the gas receiving chamber, the remaining space within the cylinder being filled with brick "checker work," in which the currents of gas passing in through the cylinder are interrupted and broken up, thus causing a thorough diffusion and mixture of the gases throughout the cylinder or retort. The top layers of the checker-work are covered with a layer of fire-brick balls *s s*, which form grate-like bottoms for the heating or decomposing chambers.

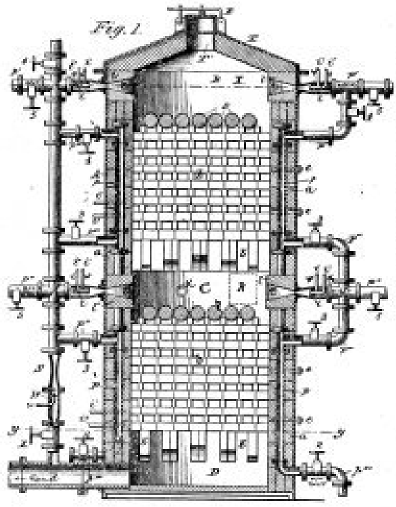
Access to the chamber B for the purpose of cleaning, repairs, and inspection is had through the valve-opening T^1, and to the chamber C through the man-hole R. The valves K and T^1 are used to admit air while the retort is being heated to the proper degree for fixing the gas and are closed during the operation of fixing.

Blocks l l^1, of suitable refractory material, which contain the curved and flared tuyeres t t^1, are set into the lining of the retort in such a manner as to cause the hydro-carbon vapor, steam, and air passing through them to spread out and rotate around the chambers, thereby diffusing and commingling the same.

The gas receiving chamber D is provided with the discharge-pipe *d*, through which the gas which has entered it from the chambers B and C and passed through the checker work *b b*, leaves the retort or generator.

Embedded in the lining of the retort are the circumferential steam pipes i^{11} i^{12} and the vertical air-pipes *p p*, which connect by means of the pipe p^{111} p^{11} and p^1 p^{11} with the tuyeres t^1 t^2. These pipes p^1 p^{11} at the point where they enter the retort are connected to the tuyeres are considerably contracted in diameter, forming nozzles *i i*, at the larger end of which, as shown in Fig. 1, enter the nozzles i^1 i^2, which admit the hydro-carbon to the retort, and behind them the pipes i^{11} i^{12} in the lining of the retort, through which is admitted steam to the retort at i^1 i^2. The nozzles *i i* are really injectors, the steam-jet spraying and vaporizing the oil as it enters the nozzles and carrying it into the decomposing chambers. The pipes p^1 p^{11} connecting with the nozzles or injectors *i i*, are used to admit air directly to the retort.

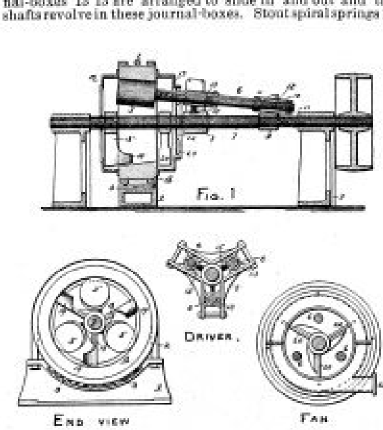
A draft pipe 8, is attached to the gas pipe *d*, and is provided with a steam jet blower W, to aid in blowing up the fire. The apparatus is started by building a wood fire in the top chamber B, and starting the upper injectors and blowing in some oil spray. At the same time the valves T^1 and K are opened, also the valves 1 and 6 in the pipe 8, and the steam jet W is started. As soon as the checker work begins to get hot, the valves T^1 and K are shut, and air is taken in only through the pipes *p*. As soon as the brick



are heated to incandescence, the valves I and 6 are shut, the air supply is shut off, and all the injectors are turned on to full capacity. The oil vapor and steam are broken up by the intense heat, and combine to make permanent water gas, which passes off to the holder by the pipe *d*. This process of gas making is continued until the checker work is cooled to the point where it will not dissociate the vapors, when the gas valve in pipe *d* is closed, and the blower W is started up, and the process of blowing up the heat to incandescence is resumed. Thus the process of gas making and heating up the apparatus are alternated at intervals depending upon the size of the apparatus.

GRINDING MILL.

No. 469,145. Samuel Hughes, Charleston, S. C. *Patented February 16th, 1892.* A represents a circular die. This die is set horizontally on a bed 1, where it is held securely by a bolt or band 2 as shown. The die is preferably constructed with a tapering bore 4, and rolls 5 5, preferably cylindrical in form, are arranged to co-operate with this die to crush, grind, and pulverize the material fed into the mill. To properly balance the machine, three rolls are desirable. These are secured on shafts 6 6, which in turn are arranged equidistant from one another around a horizontal drive-shaft 7. A pair of drivers 8 and 9 are secured to the main shaft 7 at suitable distances apart. In the former the shafts are arranged to vibrate or slide radially from the shaft 7. The end of the shaft passes through a sleeve 10, where it passes, revolves freely as occasion requires it, and to prevent endwise movement collars 11 are secured on the shafts at the ends of the sleeves. The sleeves themselves are provided with trunnions 12, by which they are supported in driver 9. In the large driver sliding journal-boxes 13 13 are arranged to slide in and out and the shafts revolve in these journal-boxes. Stout spiral springs 15

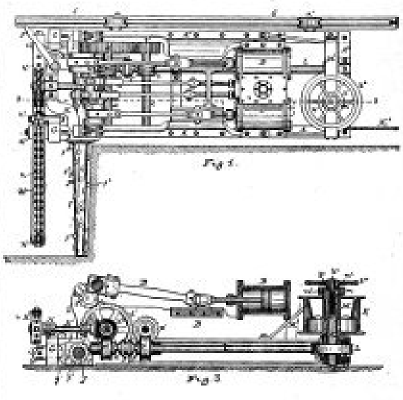


15 of sufficient tensile strength to sustain the weight of the rolls and their shafts, are interposed between the journal boxes and the hub of the driver, to resist the downward tendency of the uppermost roll or rolls when not held outward by centrifugal force. The drivers hold the rolls to their work and prevent lateral strain which would otherwise result. The heads 16 and 17 are secured to the opposite ends of the circular die, as shown in Fig. 1, and the rock is fed through the former.

To regulate the passage of the material through the machine and prevent its being fed through too rapidly, feeding-arms 18 18 are secured to the main shaft 7 just inside the head of casing 16. These arms are preferably about three in number, and as they rotate they catch the material and drive it inward. From the enormous speed there is a tendency to drive the material entirely through the die at once before it is ground; but this is prevented by bending the arms at their ends to form hooks 19 19. These catch the material and tend to stop it or retard its progress. At the opposite end of the circular die the paddles or fans 20 20 are secured. These devices create a draft, which forces it out through a discharge 21, and, in this manner, the material is removed from the mill, after which it may be screened.

MINING MACHINE.

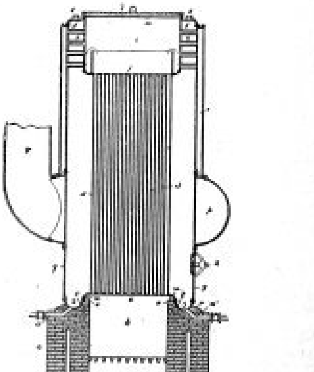
No. 469,260. Jonas L. Mitchell, Chicago, Ill. *Patented February 23, 1892.* This machine employs a long taper cutter bar F, which is armed with projecting teeth as shown, and is rotated by a pinion *f* gearing into the wheel d^1. This wheel is driven by the pinion shown on the engine shaft. The engine is double and is intended for the use of steam or compressed air. The driving wheel d^2 also drives a pinion e^1 on a shaft *e*. The machine is dragged along the face, and the cutter bar kept up to its work by a cable K^1, which is wound up by the drum K. The end of the cable is hitched to a jack-screw fixed at some convenient place ahead. The drum is driven at either of two speeds by the worms shown on the shafts *e* and *d*. Both worm wheels are loose on the shaft *l*, and turn at different speeds, in the same direction. A clutch P serves to engage either worm wheel to the feed shaft *l*, which turns the worm wheel L on the foot of the drum shaft *k*. Connection is made to the drum by means of the friction clutch M, which is operated by the screw k^3 and hand wheel k^4. In case hard coal or other obstructions are encountered, the clutch M may be eased off, and the drum be allowed to slip until the obstruction is cut through or removed. The



chips are cleaned out from the cut by a chain *h*, which is driven by a sprocket wheel H^4, and is guided by bars h^2. Motion is imparted to H^4 by the shaft H^1 and miter gears H^2, H^3 which are driven by the shaft *d*. The cutter bar is removable from the main frame of the machine, to facilitate the moving of the machine around the chamber. To do this, the cutter bar journals are made to run in square boxes. The rear end of the frame is provided with heavy straps *g* and keys as shown. The square boxes pass between the straps and are secured by driving in the keys. The tendency of the machine to work itself out of the cut is resisted by a rail C, which is laid on the floor and is held in place by suitable jack-screws. The outer bar of the main frame is supported by the wheels *a*, but the inner side runs on a shoe plate laid on the floor.

STEAM BOILER.

No. 469,124. Thomas R. Butman, Chicago, Ill. *Patented February 16, 1892.* This boiler has a plain cylindrical shell *g*, which is closed at the bottom by a semi-circular ring *s*, which provides a good receptacle for sediment and scale. The upper tube sheet is riveted to an inner shell *i* which is



closed at the top by a cover *l*, lined with brick or tile *m*. A great number of short tubes *n*, run from the smoke box through the shells *i* and *g*, to the outer smoke flue or jacket

o. This jacket extends downward to the chimney belt p. The furnace is circular, and is made with double walls, and the air for the fire is taken in between the walls, for the purpose of economizing heat and increasing the combustion of the fuel. A deflecting ring f is provided at the top of the tubes to equalize the draft through the tubes n.

The hot gases from the fire pass upward through the tubes d, into the smoke-box, and out through the tubes n, then downward through the jacket o, to the belt p, and pass from there up the stack q. The water line is carried above the top tube sheet. In all but the smallest boilers there is enough room between the shell g and the tubes, for a man to pass around, to inspect and clean the interior.

TRACTION DEVICE.

No. 468,860. Walter B. Wright, Chicago, Ill. *Patented Feb. 16, 1892.* It is found that in the case of light cars, such as tram and street cars in which the propelling power located upon the car is employed, the weight of the car is not sufficient to cause the desired degree of adhesion of the running-gear to the supporting track. Particularly is this deficiency remarked in the event of heavy grades and slippery tracks being encountered.

To remedy this trouble, a wheel O^2 running in a conduit P^4 is employed, to grip the flanges of the conduit against the traction-wheel with any desired force.

C is a traction-wheel on the short axle D, which is supported in the bearings E E, so as to move vertically on the hangers F F. G is a sprocket-wheel upon the same axle driven by the drive-chain H, from the sprocket-wheel J on the armature shaft K of the dynamo L. M M are the arms of a yoke, in which is also journaled the axle D, and these

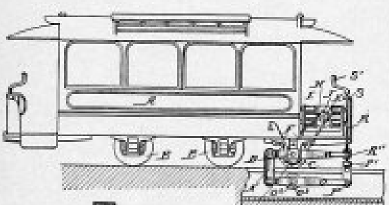


Fig. 1

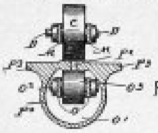

Fig. 2

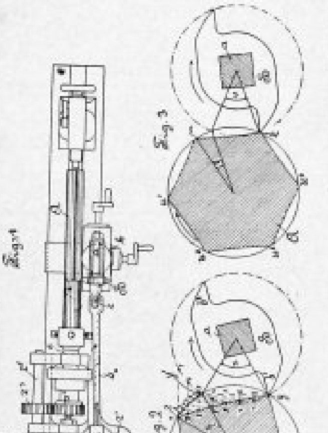
arms are linked by the link N to similar arms O O within the channel O^1. These arms support the short axle O^3, which carries the wheel O^2. At the forward ends of the arms O they are connected by the link P^1, which passes up through the slot P^2 between the side sections P^3 P^3 of the conduit pipe P^4.

The grip handle S^1 and its shaft S passes down through the platform and is provided with a screw thread on the lower end, which engages the nut P^1. The grip shaft also has a collar bearing on top of the swivel R^{11}. When the car arrives at a hill, or a piece of slippery track, the motorman can secure all the adhesion he wants by turning the handle S^1, and thus increasing the pressure between the wheels C and O^2 upon the flanges of the conduit.

LATHE.

No. 469,813. Carl G. Dahlgren and John H. Svensson, Goteborg, Sweden. *Patented March 1, 1892.* The object of this invention is to turn blanks to square, hexagonal, or other prismatic form, in a lathe of ordinary construction. Fig. 1 shows a top view of the lathe and special cutter, and Figs. 2 and 3 show the relative positions of the blank and the cutter at successive moments, when producing a

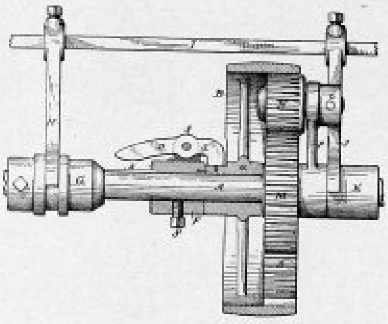


square and a hexagonal column. It is found that a cutter having two equidistant blades will, if driven with a velocity double that of the blank, cut out a four-angled figure, the faces of which are slightly convex. If driven with a velocity treble that of the blank, it will but out a hexagonal figure the faces of which will be slightly concave.

In the drawings, A is the blank, which is fixed on the live-spindle c in the usual manner. The live-spindle c drives the shaft z^1 by means of toothed wheels z^5 z^4. On the shaft z^1 is the toothed wheel z^2, which gears with the spherical toothed wheel z^3, through which passes the shaft d, connected to rotate with the wheel z^3 by means of a long feather d^1 thereon moving in a keyway in the wheel, so that the shaft d is freely movable in the line of its axis back and forth through said wheel. The shaft d is connected to the shaft a, carrying the cutting-tool b, said shaft a being journaled parallel to the blank in a rest-block with usual adjustments parallel to and perpendicular to the blank. The joint connecting the shafts d and a may be of any known construction of rocking joint, whereby the shaft d may revolve the shaft a at all times, whatever may be the relative angular position of the axis of the shaft during the working of the machine. By replacing the one or other pair of wheels z^1 z^2 or z^3 z^4 by similar gearing-wheels of different relative sizes the proportion between the velocities of the spindle c and the shaft d, or between the blank and the cutting-tool may be altered at will. If the tool be moved up too close, the blank will be merely reduced in size although it will be properly shaped, but if the tool be moved too far away it will only flat off or hollow out the sides of the blank. Thus the size of the work turned out is limited by the size of the cutter.

DRIVING PULLEY FOR LATHES, ETC.

No. 469,468. Perry R. Gilbert, Chambersburg, Pa. *Patented Feb. 23, 1892.* The shaft A is driven by the pulley B, or vice versa. The hub of the pulley is made with several notches b, which are engaged by the dog D. The shipper rod I carries two arms or forks H and J. Arm H takes hold of the cone G, which slides on a feather in the shaft, and serves to throw the lever or dog D into the position shown. The collar which carries the dog is fast on the shaft, and when the cone is moved up against the collar F, the pulley hub is seized by the dog and it is compelled to revolve with the shaft A. When it is desired that the pulley should run the reverse way, the cone G is moved away to the position shown, the spring d throws the dog



up out of the notch b, and the shipper rod is moved to the left until the arm J obstructs the hub i on the arm P, as shown. This arm turns loosely on the shaft and carries a pinion N, which gears with a spur wheel M (which is keyed on A) and with teeth on the inside of the pulley rim. While the pulley is clutched to the shaft by the dog D, and cone G, the arm P and its pinion all go around with the pulley, but when the arm P is stopped by the shipper arm J, the pinion revolves on its pin and transmits the motion of the spur wheel M to the rim S of the pulley, moving it in the opposite direction, and at a lower speed. The device is thus adapted to drive machines having a slow driving motion and a quick reverse or return movement.

LIGHTING DEVICE FOR SAFETY-LAMPS.

No. 469,918. John B. Harris, John T. Griffith, and Thomas B. Harris, Wilkes-Barre, Pa. *Patented March 1 1892.* The letter A represents an oil-reservoir of the usual construction, which constitutes the base of a lamp and is adapted to be screwed to the lower section of a lamp. This reservoir is provided with the usual wick-tube and wick-raising devices, as shown, and in proximity to the wick-tube A^1 is arranged the open-ended tube or casing B, within which is arranged the traveling fulminate-carrier, which

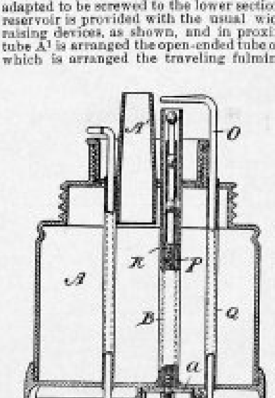


Fig. 1

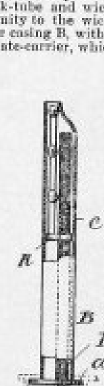

Fig 3

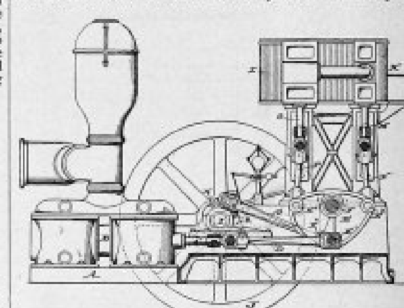
consists of a flat elongated plate R, having a screw threaded opening, through which passes the screw rod P, which is suitably swiveled at its lower end in a cap-plate a, which latter rests upon the end of the nut or screw-threaded ring T, which is secured to the bottom of the oil-reservoir by screwing the same into the ring or circular flange U, said cap-plate serving also as a cover for the lower end of the tube B, thereby cutting off all communication with the atmosphere and thus preventing the admission of air and gases through the same, the carrier for the inflammable substances being thus completely housed within the containing tube. The tube B is formed with an interior recess or niche to receive the rod P, which latter is provided at its lower end with a thumb-nut or handle e, by which it may be rotated so as to cause the fulminate-carrier R to move up or down for the purpose of bringing a pellet or the end of a match-stub into position to be operated upon by the igniting device O, for the purpose of lighting the lamp, the formation of the tube or casing being such that a number of match-stubs, as shown in Fig. 3, or other suitable inflammable substances may be placed therein at one side of the rod P and supported upon the carrier, one above another, so as to be brought successively into position to light the lamp. These simple contrivances afford a ready means for supplying a miner's lamp with a number of fulminating-pellets, for the purpose of lighting or relighting a lamp by manipulating the igniting device from the outside, without danger of explosion or the necessity for leaving the mine.

PUMPING ENGINE.

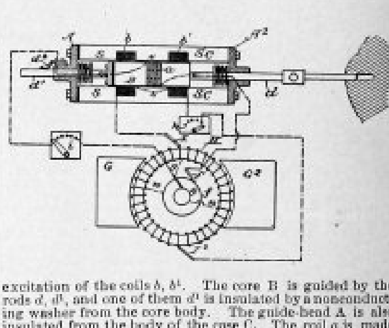
No. 469,661. Wm. E. Good, Philadelphia, Penn'a. *Patented Feb. 23, 1892.* The plungers are double acting, and are driven by a connecting rod D, which takes hold of a pin E^1 on the triangular beam E. The pistons of the high pressure cylinder K, and of the low pressure cylinder L, are connected by the rods N and P to the opposite ends of the same beam, by the pins E^2 and E^3. Two of these engines are usually built in one frame, and the fly-wheel J is located between them. Each end of the fly-wheel shaft is pro-



vided with a crank H, and the shaft is rotated by connecting rods G, which are coupled to a fourth pin E^4 on each beam. The valve mechanism (not shown) is driven by a "Fink" link, and is controlled by a "Porter" governor as shown. By this construction the working parts are made very easy to get at, and a great economy of room is secured. The foundations required are of the plainest kind and consequently the expense for buildings and masonry is smaller than with other types of pumping engines.

ELECTRIC RECIPROCATING ENGINE.

No. 469,441. Merle J. Wightman, Scranton, Pa. *Patented Feb. 23, 1892.* This engine employs a continuous current in the field coils b, b^1, which are stationary, and an alternating current in the armature coil a on the reciprocating core B, at the same time. The field coils are contained within groves in the outer iron case C, and are connected at one end to the brush I, and at the other end to the brush I^2. A resistance box h, is provided in the circuit to vary the



excitation of the coils b, b^1. The core B is guided by the rods d, d^1, and one of them d^1 is insulated by a nonconducting washer from the core body. The guide-head A is also insulated from the body of the case C. The coil a is made principally of plates, and the ends of the coil are connected to the rods d and d^1, and through them to the brushes g^1, f^1. These brushes bear on the continuous rings g and f and consequently receive an alternating current, while the brushes I and I^2 bear on opposite sides of an ordinary commutator and take off a continuous current. The polarity of the field is thus constant, while that of the core is rapidly reversed. The alternating current can be varied in strength by the resistance box i. The movement of the core may be made much stronger in one direction than in the other. This is done by connecting the armature coil a to the continuous current circuit, through a resistance that can be varied at will. If the continuous and alternating currents be equal then the core B will be inert, and its moving force will increase exactly as the continuous current is withdrawn. As long as both currents excite the core, the movement outward or away from the center of the case C, will be equal to the difference in force of the two currents, but the return will be accomplished by the combined force of the two, and will consequently be far more rapid and forcible than the outward motion. The operating currents may be derived from the same machine, as shown, or from separate dynamos. Or a continuous generator may be used with a pole changer to produce the alternating current.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 11. SCRANTON, PA., JUNE, 1892. WITH WHICH IS COMBINED THE MINING HERALD.

THE ECONOMIC GEOLOGY OF COPPER

The Mineralogy, Mode of Occurrence, and Production of Copper.

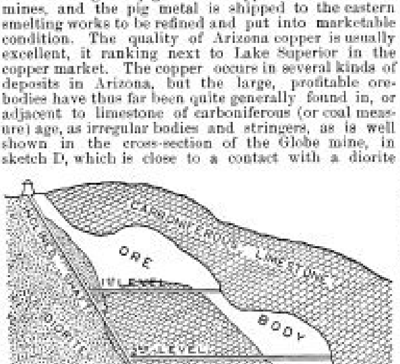
BY H. A. WHEELER, E. M., OF ST. LOUIS.

[CONCLUDED.]

Of even greater importance, at present, than the Lake Superior region, is the copper output of Montana, which since 1887, has been the heaviest producer in the world. This great output comes from the immediate neighborhood of Butte City, where a series of parallel fissure veins have been worked for a distance of over three miles. The veins occur in a dark granite, and carry ore bodies that run from 10 to as high as 150 feet wide. At first the ores were largely oxides and purple ore that ran from 10 to 50% in copper, but as the mines get deeper, the ores become more base, or change into the poorer chalcopyrite, so that to-day the ores of Butte may be said to run from 5 to 10% in copper. They all carry some silver, and usually in sufficient amounts to more than pay for its extraction. In fact, the famous Anaconda, the giant producer of the camp, was originally started as a silver mine, as no copper of any importance was struck until a depth of over 400 feet had been attained; but at that depth large bodies of very rich oxidized ores were found, which at greater depths have changed into the sulphide. On account of the lower grade of the ores since the mines have worked below the permanent water level, concentration mills have had to be erected to enrich them before smelting which latter operation produces a product called "*matte*" that will assay from 35 to 70% in copper. This copper matte is shipped to Eastern and Continental smelting works, to be further treated and converted into casting copper or ingots. Although copper ore of high grade had been previously shipped out of Butte to Colorado and other smelters, the real history of Butte as a copper camp may be said to date from 1880, when it first enjoyed railroad facilities and began to do its own smelting. Since then the output has steadily grown until it exceeded 56,000 tons in 1891, of which the Anaconda group of mines, though shut down for several months, produced 23,000 tons, the Boston & Montana Company 13,000 tons, Parrott Copper Company 7,000 tons, and the Butte & Boston 9,000 tons. In spite of these large outputs the profits have not been very large, for while the ores are much richer than at Lake Superior, the working expenses and transportation changes are much higher than at the "Lake", while the copper sells for ½ to 1½ cents a pound less than lake copper on account of its inferiority for wire-drawing or rolling. So with the comparatively low prices that have ruled for copper since Butte has become such an active competitor in the world's copper market, the dividends have not been very heavy; however, the Boston & Montana Company have paid out \$2,075,000 and the Parrot Company \$850,000, as dividends, while no official information is published as to the profits of the Anaconda Company, though it probably does not begin to rival its great lake competitor, the Calumet & Hecla, as a money maker.

Next in importance in the far west to Montana comes Arizona, which began to regularly produce copper, though in small amounts, in 1873; a new era of activity began in 1880, which has finally resulted in making this territory one of the most important producers of this country. Copper is very liberally diffused throughout most of Arizona, and if it enjoyed good and cheap railroad facilities, with an abundance of water and fuel, it would become a very heavy producer. As it is, only rich and large ore bodies can be worked at a profit, on account of the heavy expenses for operating, and the excessive transportation charges. This latter item brings the price of the coke used for smelting that costs \$2.00 at the coke ovens, up to \$20.00 to \$60.00 a ton at the mines, depending on their proximity to the railroads.

The ores thus far worked in Arizona have been almost exclusively the oxidized series, or the oxides, carbonates, and silicate, which in one smelting operation yield a pig copper that will assay about 96%. This smelting into pig or block copper is done at the mines, and the pig metal is shipped to the eastern smelting works to be refined and put into marketable condition. The quality of Arizona copper is usually excellent, it ranking next to Lake Superior in the copper market. The copper occurs in several kinds of deposits in Arizona, but the large, profitable ore-bodies have thus far been quite generally found in, or adjacent to limestone of carboniferous (or coal measure) age, as irregular bodies and stringers, as is well shown in the cross-section of the Globe mine, in sketch D, which is close to a contact with a diorite



SKETCH D.—CROSS SECTION OF THE GLOBE MINE, ARIZONA.

dike (after Wendt). The ores as delivered at the furnace, after sorting or concentrating, will assay from 8 to 20% in copper; but as the mines become deeper, as they are still quite shallow, the oxidized ores will give place to the poorer, and probably less pure sulphide ores. The largest producer in Arizona is the Copper Queen Mine, which has for the past four years shipped about 4,700 tons of copper a year, and has paid \$1,500,000 in dividends since it began producing in 1880. This mine and the Halbrook & Cave properties, which produced 1,400 tons in 1891, are in the Bisbee district, near the Mexican border.

Next in importance to the Copper Queen Mine is the Old Dominion Mine, in the Globe district, in the central portion of the territory. This district is the most disadvantageously located of any of the copper producers of Arizona, as all the supplies for the mine, and the pig copper sent out has to be hauled 120 miles by wagon, before reaching the Southern Pacific R. R., at an expense of \$30.00 a ton. But on account of the richness of the ore it has been a very profitable property since 1882 on an annual product ranging from 2,300 to 3,900 tons of copper.

The Arizona Copper Co., at Clifton, in the south-eastern part of the territory, built a railroad seventy miles long in order to do away with the heavy haulage charges that they formerly had to bear in working a property that yields from 2,300 to 3,800 tons of copper a year. The Detroit Copper Co., which produces about 2,500 tons of copper a year, is also in this Clifton district, which is the oldest in the territory, it having been a constant producer since 1873.

The United Verde mine, in Yavapai County, with a production of about 3,300 tons in 1891, and a few small mines bring the total production of Arizona up to about 20,000 tons in 1891, which is the largest record in the history of the territory.

As Lake Superior, Montana, and Arizona produced about 93% of the copper product of the United States in 1891, it leaves but little to be considered as the present results of the other copper-producing districts.

Colorado produces but little copper from mines worked solely for this metal, but considerable is obtained as a secondary or by-product in working the gold and silver ores in several parts of the state, especially in Gilpin and Clear Creek Counties, and the total output in 1891 was about 3,400 tons.

California produces a little copper from a property in the southern part of the state that is now operated by a French company, and which at one time promised to become an important producer. The output of this state in 1891 was only about 1,800 tons.

Utah produces some copper, but mainly as a by-product in working copper-bearing gold and silver ores, the amount not exceeding 1,000 tons in 1891.

New Mexico and *Texas* have had flattering prophesies made of their copper resources, but thus far their copper production has never been large or important, the New Mexican output having been only about 800 tons in 1891.

The Appalachian belt, from Canada to Alabama, contains more or less copper, and many attempts have been made to work these deposits in Maine, Vermont, New

Hampshire, Pennsylvania, Virginia, Tennessee, and other Eastern States, but with the exception of Vermont, they have not proved a success as a financial investment. At Ely, Vermont, the copper vein, which is a segregated deposit, has been exceptionally rich and persistent for these Appalachian chalcopyrite ore-bodies.

This Ely Mine has been worked to a depth of over 2300 feet, on the pitch of the vein, in working an ore that runs 3 to 7%, and formerly produced as much as 1500 tons annually, which is a very large output for an Eastern copper mine. The total product of the Eastern and Southern States in 1891 was less than 1000 tons.

In considering the copper production of the world, the heaviest pro,ducing district after those of the United States, is the be't of crystalline rocks of Paleozoic age that stretches for a distance of 140 miles from Western Spain into Portugal, and on which are the famous Rio Tinto, Tharsis, Mason & Barry, and other mines. In this belt, which is 30 miles wide, occur lenticular masses of copper-bearing pyrites, as contact deposits, along porphyry intrusions. The ore varies somewhat in richness, but usually runs from 2·5 to 3·5% in copper, while the ore bodies vary from a few inches to over 500 feet in thickness, and as much as 3000 feet long. Large quantities of this low grade ore is shipped to Europe, where its high sulphur contents is first utilized in making sulphuric acid, before the copper is extracted by smelting from the roasted residue. Much larger quantities of the poorer grades are treated at the mines, and the total production of these Iberian mines in 1890 is given as 53,000 gross tons, of which the Rio Tinto company is credited with 30,000 gross tons.

Next in importance to Spain in Europe are the copper-bearing slates of Mansfeld, Germany, from which large amounts of silver-bearing copper ore has been mined from a 12 to 22 inch seam of Bituminous slate for a long time. The ore will average from 2·5 to 3·0% in copper, though some is as poor as 2% and a little as rich as 10%. The usual output of this district, at present is from 12,000 to 16,000 tons of copper per annum.

None of the other European countries produce any large amount of copper, and the famous Cornwall district in England is now of trifling importance as a copper producer, as its output in 1890 was only about 1,000 gross tons.

Chili was one of the most important copper producers of the world for quite a long period, but its annual product quite steadily declines, through the impoverishment and exhaustion of its mines, and the output in 1890 was 26,000 gross tons, which is about half as much as was produced in 1879.

Japan is quite a copper producer, its output in 1890 amounting to 15,000 gross tons.

Australia, South Africa, Venezuela, and Mexico produce some copper, which when added with various other scattering countries of still less importance, assist in bringing the total copper production of the world up to about 270,000 gross tons in 1890, according to the annual statistics of the *Engineering and Mining Journal*, from which most of the preceding statements of production have been obtained.

Nova Scotia Explosives Commission.

Reference was made some time ago in our columns to the appointment of a Commission by the Government of Nova Scotia, to examine into the question of replacing gunpowder by an explosive equally effective but less dangerous in the presence of gas and dust. The question was forced upon the Government owing to the inquest upon the Springhill disaster proving that the immediate cause of the explosion was due to the flame of a charge of gunpowder used in blasting. The Commission, with the Inspector of Mines as chairman, has had several meetings and has experimented with the most promising explosives in the Pictou and Cape Breton mines. The results are not yet known, but it is understood that two explosives have proved satisfactory so far. One of these is roburite, already well known in England, although not yet officially endorsed by the British Government; the other is understood to be similar to the mixture of dynamite and nitrate of ammonia approved of by the French Government as having, when detonated, a temperature less than that of the ignition of fire-damp. As the exact compositions of these explosives calculated to be safest for coal mining have not yet been settled, the labors of the Commission are still unended. This subject is one of great importance, and has been studied by many of the leading chemists of the present day. The report of the French Commission is considered the most valuable contribution to the literature of modern explosives. They started out to find an explosive which, when fired in a mine, would not produce heat enough to ignite fire-damp. After researches and experiments extending over several years, they have announced four such compounds. Two of these have hitherto appeared desirable to the Nova Scotia Commission. If the further investigations of this Commission, which appear to be deliberately and carefully conducted, result in giving the public a safe explosive, the Nova Scotia Government will have rendered a great service to the coal mining industry of the Continent. Undoubtedly public opinion in the United States will follow that of Nova Scotia and demand that where gas is found in coal mines a safe explosive must replace gunpowder, and as the difference in cost of these explosives, as compared with gunpowder, is pound for pound, inconsiderable operators will not be able to raise the cry of increased cost of production. It is understood that as soon as a definite conclusion is reached by the Commission, the miners of British Columbia who have suffered from explosions will demand at the hands of their Provincial Government a similar measure of protection.—*Canadian Mining Review.*

EXTRACTION OF ORE FROM WIDE VEINS OR MASSES.

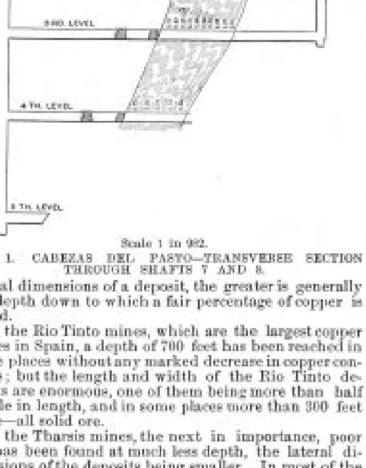
BY G. D. DELPRAT, LONDON, ENG.

[From the Transactions of the American Institute of Mining Engineers.]

The object of this paper is to describe an application of the cross-cut system of mining, as carried on in the Cabezas del Pasto mine, one of the copper-mines in the south of Spain. The system is not new; but it is not very generally adopted. It offers, however, decided advantages over other systems more in use; especially where the ore is found in large masses or wide lodes, it allows the extraction of all the ore without leaving any pillars or roofs. A somewhat detailed description of the various operations and costs of working may not only be interesting, but may possibly lead to a more general adoption of this method in cases where at present the pillar and stall system is preferred.

The copper-lodes in the south of Spain and Portugal are the following: They are nearly all lenticular masses of great lateral dimensions and unascertained depth; their direction is approximately east-west, and their dip towards north. Some are contact-lodes, having slate on the hanging-wall and porphyry on the foot wall; others are imbedded in porphyry, and others again are imbedded in clay-slate.

The upper portion of these lodes consists of "gossan," a siliceous peroxide of iron, mixed with more or less clay. The depth to which the gossan goes down varies in different localities, from 40 feet to 120 feet, and more. Below the gossan is found the iron pyrites, with about 2 to 3 per cent. of copper. The gossan is generally admitted to be the result of the decomposition of the pyrites, the copper rendered soluble, filtering into the underlying layers of undecomposed ore, and enriching the ore below the gossan above the general average. Very rich pockets and streaks of ore, containing sometimes 10 per cent. of copper and more, are often found in the upper portions of the lodes. The copper contained in the ore is generally in the shape of gray and black sulphides and copper pyrites; rich pockets often show chalcopyrite and fahlerz. In nearly all the mines the ore has been found to get poorer in copper with greater depth; a cross section through the Cabezas del Pasto mine (Fig. 1) shows this dimunition, and may be taken as a fairly representative case. The greater the



Scale 1 in 982.

FIG. 1. CABEZAS DEL PASTO—TRANSVERSE SECTION THROUGH SHAFTS 7 AND 8.

lateral dimensions of a deposit, the greater is generally the depth down to which a fair percentage of copper is found.

In the Rio Tinto mines, which are the largest copper mines in Spain, a depth of 700 feet has been reached in some places without any marked decrease in copper contents; but the length and width of the Rio Tinto deposits are enormous, one of them being more than half a mile in length, and in some places more than 300 feet wide—all solid ore.

In the Tharsis mines, the next in importance, poor ore has been found at much less depth, the lateral dimensions of the deposits being smaller. In most of the smaller mines the ore gets too poor to be worked at a profit at a depth less than 300 feet. One per cent. of copper is generally taken as the limit of workable ore.

The following is a complete analysis of a fairly representative sample of ore from the Rio Tinto mines:

Sulphur	48·3
Copper	3·44
Iron	43·33
Bismuth	·02
Lime	·36
Lead	1·00
Gold	·0005
Silver	·004
Cobalt	·05
Arsenic	·75
Antimony	·07
Calcium oxide	·23
Manganese	·05
Silica	1·80
Moisture	·48
Selenium	traces.
	99·95405

There are some exceptional deposits, which are of a different nature, such as the "Esperanza", near Tharsis, where the copper is found as a sulphide impregnating the slate, but they need not here be mentioned.

The ore is generally sorted by hand into two classes. The richer ore is sent to England and the Continent, to the sulphuric acid manufacturers (who, after burning off the acid, send the residue to the copper-works), and the purer ore is generally treated for copper only in proximity to the mines.

Two systems of mining are very generally adopted.

When the gossan is comparatively shallow, and the mineral mass is wide, the ore is generally got by open-cast working; the over-burden is removed in benches about 30 feet high, and the ore, thus laid bare, is quarried.

The cost of removing the over-burden varies with the nature of the ground and with the facilities for getting proper dumping facilities. The following statement shows the average cost over a whole year in the "Joya" mine, which is worked by the open-cast system. The greater part of the material removed is decomposed porphyry, and, as a rule, fairly hard.

COST OF REMOVING OVERBURDEN AT THE "JOYA" MINE PER CUBIC YARD IN THE SOLID (CALCULATED ON THE TOTAL QUANTITY REMOVED DURING 1891.)

Labor.—Superintendence	$0·009	
Excavation	0·032	
Loading into wagons	0·049	
Mule drivers	0·005	
Unloading wagons and repairing roads	0·016	
Various	0·001	$0·112
Materials.—Explosives		
Baskets (used for loading wagons)		
Railway material		
Wagon material		
Oil and grease		
Various		—0·011
Shops		0·006
Stable expenses (mules)		0·013
Tools		0·002
Amortisation of railway material		0·006
Total cost per cubic yard		$0.15

The open-cast working is certainly the best system in mines where the overburden is shallow and the deposit wide. The limit at which the removal of overburden becomes unprofitable is generally put at 4 cubic yards of overburden for every ton of ore laid bare. The cost of quarrying the ore, after having laid it bare, may be taken as follows, exclusive of general charges:

COST OF QUARRYING ORE IN THE OPEN-CAST IN THE "JOYA" MINE PER TON OF 1000 KILOS (AVERAGE FOR THE YEAR 1891.)

Breaking the Ore.—Miners	$0·038	
Materials (explosives)	0·012	
Shops	0·004	
Tools	0·005	—$0·059
Loading into wagons		0·038
Weighing		0·003
Total cost per ton, put into wagons and weighed		$0·10

Examples of open-cast working are found at the Rio Tinto (south lode), Santo Domingo, Tharsis (north lode Sierra Bullones, and center lode) La Zarza, La Joya, Las Herrerias, Lagunazo, etc.

When the proportion of overburden is too great, the mine is generally worked on the pillar-and-stall system. The lode is divided off vertically in floors, 30 to 40 feet apart, and in each of these floors galleries and cross-galleries are driven, intersecting one another at right angles, leaving large pillars of mineral to support the roof between the floors. The roof is generally left about 12 to 15 feet thick, and the square pillars have sides of 15 to 20 feet, the galleries being of the same width as the pillars, and about 20 feet high. It is evident that by adopting this system of working, a large quantity of ore is left in the mine; taking floors, 35 feet apart, with a roof of 12 feet, galleries 23 feet high and 16 feet wide, and pillars with sides of 16 feet, the quantity of ore extracted by means of the galleries is only one-half of the total quantity. In several mines, considerably less than one-half is extracted. It is generally maintained, by those who adopt the pillar-and-stall system, that after honeycombing the mass, more ore may be gained by robbing pillars and roof. This is, however, a very dangerous operation in mines where the lode is nearly vertical, where the width is considerable, the ore very heavy (specific gravity about 5), and where often ten to twenty floors are formed one above another. Only in one mine (the Carpio mine) has this been done; and the result was not encouraging. Only four floors had been formed, yet, although a good deal of ore was extracted by robbing, still by far the greater part remained in the mine, and could not be got out—the comparatively great height of the galleries being a great element of danger. That the operation of robbing is a very delicate one is confirmed by the fact that most of the mining companies, after extracting all the ore they could get by means of galleries, and finding their ore reserves disappearing, have determined, instead of robbing the pillars, to remove the overburden and quarry the honeycombed mass in the open air. Instances of this are found in many places. It is needless to say that a great deal of money would have been saved if the overburden had been removed from the beginning.

Another disadvantage, in connection with the "pillar-and-stall" system is the great cost of breaking the ore. Although galleries may be driven of considerable dimensions, as long as the ore is firm, still breaking ore in galleries, especially in hard ore, is always very costly. Whilst the breaking of ore in the open-cast may cost $0.07 per ton, the breaking in galleries will cost, on the average, from $0.52 upwards. When the ore is very hard, it may be as great as $0.85. The reasons for this higher cost are too evident to need any mention. A miner will break, per shift, in galleries about ⅔ of a ton; in the open-cast he will break from 12 to 15 tons of ore—and even more in favorable cases.

Examples of pillar-and-stall workings are found at Rio Tinto, in the San Dionisio lode; at Tharsis, in part of the north lode, and formerly, in the Sierra Bullones and La Tarza Tharsis (both these lodes are now open-cast); at Lagunazo, in the eastern portion of the lode, at Sotiel-Coronado, Pena de Hierro, Lapilla, Aznalcollar, Caridad, etc.

The Cabezas del Pasto mine is worked on a different system which allows all the ore to be extracted, without any danger, and at a low cost; and there seems to be no reason why the system should not be adopted in all places where the pillar-and-stall is now used, and where the height of overburden excludes the open-cast system. The mineral deposit at this mine is about 500 feet long, with a width varying from 20 to 75 feet, the average being about 32 feet. The gossan goes down about 100 feet; and it was, therefore, impossible to work the mine by open-cast. The lode is nearly vertical, as shown in Fig. 1, which presents a cross-section, approximately in the center of the mass.

After fairly ascertaining the bearing and extent of the lode, an extraction shaft and a pumping shaft were sunk in positions outside of the lode, as shown in Fig. 2. The dimensions of these shafts were 10 feet by 5 feet and 11 feet by 5 feet. The extraction shaft was divided by a partition in the center, so as to accommodate two cages. They were originally sunk to a depth of 230 feet, and subsequently deepened to 350 feet. The lode was then divided in floors, about 65 feet apart. From the extraction-shaft galleries were driven, at every floor, cross-cutting the lode entirely. When these galleries reached the ore, narrow galleries (A Fig. 2) were driven east and west, following the hanging-wall (the extraction shaft being in that wall) along all the sinuosities of the lode, and accurately determining its shape. From these galleries, again, cross-cuts B were driven through the lode at every 33 feet. After thus learning the exact shape of the lode, a "side-tie" C was driven in the country-rock, alongside the lode and at an average distance of about 15 feet, and from this side-tie cross-cuts were driven towards the lode at regular intervals of 33 feet. The side-tie was kept nearly straight, and was used as an extraction-gallery a tramway of 2-foot gauge, with rails of 30 pounds to the yard, being laid in it. There were various reasons why the gallery A, along the wall of the lode, was not utilized as an extraction-gallery; the two principal ones being its crookedness, and the fact that it became surrounded by "stowing" or "gobbing," which necessitated constant timbering to keep it open. On one of the levels it was, indeed, attempted to make this gallery serve for extraction; but it was found very difficult and expensive, and quite unsuitable.

Both walls of the lode are slate, in which all galleries had to be closely timbered.

When the cross-cuts from the gallery along the hanging-wall had reached the foot-wall, they were filled with stone, carefully piled up, and new cross-cuts, D, were then driven alongside the first ones; these were again filled up, and again new ones, E, were made, and so on, until a complete slice of ore had been removed over the whole length and width of the deposit. All the galleries and cross-cuts had a uniform size of 6 by 6 feet, so that the height of the first slice removed was 6 feet. When this had been accomplished, the gallery A, along the hanging-wall, was filled up and a new gallery was driven right above it. From this new gallery cross-cuts were again driven through the mass, and filled up the same way as below, but with one important difference; while the first slice of 6 feet had to be broken out of the solid body of ore, the slice next above was now undercut over its whole area; in fact, it was resting on the packing. This made the blasting very much cheaper; so that, whereas the contract-price given to the miners in the first slice averaged $0.50 per ton of ore, it was only $0.25 in the slice next above. Again, in the first slice the first cross-cuts in the solid ore cost $0.76 per ton of ore, and the secondary cross-cuts, which were really widening out the first ones, only cost $0.42 per ton. These figures show the enormous advantage of having free sides for the working-faces—an advantage, by the way, which is never got in working by pillar-and-stall. After the second slice has been removed, a third was taken away in the same manner, and so on, until the whole lift of 65 feet was removed. The working was not limited, however, to one lift or level, but three were attacked simultaneously in the same manner; and, at the present day, the second, third, and fourth levels are in active work, and the fifth is in preparation. Fig. 3 shows, in vertical longitudinal section, the condition of the workings, July 1, 1891.

It might be expected that some difficulty would be experienced when workings of one floor reach the stowing of the floor above. In practice, however, it is found that the stowing gets so tightly packed as to be quite firm, and, with a little additional care, it is comparatively easy to mine below it. No galleries nor cross-cuts were made more than 6 feet high and 6 feet wide, and no new cross-cut was started before the adjoining one had been properly filled in.

During the filling in of the gallery A, on the hanging wall, a chute was built up in rough stone, above the cross-cut, from the side-tie. Through this chute the ore from the second slice was thrown down to the cross-cut. When the second slice had been removed, and the next gallery filled in, these chutes were carried up, and so on; and these always served for sending the ore down to the cross-cuts and thence to the side-tie, where the ore was loaded into wooden hutches holding about ½ ton each, and subsequently trammed to the extraction-shaft.

The material used for stowing is quartzite. This is quarried on the top of a hill, about 700 yards from the lode. The stone is lowered by means of an inclined plane to the level of the mouths of two special shafts (marked No. 7 and No. 1 in Fig. 2), sunk for the purpose of delivering stone to the workings, and extending, at present, to the third level, with loading-platforms at each floor. The stone, loaded in hutches, similar to those used for the ore, is lowered in these shafts by means of double drums with brakes, the full wagon going down pulling up the empty one. The stone required in the fourth level is landed in the third level and trammed through the extraction-gallery of this level. This extraction-level is connected with the workings below by means of winzes; the stone is tipped in the winzes and falls almost at the foot of the working to be filled up. As the slices are removed, these winzes get filled up also, and therefore gradually disappear, while the ore-chutes always get longer. Each level is thus supplied with stone from the floor above, and the stone need never be raised by hand. All the winzes for throwing down stone are made in the hanging-wall; they are about 3 feet square and very securely timbered.

A good deal of small stuff is produced in the quarry. At various times trials were made to use these smalls in the filling up, as it seemed a pity to throw them away. It was found, however, not economical to do this, as the smalls were more expensive to handle in the mine than the big stones, and also because stowing done with smalls settles down far too much, and loosens the ore above to a dangerous extent, making a very treacherous roof in the workings higher up.

The stowing with large stone is so firm that no subsidence of the ground over the mine can be noticed, although a very large quantity of ore has already been removed, as may be seen from the longitudinal section, Fig. 3.

This system has now been in operation for eight years, during which a total of 230,000 tons has been extracted. Only one man has been killed by falls of the roof during all this period, which shows that the system is not a dangerous one. All the cross-cuts are kept narrow (6 feet); very few props are used, and even these few are generally taken away before stowing.

The average quantity of ore broken by a miner in this mine is 3 tons per shift of ten hours, as against ½ ton under the pillar-and-stall system, the difference being due to the ore being always under-cut and requiring little blasting. (See Fig. 4.)

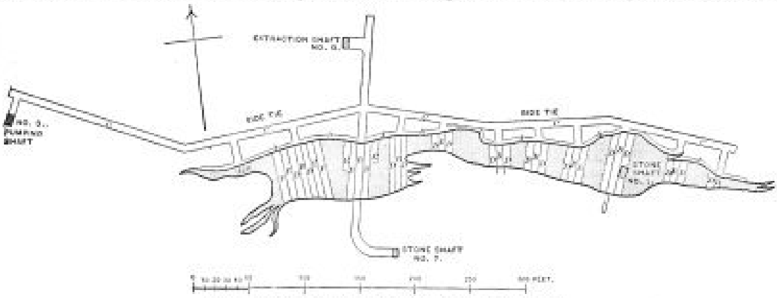


FIG. 2. CABEZAS DEL PASTO—PLAN OF THIRD LEVEL.

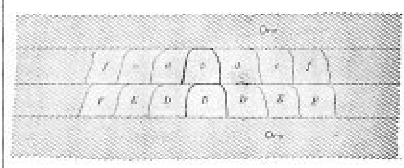

FIG. 4.

The average cost of work in 1891 was for different parts of the system, as follows:

First cross-cuts, B, in the solid ore	$0·76
Cross-cuts D, E, F, etc.	0·42
First cross-cuts, b, in next slice	0·28
Following cross-cuts, d, e, f, etc.	0·26

This shows the increased economy in breaking when the ore is under-cut.

The cost of extraction for the year 1890 was as follows:

COST PER TON APART FROM GENERAL EXPENSES.

Labor.—	Superintendence,	$0·0128	
	Breaking the ore,	0·2372	
	Loading into wagons and tramming,	0·0501	
	Engine-men, etc.,	0·0362	
	Stowing,	0·1569	
	Timbering,	0·0152	
	Unwatering,	0·0048	
	Various,	0·0078	—$0·521
Shops.—	Carpenter shop,	0·0091	
	Smithy,	0·0148	— 0·024
Materials.—	Explosives,	0·0136	
	Coal,	0·0053	
	Timber,	0·0331	
	Steel,	0·0022	
	Caskets,	0·0074	
	Grease,	0·0008	
	Various,	0·0031	—0·132
Tools,		0·0091	
Depreciation of machinery,		0·0273	
Depreciation of wagons and rails,		0·0035	—0·040
Total per ton,			$0·717

The cost of stowing per cubic yard may be detailed as follows, one cubic yard corresponding to about 2·7 tons of ore:

COST PER CUBIC YARD FOR 1890.

Superintendence,	$0·0114
Quarrying stone, inclusive of explosives,	0·0556
Throwing small stuff over dumps,	0·0540
Transport of stone to shafts and lowering down in shafts,	0·0931
Underground transport from shafts to winzes and topping,	0·0664
Underground transport from winzes to workings,	0·0720
Building up in workings,	0·0390
Various,	0·0164
Total per cubic yard,	$0·40

For the better appreciation of these cost-sheets, I may here give the average daily wages earned by workmen in the district:

WAGES EARNED PER DAY.

	Reals.	Dollars.
Foreman of the mine,	24	1·00
Engine-drivers,	20	0·87
Stokers,	10	0·43
Carpenters,	20	0·87
Smiths,	20	0·87
Masons,	16	0·70
Miners,	12 to 16	0·52 to 0·70
Trammers,	12	0·52
Ordinary laborers,	10	0·43
Boys and girls,	6 to 8	0·26 to 0·35
Cost of coal,	150	6·54
Cost of firewood,	45	2·00
Cost of six-foot props, each,	10	0·43

The following is the cost of a ton of ore, mined by the pillar-and-stall system, where other conditions are the same as above:

COST OF PILLAR-AND-STALL SYSTEM PER TON OF ORE.

Labor.—	Superintendence	$0·0128	
	Breaking the ore	0·6540	
	Loading into wagons and tramming	0·0501	
	Engine men, etc	0·0362	
	Timbering	0·0152	
	Unwatering	0·0048	
	Various	0·0078	—$0·781
Shops			0·024
Materials			0·132
Tools			0·009
Depreciation			0·031
Total per ton			$0·977

The cheaper working over the pillar-and-stall system is entirely on account of the cheaper breaking of the ore, the difference being about $0·26 per ton.

The system here described was started by Mr. C. Roepell, M. E., and subsequently carried on by the writer and Mr. P. E. Carr, M. E. It can be applied in all large masses and wide lodes, and is a safe and economical mode of getting all the ore.

The Cabezas del Pasto mine is one of the mines worked by the Bede Metal and Chemical Company, Limited, of Newcastle-on-Tyne.

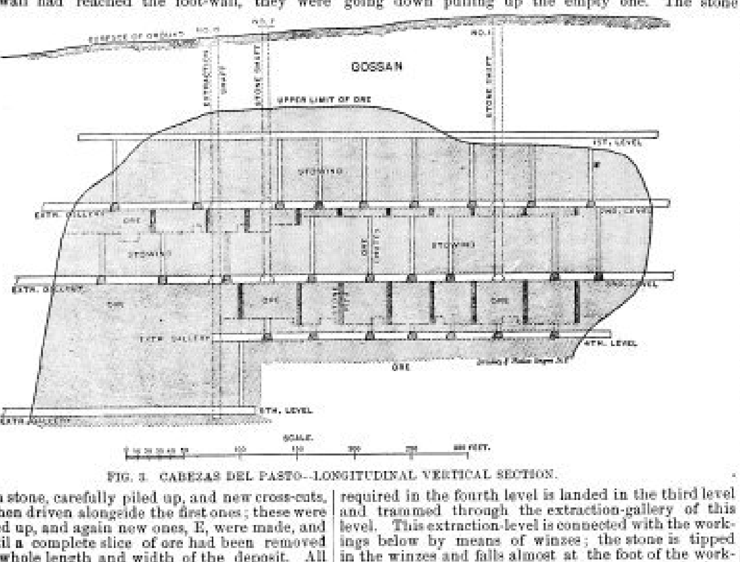

FIG. 3. CABEZAS DEL PASTO—LONGITUDINAL VERTICAL SECTION.

A HAND-TELESCOPE FOR STADIA-WORK.

BY ROBERT H. RICHARDS, BOSTON, MASS.

[From the Transactions of the American Institute of Mining Engineers.]

If one holds up a prism, or wedge of glass, with narrow angle, say 1° to 2°, and compares the transmitted image with the image seen above or below the prism, the former will be found to be thrown to one side by an amount varying with the angle of the wedge. Speaking of the two rays as the direct ray and the bent ray, we may say that when the bisecting plane of the prism is at right angles to the line of sight, the angle between the direct ray and the bent ray will be constant for any given prism.

Fig. 1.

If now we place a prism or wedge of glass in such a position that it half-covers the objective of a telescope, we shall obtain on looking through it two images of every object seen—one image by the direct ray, which comes through the uncovered half of the objective, the other which comes through the prism, and is the image by the bent ray. The angle of divergence of these two rays will be constant and unalterable, whether the telescope is directed to a near object, with its eye-piece at increased distance from its objective, or upon a distant object, with eye-piece nearer to the objective. That is to say, if the "throw" or apparent dislocation of the image is one foot in one hundred feet it will be two feet in two hundred, ten feet in a thousand, and so on.

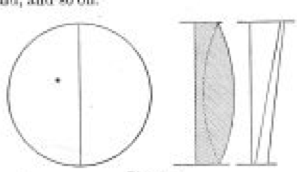

Fig. 2.

The usual form of stadia-telescope has at the focal point of the objective two spider-lines, placed at a definite distance apart and intended, let us say, to represent a throw of one foot in one hundred feet. But as the distance between lines remains the same, while the distance from the objective to the webs differs with every variation in the distance of observed objects, it follows that the angle between the lines of sight which these two spider-lines define cannot be constant, but must vary with every increase or decrease of distance between the instrument and the object viewed.

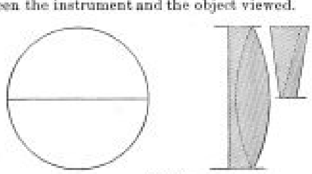

Fig. 3.

If in Fig. 1 we represent three positions of the spider-lines by W_1, W_2, W_3, and three objects corresponding to those positions by O_1, O_2, O_3, at near, medium, and distant positions, we see at a glance from the figure that there is no constant angle represented by the spider-lines, and that the only way to graduate a rod for the practice of stadia-measurement by this method is to determine values for one foot at a sufficient number of distances, and to provide the rod with a graded scale accordingly.

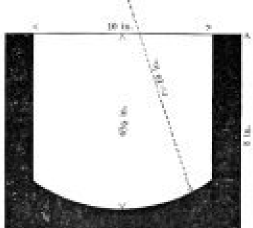

Fig. 4.

The prismatic stadia-telescope, on the other hand, has a constant angle for all distances and all focal lengths; and when the factor has once been obtained, it may be used to graduate a rod with uniform scale from end to end.

Again, the usual stadia-instrument involves two points of observation. The operator adjusts the lower [spid]er-line on the zero of the rod and then observes the reading of the upper line on the rod. There are, therefore, two personal equations in the operation of taking readings. With the prismatic stadia-telescope, on the other hand, both observations are made at once, just as the sailor, in taking the altitude of the sun at sea, brings the sun's image to the horizon and observes the contact. Only one personal equation is thus involved.

The spider-line stadia-telescope cannot be used by simply holding it in the hand, but requires a firm support; for, if it were used in the hand, the first line would wander from the zero on the rod before the reading of the second line had been taken. The prismatic stadia-telescope, on the contrary, can be used in the hand just as a sextant is. Nevertheless, as the readings to be made with it are much finer than those of the sextant, a support will be preferred for most purposes.

The one great advantage of the spider-line over the prismatic telescope is, that it uses the full light of the whole objective at all times, while the prismatic has only half-light. This objection to the latter is completely removed when the spacing target-rod is used; and it is fairly well met by the employment of self-reading rods, to which reference will be made below.

In adapting the prismatic stadia-telescope to the needs of the surveyor, several important matters have to be determined, relating to the prism and also to the telescope and the rod.

In my experiments I have combined a telescope of 30 diameters magnifying-power with a prism of one foot throw to 100 feet, and also with a prism of one foot throw to 150 feet. I shall speak of these two combinations respectively as 30 *d* : 100 and 30 *d* : 150. I have also combined a telescope of 20 diameters magnifying-power with three prisms, throwing respectively 1 foot in 50 feet; 1 foot in 100 feet; and 1 foot in 150 feet; and I shall speak of these combinations as 20 *d* : 50; 20 *d* : 100; and 20 *d* : 150. Finally I have combined a telescope of 10 diameters magnifying-power with prisms of 1 foot to 50 and 1 foot to 100; and I shall call these combinations 10 *d* : 50 and 10 *d* : 100.

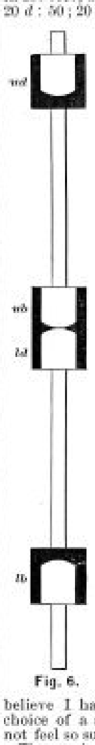

Fig. 6.

The first fact I encountered in these experiments was, that 10 *d* : 50 and 10 *d* : 100 can be used with uncorrected prisms, since the amount of color does not seriously injure the observation; while no prism not thoroughly achromatic was found satisfactory for either the 20 *d* or the 30 *d* telescope.

Fig. 2 represents what appears to me to be the rational and proper mode of combining the prism and the objective; while Fig. 3 shows an improper combination. In Fig. 2 the bent rays are exact counterpart of the direct rays, while in the adjustment of Fig. 3 this is not the case.

Choice of a Prism.—For hand-use a wide prism is preferred, say 1 foot displacement in 50 feet distance. For a fixed telescope 1 : 100 or 1 : 150 would be preferred, according to the distances to be sighted and the length of the rod to be used. A prism throwing 1 : 150 will permit readings at 1500 feet on an 11-foot rod, while a 1 : 100 prism will read only to 1000 feet on the same rod. On the other hand, where a standard steel tape with sliding targets is used instead of a rod, we may say that the wider-angle prism will give more accurate work than the narrower.

Choice of a Telescope.—Since a large field is not needed, we have to deal with two considerations only: the lightness of the instrument and its power. If the former consideration governs the choice, I would recommend a light 10 *d* or a light 20 *d* telescope; if the latter, I would recommend a 20 *d* or 30 *d* telescope.

Choice of Rods.—In this direction I believe I have settled the question as regards the choice of a spacing rod with sliding targets; but I do not feel so sure with respect to the self-reading rods.

The spacing-rod represented in Figs. 4 to 9 is so pre-eminently superior to every other which I have tried that I strongly recommend it.

This target stands out strong and bright under any circumstances. It can be read against a dark background in the woods and also against a light sky background on a hilltop.

In Fig. 5 the rod is represented as seen by the eye. Fig. 6 shows it as seen by the prismatic stadia-telescope. In this figure *ud*, *ld* are the upper and lower images by the direct ray, and *ub*, *lb* are the upper and lower images by the bent ray. The observer of course neglects *ud* and *lb* and uses for his contact *ub* and *ld*. The important advantages of this form of contact are shown in the subsequent figures.

Fig. 7 represents the targets approaching contact; Fig. 9 shows the images lapping, in which case there is a bright lens-shaped image, indicating the amount of lap. Upon its appearance the assistant is signalled

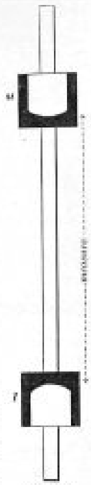

Fig. 5.

to draw the targets slowly apart; and the instant the white lens become invisible the reading, Fig. 8, is taken. The disappearance of this white lens gives a close and positive reading. The results stated below were obtained with this reading.

A target of the size shown in Fig. 4 can be read easily at 2000 feet distance with a 20 *d* telescope, in an even atmosphere. A much smaller target will suffice for short sights. The design of Fig. 4 has more strong points in its favor than any other yet tried by me.

The spacing-targets, Figs. 4 to 9, may be used on a steel tape if the following conditions are observed: The tape must be held at right angles to the line of sight. If the right angle is at one of the targets, it will be found easier to reproduce them at a point half-way between the targets. For distances much greater than 2000 feet a larger target or a higher-power telescope, or both, will be needed.

Fig. 10 represents a tape, as used by me on a 1970-foot sight with the above targets and a 20 *d* telescope.

Self-reading Targets.—Three forms which have been experimented upon are represented in Figs. 11, 12, and 13.

Fig. 11 gives good results with a 10 *d* : 50 combination for short distances. It may be graduated, as shown, with 2-foot unit or with 5-foot or 10-foot unit. In the latter case, it would be used for long distances with a 20 *d* : 100 combination up to 30 *d* : 150 combination; but the individual feet would have to be divided by the eye. The skeleton second image on it reads 68 feet.

Fig. 12 may be graduated with 1-foot, 2-foot, 5-foot, or 10-foot units, according as a short distance or a long-distance rod is wanted. The skeleton-reading of the second image upon it indicates 265 feet. Possibly, for certain distances, this graduation may be found easier to read than that of Fig. 11.

Fig. 13 represents a target-rod with an optical vernier. The space from 0 to 100 feet on the rod is graduated into 11 parts, while the spaces from 100 to 200, also from 200 to 300, and so on down, are graduated into 10 parts. Moreover, the space from 0 to 100, which we may call the vernier, is graduated on the opposite

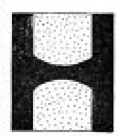

Fig. 7.

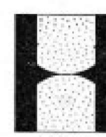

Fig. 8.

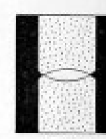

Fig. 9.

side to the other readings, so that the second imag can bring it down and give a vernier-reading between the two images. The partial skeleton second image gives a reading of 423 feet, no dividing by the eye being required. By this system an 11-foot rod may be made for a 30 *d* : 100 combination, which will actually give readings of individual feet at 1000 feet distance.

The vernier-reading is the most fascinating idea I have met in my investigations. Whether it is really practical can only be decided in the field. The images which are important for the reading are half-light images, and therefore dim, while with the other two forms of target a full-light reading is obtained.

Limits of Error.—Partly by reason of the limited time at my command for experiments, and partly because every time I went out to get definite records of practice, I made some discovery which led to an improvement in the apparatus, I can only promise at this time to give detailed figures at an early day as a supplement to this paper. The figures I am now prepared to publish were taken with a curved spacing-target of the design shown in Figs. 5 to 9.

With a 20 *d* : 150 combination, holding the rod at 100 feet distance, I obtained five separate readings of the distance in feet between the targets, which were 0·653; 0·654; 0·653; 0·653; 0·653. With a 30 *d* : 150 combination I made these four successive readings at 100 feet distance: 0.675; 0·675; 0·675; 0·675; all with the spacing-target described in Figs. 4 to 9.

If I had made an error of 0·001 foot upon the rod, this would correspond to an error of 0·15 per cent. or 0·15 foot in 100 feet. But I did not make this error in four readings with 30 *d* : 150, and only made it once in five successive readings by the 20 *d* : 150 combination. If the prism had been a 1 : 100 prism, the error referred to would have been 0·1 foot in 100. If the prism had been a 1 : 50, the error would have been ·05 foot in 100 feet. I cannot imagine a reason why the percentage-error at 1000 feet or 2000 feet when the atmosphere is steady, should be any greater than it is at 100 feet. From the above considerations, I believe I am safe in saying that the error of the prismatic stadia is well inside of 0·1 per cent.

I hope to present, in the near future, some figures actually obtained for both short and long distances.

If one desires to determine the distance to a point without the trouble of sending an assistant there, it may be done with a pair of Wollaston camera-lucidas, as shown in Fig. 14, in which W_1 W_2 are the two cameras.

If the Wollastons both give 90°, then the requisite

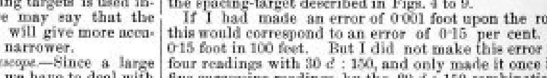

Fig. 10.

deviation from 90° may be obtained by inserting a prism, P, as shown. If, however, the two Wollaston angles add up to say 177° to 178°, then the apex-angle will be 2° or 3°, and will answer without the addition of another prism. After the two observers, E_1 E_2, have found their places, so that their respective images coincide, then they can measure the base-line between them by a prismatic stadia-telescope; and knowing the factor of the Wollastons, three feet or four feet to the hundred, the distance to the unknown point may be determined approximately by multiplying the observed distance between E, and E, by the factor, 3 feet to 100; 30 feet to 1000; 300 feet to 10,000; and so on.

In making my designs and in testing my instruments, I have been helped materially by Captain A. H. Russell and Messrs. J. Hays Gardiner, W. H. Weston, Franklin Knight, Luis T. Verges, and W. S. Hutchinson, friends to whom I wish to make acknowledgment.

Fig. 11. Fig. 12. Fig. 13.

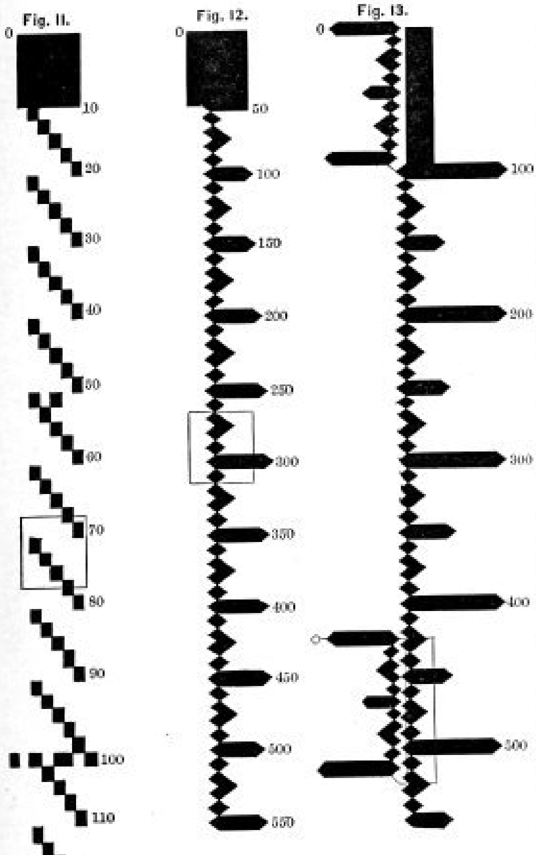

Fig. 14.

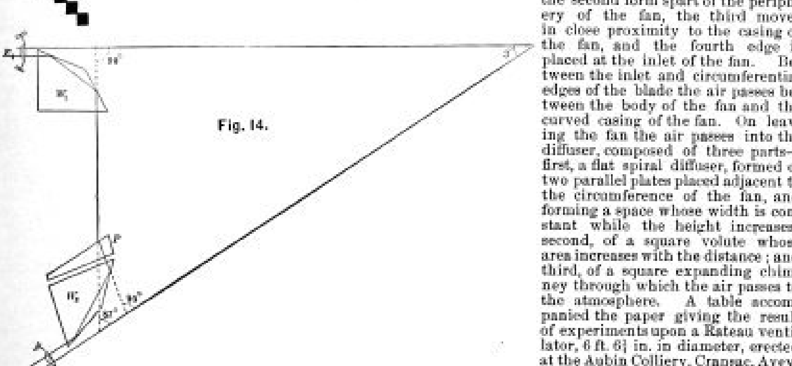

Chandler & Taylor Company, of Indianapolis, Indiana, report that they are now working on a complete new line of saw-mill machinery which they expect to have ready for the market by early summer. Their standard mill has already been completed and has been favorably commented on by all who have seen the mill. The design is neat, the working parts are heavy and the proportions and convenience are at once apparent and leaves nothing to be desired. The Heacock patent variable belt feet works will be used on all mills, which will largely increase their output.

We will inform our readers farther as soon as complete catalogues are issued of these machines which the makers will be glad to send on application.

Messrs. Copeland and Bacon, the widely known builders of Hoisting Engines and Mining Plants, whose general offices are at 85 Liberty St., New York, and who for several years have had a branch store at 535 Arch St., Philadelphia, have opened another branch store at No. 62 South Canal St., Chicago, for the convenience of western purchasers.

THE PROGRESS IN MINING.

Reviews of Important Papers Relating to Mining in the Proceedings of the Mining and Scientific Societies, and in the Mining Journals of Europe, United States, and Canada.

Coal Cutting Machinery. Mr. John B. Atkinson, of Earlington, Ky., contributes a short article in a recent issue of the Transactions of the Engineering Association of the South on his experiences with coal cutting machinery.

While electricity is making rapid advances in its application to mining work, Mr. Atkinson doubts if it will ever displace compressed air as a motor for coal cutters. He points out that while constant feed rotary machines may be successful in seams with an even plain holing they are costly where the holing contains iron or sulphur balls. We think this is an opinion pretty generally held by mining men. In the latter case, Mr. Atkinson found that a pick machine (the Harrison) was the best. He considers that machines are too cumbrous for thin veins but that in a vein of ordinary thickness they can be profitably used. Ordinary labor can be used, and two weeks' experience will convert a farm hand into a fair runner. The machine does the hardest part of a miner's work, does it quicker, gets a greater percentage of lump coal, and saves 50% of the cost of powder. With 60 rooms of work at Earlington these machines can produce 250 tons of lump coal per day, whereas by manual labor 100 rooms would be required for the same output. This is a consideration as a smaller number of mules are necessary, and the general underground cost would be less.

A New Ventilator. At a recent meeting of the North of England Institute of Mining Engineers, Mr. M. Walton Brown read a paper descriptive of the "Rateau Ventilator," which, he stated was so designed that air might pass through it at a high speed, and without interruption. The wheel is mounted upon the shaft, and is fitted with thirty blades of a special form. Each vane has four edges, one of which is fixed upon the face of the wheel, the second form apart of the periphery of the fan, the third moves in close proximity to the casing of the fan, and the fourth edge is placed at the inlet of the fan. Between the inlet and circumferential edges of the blade the air passes between the body of the fan and the curved casing of the fan. On leaving the fan the air passes into the diffuser, composed of three parts—first, a flat spiral diffuser, formed of two parallel plates placed adjacent to the circumference of the fan, and forming a space whose width is constant while the height increases; second, of a square volute whose area increases with the distance; and third, of a square expanding chimney through which the air passes to the atmosphere. A table accompanied the paper giving the result of experiments upon a Rateau ventilator, 6 ft. 6¾ in. in diameter, erected at the Aubin Colliery, Cransac, Aveyron.

Deep Boring at Schladebach, Prussia. We are indebted to the *Colliery Guardian* (Eng.) for the following article on this subject.

At the closing *seance* in 1891 of the Societe Industrielle de Mulhouse, M. Charles Zundle gave some particulars gathered from two reports sent to the society by the German Mine Department, of the deepest borehole which has yet been put down, viz., that at Schladebach, near Kotschau, in Merseburg, Prussia, which attained the great depth of 1,748 meters, or 956 fathoms.

The boring was begun in August, 1880, by the Royal Division of Prussian Mines, and finished in the Autumn of 1886, having occupied 1,247 actual working days, with a mean daily advance of 1·4 m. (4 ft. 7 in.) and at a total cost of 212,304 marks ($50,912.00) or, say, $38.08 per yard of boring. A 25-horse power portable engine sufficed for the motive power necessary to work the boring rods and also the pumps, a tower 27 m. (89 ft.) high, permitting of 20 meters of tube lining being raised or lowered at a time.

The initial diameter of the hole was 280 mm. (11 in.) After 20 m. of sand, gravel and marl, passed through by the system of *Schappenbohrung*, or tube boring, the variegated sandstone was struck, which was attacked by the *Hohlfreifallinstrument*, or free-fall apparatus, a cast-steel drill with end in the form of a cross with guides, water flowing down outside the tabular rods and rising up the inside. At the depth of 57 m. (31 fathoms), the lining could not be got to descend further, so an attempt was made to go on without lining; but the *débris* detached from the sides of the hole rendered it necessary to put in a tube lining of 230 mm. (9 in.) diameter. At 164 m. (90 fathoms) strata of gypsum and anhydrite were encountered, and also water charged with sea salt. At the depth of 175 m. (95 fathoms) the free-fall apparatus was abandoned for rotary boring by means of a soft iron crown, of 210 mm. (8¼ in.) diameter, set with borts or carbonate diamonds, producing cylindrical cores of 140 mm., or nearly 6 in. diameter. In the dolomitic limestone it was found impossible to detach one of these cores; and the crown became fixed so fast that it became necessary to draw up the rods and bore into the core with a small crown, in order to detach it, a work that occupied three weeks.

After several accidents and difficulties—such as the rods bending and having to be cut and lifted, a crown sticking in the bottom of the hole and having to be perforated and ground up by the free-fall apparatus, or a tool falling by accident into the hole and necessitating the cutting of the rods at great depths—the depth of 1,070 m. (585 fathoms) was reached, the diameter of the hole having been reduced seven times. Between this depth and that of 1,724 m. (943 fathoms) the hole was continued with a diameter of 48 mm. (2 in.) yielding cores of 23 mm. or less than 1 in. diameter. The old red sandstone had been passed through between 327 and 1,630 m., when the Devonian rocks were traversed without, however, encountering a seam of coal, which might have been met with at that geological depth. A stratum of cuprose schist, struck at 326 m., was not considered rich enough to warrant its being worked.

Nevertheless, the hole was continued, with a purely scientific object, and at the beginning of 1886 a lighter tubing, of 33 mm. (1⅓ in.) diameter, was put in, in which boring was carried on with a crown of 31 mm. (1¼ in). giving cores of 12 mm. (½ in. bare) only. But, finally, after successive accidents—such as breakage of the rod and fall of the crown, and breakage of the screw of the core-extracting apparatus—at the depth above mentioned it was found necessary to stop the work, which could only have been continued at a great expenditure of time and money. The following are the rocks passed through with their depths and thicknesses:

	Thickness Feet.	Depth Feet.
Vegetable earth	1·97	1·97
Sand	14·01	15·98
Clay	58·28	74·26
Variegated sandstone	465·65	539·91
Gypsum and anhydrite	52·61	592·52
Permian limestone (Zechstein)	152·18	744·70
Gypsum	34·16	778·86
Anhydrite	292·71	1071·57

	5737·88	

Careful thermometric observations were made as the work proceeded, and naturally delayed its progress considerably. From a depth of 3937 feet they were continued regularly every 98·4 feet, and before the tube lining was put in, so as to avoid any disturbing influence from conduction, while to counteract that of water currents, the thermometer was immersed in a fixed column of water between two clay plugs, and left there for sixteen hours. To prevent the glass from being broken by the great pressure, it was enclosed in an iron case; and there were always three superposed thermometers from which a mean of the readings was taken. The observations of the first 3937 feet were taken subsequently. The observations went to show that the increase of temperature does not diminish with depth, as had heretofore been imagined, but follows a constant arithmetical progression. The last reading taken viz., at 1·716 m. (938 fathoms) was 45·3 degs. Reaumur, or 56·6 degs. Cent. or 134 degs. Fahr., which shows an increase of 1 deg. Reaumur for every 46·09 m., equivalent to 1 deg. Cent. for every 36·87 m. At this rate potassium, the fusion point of which is 48 degs. Reaumur = 60 degs. Cent. = 140 degs. Fahr. would melt at a depth of 1,845 m. (1,000 fathoms), and grey foundry pig (1,240 degs. Reaumur = 1,550 Cent.) at 50·775 m., or about thirty-five miles, while the greatest temperature of blast furnaces, which according to Scherer is 2,230 degs. Reaumur (4·037 degs. Cent.) would be attained at a depth of 104,708 m., or a little over 14 geographical miles.

M. Zundel concluded his interesting communication by calling upon the Societe Industrielle to urge the putting down of a deep borehole in Alsace-Lorraine, or the deepening of two Hasenrain and Dollfus holes, in order to prove the existence of coal or Bituminous shales yielding petroleum, or even to demonstrate practically that a source of heat and power exists beneath our feet, that shall maintain warmth in our bodies, and keep our mills and factories going, when all the coal deposits shall be exhausted.

The Practical Working of Coal-Cutting Machines. At the meeting of the Manchester Geological Society, held last week, Mr. Richard Sutcliffe read a paper on the "Practical Working of Coal-cutting Machines," of which the *Colliery Guardian* (Eng.) gives the following summary: "In the course of his remarks Mr. Sutcliffe said that he quite agreed with Mr. G. Blake Walker, of the Wharncliffe Silkstone Colliery, who was the largest user of coal-cutting machines in England, when he said that actual experience points to 100 yards per eight hours shift as being a satisfactory performance with coal-cutting machines when the ordinary conditions of work in a coal face were in force. The writer had found that the most convenient machine, and a better one for all-round work than any, was one having a cylinder at each end, with the cutting wheel in or near the middle. By this arrangement as comparatively light machine would keep the rails without extra fittings in working, and was capable of cutting either coal or fire clay, and the power could be varied to suit the material to be cut, by making it to run from 3 to 1 to 12 to 1 between the crank shaft and cutting disc, and its total length need not exceed 7 ft. To get anything like good results from the best machines, when cutting 3 ft. deep or more, the *debris* should be kept removed, as the fore or cutting portion of the wheel brought it from the groove or cut, otherwise it would be taken back in part by the back portion of the wheel, until it becomes jambed. As the attendant might have many things to look after, as well as the removal of this *debris*, it was often neglected, and therefore much of the power wasted. This fact must suggest to the contemplative mind the desirability of making a coal-cutting machine capable of dealing with its refuse automatically, so as to prevent its return into the groove. The fixing of the chisels or cutters in the periphery of the rotating disc had a great influence on the working of a machine in cutting hard material. The proper way was to fix the cutters radial in the disc, and hook them near their edges, sufficiently forward to cut, and then, as a cutter shank wore loose, it got less, instead of more work to do. Even the sharpening of the cutters had an important effect on the working of a machine, and a set of twenty was sometimes blunted in as low as 10 yards, and sometimes would cut as much as a thousand yards, even when properly edged and tempered, according to the material to be cut. If the holing was fairly free from iron pyrites, or such-like impurities, the set of cutters should do from 50 to 100 when each cutter was doing its share in either coal or fire-clay. A good coal-cutting machine should be strong and simple in construction, with few working parts; it should have sufficient base and weight to keep on the rails when working without extra fittings; it should be able to cut either way, and be easily reversed, and should automatically remove the *debris*, so as to prevent it getting into the groove, and it should not exceed 3 ft. in width, nor 7 ft. in length. Where coal had to be blown down after being cut it was best to make a deep holing, but where it fell from gravitation it was sometimes advisable to take a lighter or shallow cut, which enabled the machine to cut a greater distance, and the fillers to fill out a greater length, each in the shift, allowing the gates to be farther apart; but whether the cut were deep or shallow, it was undesirable to dress down the face more than was necessary to the machine to pass, as it saved labor, and made less small, when allowed to remain for next fall. At Gartness Colliery, near Airdrie, in Scotland, where machines had worked successfully for many years in a 30-inch seam, with good roof and strong floor, they made the gob roads 14 yards apart. The corves were filled in the gob road at about 17 cents per ton, and the filler had to throw the coal when it got out of his reach, filling 6 yards at each side of the gate. The cutting was done by one contractor at 9 cents per ton, and the filling was done by another. In Yorkshire the system was to take the cars into and along the face, necessitating the use of small cars in thin seams, but allowing the gob roads to be made at any desired distance apart, and accordingly they were made at from 12 to 50 yards apart to suit the ideas of those adopting them, and it often took from two shifts upwards to fill out the coals. This necessitated irregular working of the machines, without any regular quantity of work being laid out for them per shift, and it was not nearly so methodical a system as the Scotch. It also compelled the filler to take up the floor clay instead of confining his energy to the filling out of the coal, which could not very well be done but while the pit was drawing, and the floor clay could be removed at any time. In some cases the machines were made to cut all in one direction, having to be taken back through the gob roads every time it cut through the length of the face, but almost all the recent installations were made to cut back and forwards. His (the writer's) opinion was that money spent in taking them through the gob road, except for repairs, was simply wasted. The best mode of working seemed to be to sub-divide the labor into something like the following divisions: Holers, blowers, and timberers, fillers and packers, and rippers. The holers would include a man to drive the machine, one man to lay the way in front of the machine, and a youth to clear away the *debris* from the cut. The fillers to devote the whole of their time in filling out the coals. The blowers would include men to bore the holes, timber up the face, and blow down the coal. The packers to take up the floor clay, and rip and pack the gob roads. The whole of those about the machine should be under the control of a capable man—more especially at the commencement—who understood machinery and mining in a general way. He might have it on contract or it could be left to the section under him, but he should have complete control of the men, without interference of subordinate officials, whose prejudices and jealousies could only hamper and impede the work. Energy, perseverance, and system would work machines in any mine with a fairly good top, but of course their proper place was in thin seams, where holing forms the greatest part of the labor, and where properly worked they should benefit both the miner and the mineowner; the former, in doing the most laborious part of the work, and the latter, by increasing the output, reducing cost of getting and in reducing the proportion of small coal made in getting. Mr. G. B. Walker gives the saving effected in the reduction of cost of getting at from 6 cents per ton in a 3 ft. seam, to 21 cents in an 18 in. seam, and that effected by the value of the yield of coal, as compared with hand labor, at from 13·4 cents in the 3 ft. to 21 cents in the seam 18 in. thick, per ton, making together a total saving of from 19·4 cents in the 3 ft. to 42 cents per ton in the 18 in. seams. In concluding his paper, Mr. Sutcliffe said that the boring type of machine had obtained a strong footing in America, but compressed air was the motive power in both countries, with few exceptions, and in the mining districts of the United States machine mining was steadily increasing, there being scarcely any coal-producing territory of the Union where machines were not being, or had not been used with more or less success.

The Miner's Safety Lamp and Improvements by The Double Chamber.

A correspondent in a recent number of the *Colliery Guardian* (England) writes: Out of the vast number of people interested directly or indirectly in the improving and perfecting of the miner's safety lamp, comparatively few have interested themselves to understand its fundamental principle. The history of the safety lamp with enumeration of its development, would undoubtedly, if written, be interesting from more points of view than one, and provided one possessed the necessary time and data for compiling, there is here material of great value. The primitive Davy lamp was not destined to reign for very long. Its dim and murky light, its proneness to get blown out with currents that it had to contend with in the mine, together with its unsafeness, were features that made the work of supplanting it easy. The acute feeling of relief that accompanied the advent of the Clanny can be conceived only by those who have had experience with the Davy.

Without making further mention of the Clanny, and passing over a host of other forms of lamps, which, from their very number, form a splendid monument of the patient endeavors and labors of inventors in trying to solve the problem, we eventually come to the Mueseler lamp, which, in its first days, created a good deal of stir and enthusiasm, and bade fair to satisfy scientific men and miners. But it would appear that the size of the inside tube and its position are such that tilting the lamp to an angle of but 20 degs. from perpendicular or even less is in most cases sufficient to deviate the feeding current from the flame to such an extent that it will die out. The Mueseler lamp, however, must be credited with having introduced a new principle. Without doubt, the tube in the Mueseler is one of the features necessary in the construction of an absolutely safe lamp, but it should be modified to some extent. It should be altogether larger, say 1½ in. at the base and tapered to ¾ in. at the top, a bell-mouth to be formed at the base in order to deflect the incoming current that it may pass down close along the inner side of the glass, and thus be brought to impinge directly upon the flame. Thus nearly all the oxygen of the air passing through the lamp will be available, although it will not, of course, be all consumed. The unconsumed portion, together with the products of combustion—carbon dioxide and steam and the diluent nitrogen—all at a considerably elevated temperature, will intermix and pass up through the tube with considerable velocity into the gauze beyond. And now by preventing any further ingress of air, or, more precisely, of oxygen, into this mixture, it will be quite impossible for any inflammable gases which may have passed into the tube with these products to be consumed in the gauze beyond the tube. The chance of its ignition will be noted further on. As stated, the foul products will be considerably heated and very much rarified, and we know that although combustion may be carried on with great freedom in an atmosphere of normal density at some given temperature, we can by sufficiently attenuating that same atmosphere, prevent combustion entirely at that same temperature or even at a higher one. Thus the rarefaction of the gases will further reduce the chances of combustion beyond the tube. But the principle, the importance of which I wish to note, is that the products, after once passing through the Mueseler tube, should be kept strictly intact from the outside atmosphere (thus preventing any increase in the amount of oxygen present) until the products emerge again through the shield at the bonnet. Now if the greater part of the gauze be so shielded up that the outside atmosphere cannot intermix with the combustion products and any inflammable gases mixed with them as they pass through the Mueseler tube and until they again pass out through the bonnet at the top then the ventilating of the lamp will be more or less of a circular column of heated gases co-axial with the tube. The gauze of the lamp will thus be constantly immersed in an atmosphere of foul gases surrounded as it were, by thick walls of carbon dioxide and foul air—the ventilating current, in fact, having to force its way through a chamber containing a non-supporter of combustion. The result of this is that, although ignited gas may be forced through the tube as previously explained, the flame cannot possibly live for any length of time in the atmosphere that now surrounds it. It therefore dies out. Thus far, theory and facts lead to this conclusion, that a lamp of this description will always extinguish except in an atmosphere containing a percentage of fire-damp less than that necessary to form a mixture of the least explosive properties. In case the percentage of inflammable gas mixed with the incoming air be a little less than is required to form an explosive mixture, say 5 to 6 per cent. and is more than sufficient to form a cap on the flame, a faint combustion may be carried on (though unstable) at the base mouth of the tube. This cannot possibly be any source of danger, even though it is continued all day, as it is quite clear of the gauze, and will not produce more heat than that which the lamp can easily radiate; the temperature of no part of the lamp will therefore be dangerously high. It should be stated that these features appear to have been combined in a lamp patented by Mr. Thomas Thomas, of Ynishir, South Wales.

Mr. A. H. Osterloh, Jr., an energetic and progressive young man, has entered into the Mine, Mill and Railway Supply business at No. 89 Water St., Pittsburgh, Pa., under the title of The Osterloh Supply Co. He will handle first class new and second hand machinery of all kinds, and is prepared to contract for the erection of complete colliery plants. He is also prepared to furnish first-class supplies and tools promptly and at reasonable prices. It will pay to send to the Osterloh Supply Co. for circulars and catalogues.

MISSOURI COAL.

The Coal Production—The Coal Market—The Uses and Adaptabilities of the Coals—The Available Tonnage and Duration of Supply—The Value of Coal and Coal Lands.

(From the Preliminary Report on Coal of the State Geological Survey.)

The total production of coal in Missouri for the year ending June 30, 1891, was 2,650,028 tons, valued at 3,480,867 dollars. According to Bulletin No. 10 of the Eleventh Census, Missouri ranks second as a coal producer among the States west of the Mississippi River, Iowa being first with a production of a little over four million tons. Colorado is ranked next after Missouri, her production being 2,544,144 tons, and Kansas is fourth with a production of about 2,200,000 tons per annum. After these no other of the western states approach Missouri in the amounts of coal produced. According to the same Bulletin Missouri ranks ninth as a coal producer among the States of the Union, Pennsylvania leading off with the magnificent figure of over 80,000,000 tons. Illinois being next with about 12,000,000 ton, Ohio third, with nearly 10,000,000 tons, West Virginia next with over 6,000,000 tons and then Iowa, Alabama, Maryland, and Indiana preceding Missouri in the order given.

The amount of coal produced in the State is, thus, both absolutely and relatively large. Its value is greater than that of any one other mineral product in the raw state, the production of lead for the year ending June 30, 1891, according to the State Mine Inspector's figures, being valued at $2,411,399, that of zinc at $2,673,073, and of iron at $331,065.

According to the list of coal mine operators appended to this report there are, in all, 385 individuals and corporations engaged in mining coal. Of these, one organization mines *about a fourth* of the total amount produced each year; ten companies mine together nearly two-thirds of the total amount and sixty individuals and companies mine together about five-sixths of the total, leaving for 325 individuals and companies the production of one-sixth.

The principal coal producers, in the order of the amounts of their products, are: The Rich Hill Coal and Mining Company, the Western Coal and Mining company, and the Lexington Coal and Mining Company, these three being under one management, with mines in Bates and Lafayette Counties; the Kansas and Texas Coal Company, with mines in Macon, Ray, and Linn Counties; the Keith and Perry Coal Company, with mines in Henry and Bates Counties; the Richmond Coal Company with mines in Ray County; Loomis & Snively, with mines in Macon County; the Mendota Coal Company, with mines in Putnam County; the Inter-State Coal and Mining Company, with mines in Randolph County, and the Randolph Coal Company, with mines in Randolph County.

The conditions affecting the market of the coals west of the Mississippi River are, in some respects, different from those in the eastern part of the country. The Western Bituminous coal field is surrounded on all sides by large expanses of country destitute of merchantable coal.* These great areas with their constantly increasing population and needs, must, under natural conditions, draw their supplies of coal largely from the mines of Iowa, Missouri, Kansas, Arkansas, Indian Territory and Texas. The area of workable coal is also restricted in Kansas, Arkansas, Indian Territory and Texas, only a small portion of the coal measure areas there being productive. East of these areas their coals are brought into competition with the coals of Illinois, Indiana, Kentucky, and Ohio in the North, and with those of Tennessee and Alabama in the South; even the Anthracites of eastern Pennsylvania are sold within the very limits of these western coal fields, on account of their special adaptabilities. The natural facilities for transportation provided by the Ohio and Mississippi Rivers enable the coals of western Pennsylvania and of Ohio to compete very successfully with the geographically much nearer western coals, especially along the lower Mississippi. Further, through the distribution of railway lines and adjustments of rates, Illinois coals force the competition line much farther west than would seem possible from geographic considerations. Thus the territory affected by this competition to the east, is large, and it will probably always be considerable, though subject to variations.

Towards the west, however, there stretches a great area of country in Nebraska, Kansas, Indian Territory, and Texas, which is not only destitute of coal, but which, has, further, a sparse supply of timber to answer as a substitute for such mineral fuel. This is especially the case in Kansas, and its effects upon the Missouri coal industry is important. West of this coal-barren area are the deposits of Dakota, Wyoming, Colorado, and New Mexico, which are to a certain extent competitors in the market and which may become more so in the future. It is not to be anticipated, however, that this competition with the coals of Missouri and adjacent states will reach very far east, for the latter coals are generally superior in quality to those farther west, which are largely lignitic, and the supply of superior coals in Colorado and New Mexico appears to be not more than is needed to satisfy the home needs and the more imperative demands for coal still farther west.

Thus the coal-barren area surrounding the Western

*In eastern Texas and Southeastern Arkansas are large areas underlain by lignites, or brown coals. These have been in the past, only of limited local use. Recent investigations, by the Geological Survey of Texas, have shown that these lignites are equal in character to those which are widely used in Europe. They will probably become merchantable in the future. That they will be extensively substituted for Bituminous coals in the most important uses of the latter, is, however, an expectation which does not seem at present warranted.

Bituminous Coal Fields may be looked upon as a most promising market for the future, especially that to the west where the population is destined to increase rapidly in the next few years, with a proportionate increase in coal consumption.

In addition to the foreign market however, there is in Missouri a good home market; one which is destined to increase greatly in the future and which will always be a steady consumer of coal and the most substantial supporter of the coal industry. The coal fields of Missouri are not located in a mountainous, rugged, or sterile country; on the contrary there are in a country of moderate elevation, with gentle undulating surface, where bluffs and steep declivities occur only along the largest streams; a country with a most fertile soil in a well advanced stage of cultivation. It is already well populated, a network of railways traverses it, small towns are numerous, and cities occur at short intervals. These conditions furnish consumers for the coal at the very mouth of the mine, they cause small operations to be numerous and to be profitably prosecuted, and they further permit the mining of coal for local uses under conditions which would not be profitable for the general market. In addition, these conditions furnish opportunities for obtaining labor, and inducements for retaining it, which are entirely absent in many coal mining regions.

The railways of the State constitute, without doubt, the largest class of consumers of coal. Hence the greatest single use to which coal is put is for the production of steam in locomotives; but, for manufacturing purposes, a large amount of coal is also used in steam production. Domestic consumption in stoves and furnaces ranks next in importance. For the production of illuminating gas a few coals of the State have been roughly experimented with, but not with generally satisfactory results, and very little of the coal product is used for this purpose. Thus coal from the vicinity of Moberly has been used there at the gas works, and, when well purified, the gas from it was excellent, but the cost of purifying it from sulphur was too great. The coal mined at the Hamilton Coal Co.'s shaft in Caldwell County has been tested for gas production and is reported to have yielded an abundance of gas, but it would not coke in the retorts, and, therefore, could not be profitably used. The coal mined at Trenton, in Grundy County, has also been tested with similar results. In Henry County are several coals which have been used for gas production, with reported favorable results. The thick coal bed south of Lewis station is such a coal, and also that from the Pitcher mine south of Clinton. These coals have been used, not only in the immediate vicinity of the mines, but have been shipped to remote points in the State for this special purpose. The coal mined at Minden, Barton County, also gives promise of being a gas producer, inasmuch as coal from the same bed mined at Cherokee and other points farther west in Kansas, is largely used for that purpose.

No coal in the State, to the writer's knowledge, is used for coke manufacture. Partial tests have been made of a few coals, but the results were not encouraging. The coal from the Excelsior Coal and Coke Company's shaft, at Higginsville, in Lafayette County, was thus experimented with. The product was of fair quality for domestic use, but was too weak and contained too much sulphur for furnace use.

Concerning the adaptabilities of Missouri coals we know, therefore, little even in a general way, and practically nothing in a detailed and authoritative way. As steam producers we know that they are extensively used, but what their relative evaporative powers are as compared with each other we can say nothing at present; and we are equally in the dark as to how they compare, in this respect, with the coals of other states with which they are brought into competition. We know that the same coal burnt in different furnaces will yield very different results, and *vice versa*, that the same furnace fired with different coals produces different amounts of steam; yet we are unable to say of the various Missouri coals in just what furnaces the best results may be attained with each. We know that some coals are better for steaming purposes, some for domestic purposes than are others; but which are the best domestic and which the best steaming coals of Missouri we cannot say. Gas coals and coke are imported into this State from Pennsylvania and are sold here at necessarily high prices. It is by no means improbable that there exist coals in the State which could be used more economically for the purposes for which these coals are imported. It is, therefore, in the interest of both the owners of coal lands and the producers of coal, as well as of the consumers, that the adaptabilities of the Missouri coals be first definitely established and then that the various coals be applied to those uses for which they are best suited.

Estimates have been made in publications of past years of the probable amount of coal in the State. Such estimates have been made by assuming an average thickness of coal for the whole area of the coal measures and then multiplying this thickness into such area. This method does not commend itself for further use, and, in general, we are of the opinion that the attempt to make such an estimate in the past was altogether premature and would still be so now. We are not in a position to make as much as an approximate estimate in this direction, even were we to leave out of the question entirely the considerations affecting the availability of the coal in the present and in the future. The data necessary for such an estimate are the number of coal beds, their respective thicknesses, the area underlain by each bed, and the depth of each beneath the surface. Some of the principal causes restricting the distribution and availability of Missouri coals have been described in the preceding chapter of this report. To properly make such an estimate it is necessary that we define the nature and extent of such limiting causes, and this can only be done by the most detailed local work.

The question of the distribution and of the amount of coal in the State, is one which the state as a whole, as well as the individual property owner cannot afford to neglect. Coal is, probably, of all others, the most substantial of a State's mineral possessions. Every industry is dependent upon it and it is the main spring of our Nineteenth Century civilization. In Great Britain, from the results of carefully executed geological surveys, estimates have been made by special commissions of the amount of coal in the United Kingdom, over one foot in thickness and situated within a depth of 4,000 ft. beneath the surface.

An acre of ground contains for each foot of coal underlying it about 1,700 tons. With two feet of coal the tonnage per acre is 3,400 tons. With the methods of mining pursued generally in the State, certainly not less than 2,500 tons of these 3,400 tons could be marketed. This would be 1,600,000 tons per square mile, and, thus, the product from a two-foot bed of coal, over an area of two square miles, would more than equal the present annual production for the whole State. Or, in other words, at the present rate of production, there is annually exhausted in the State an area of less than two square miles, and probably much less, inasmuch as the coal under a large part of the mining territory is three and four feet thick. The total area of the coal measures in the State, as already stated, is about 23,000 square miles. If only one-tenth of this area be underlain by available coal two feet thick, the supply will be sufficient to furnish coal at the present rate of production for over a thousand years. It is allowable to assume that a much larger area of available coal exists but, on the other hand, the rate of production is constantly increasing and will doubtless continue to do so for many years to come. Hence estimates of duration of supply can never be anything more than approximate and provisional. With the present indefiniteness as to the amount of coal present, even an approximate estimate cannot be presented. What is above given is offered merely as a suggestion.

The total value of the coal in the State must remain indeterminable until the question of the amount of the coal is settled. With a coal bed two feet thick the value of the 2,500 tons of available coal per acre, at $1.30 per ton, is $3,250. The value of the product of a square mile of such coal is $2,080,000. If we allow a profit of ten cents per ton, the net value of the coal from an acre of such land is $250, and for forty acres of such land it is $10,000. The value of the coal contents of such land, based upon the present market prices of the same substance, is thus many times what the land is valued at for farming purposes. Coal, however, is a possession which is not convertible until excavated and transported to market, and, until this is done, it represents just so much capital lying idle in the ground. Moreover, the coal of any one track cannot be opened upon, excavated and thus converted into ready money in a short time; but the work will proceed slowly and the returns will come in gradually from year to year. Thus, if a man own a property of forty acres, of which, according to our calculation, the net value of the coal is $10,000, and if he does not receive any of this $10,000 until the expiration of fifteen years, then the present value of his land is a sum, which at compound interest at current rates, will amount to $10,000 in fifteen years; this at six per cent. interest will be about $4,160, or about $100 per acre. The exact time when a man may receive the full net value of the coal contents of his land depends upon many indefinite factors, such as the growth of facilities of transportation, the demand for the product, etc. It is thus impossible to give any one value per acre which will apply to all coal lands, even though their coal contents and the conditions under which it occurs be similar. Considering the conditions affecting the coal market already described, and, considering further, the undoubted prospect of a great growth of coal consumption in this and adjoining states, it would seem, however, a well assured fact that any and every large body of coal land may be made a profitable producer of coal during the course of a few years. Coal rights covering many square miles of land in the State have been purchased at the rate of a few dollars per acre, the amount seldom exceeding $5. In the case of a single large property, only a portion may be operated at any one time, but a moderate production from this portion, on a very small margin of profit per ton, will yield many times 6 per cent. on the amount of the original cost, not only of the area actually worked, but of a large surrounding area also. Thus, the original cost of the coal rights over ten square miles, at $5 per acre, is $32,000. If the bed be only two feet thick, and if the coal underlying only 40 acres be removed per year, and sold at a profit of ten cents per ton, the income would be $10,000, as above calculated, or about 30 per cent. of the total original investment. On the basis of these figures it is plain that the results of a few years work, and the exhaustion of a very small fraction of the entire track, will suffice to return to the investor the total amount of the first cost of the coal land. The net receipts after this will continue to be large and will be clear profit.

Thus, the coal lands of Missouri would seem to be promising fields for investment, even at rates much higher than have been so far maintained. The statistics of shipments show that the tendency is towards large operations by companies controlling thousands of acres of lands. Pursued on this large scale mining can be prosecuted undoubtedly much more economically and larger markets can be reached. The coal can also be sold on a smaller margin of profit, which is a benefit to the consumer. The small operator is sometimes, if not generally, the sufferer through such conditions; and, further, the small land-owner is often, through lack of local competition, induced to part with his land, or its mining rights, to the adjacent large owner and operator at extremely low figures. Once the value of these coal lands well established and their extent defined, however, wide interest will be excited and strong organizations will be led into keener competition for the possession of these lands than has heretofore been the case, we may, therefore, look forward, in the march of events, to a large increase in the coal industry of the State, to profitable returns to those who invest their money sagaciously in coal lands and in the support of the dependent industry, and to an enhancement of the value of such lands now largely held and used purely for agricultural ends by private citizens of the State.

WHY DIP IS MORE LIKELY TO BE REGULAR THAN STRIKE WITH FISSURE VEINS.

BY ALBERT WILLIAMS, JR., M. E.

Faults may throw a vein out of plane as to either dip or strike, or both; perhaps more frequently the former. But, barring the effects of faulting, experience has shown that most fissure veins are tolerably uniform in their downward trend, while more or less wavy in their horizontal course, and that the dip often remains constant even where the average strike may be distorted by large scallopings. Reference here is not to the outcrop, which may be apparently twisted from the real course by the manner in which the topographical contours cut the plane of the veins, but to the flexures shown underground, where no such cause misleads observation. The splitting of veins into offshoots and the irregularities where two parts of a vein widen apart to inclose a horse, also occur in such ways as to affect both dip and strike, or either; but again the effect is more commonly to deflect the strike than the dip. While there are few positive laws thus far established regarding ore deposits (about the safest deduction of all being that what we do not know about them far exceeds what we do), the characteristics just referred to seem to be sufficiently frequent to have some significance; and though this frequency may not be enough to lead to anything that could be fairly called a law, yet even if it is established in a preponderance of cases only—and this at least may be conceded—it has a direct bearing upon the choice of plan to be adopted in mining where not much is known in advance as to the character of the ground to be opened. Probabilities are certainly better than nothing to work upon.

If, then, it is really true that the dip of fissure veins is likely to be more reliable in point of uniformity than their strike, the question naturally comes up, Why should this be so?

The most satisfactory answer seems to be that a large proportion of the veins are on the lines of *fault* fissures. This is pointed to by the occurrence of smooth walls, slickensides and clay selvages, which perhaps might also be accounted for by assuming small movements of the ground up and down during a long time, where the throw is not large enough to be dignified by the name of fault, but when these marks are very pronounced and there is found besides in the vein crushed rock indicating violent disturbance, the testimony becomes stronger, and when, as sometimes (though rarely) happens, the amount of throw can be measured and disjointed rock formations actually matched, then the evidence becomes conclusive. As to such veins as most probably were filled by hot ascending solutions, on the solfataric theory, there are parallel examples in the case of existing thermal springs (whether metalliferous or not), for these are often found in lines along the tops of evident fault fissures. Now, faulting means a movement more in an up-and-down direction than in any other. This being so, it is easy to understand why, when a rupture of rock masses has taken place, one being heaved up or the other slid down, or both walls moving in opposite ways or in the same direction, but with different degrees of motion, the fracture along the line in which the force was applied should have been more or less straight, while in other directions the result might have been a warped surface, since there the line of least resistance would be determined rather by the character of the ground than by the direction of effort, that is, where the impulse was most intense the break would be a clean one, whereas sidewise it might be irregular. Indeed, if it is conceivable that, in faulting, the up-and-down surfaces might have split off in waves, the continuance or renewal of the movement would cause the walls to act upon each other like huge planing machines, or rather like two slabs which the stone-dresser is surfacing, thus grinding off the inequalities with irresistible power and leaving the wall faces smooth and slickensided, with broken rock in the vein and clay gouges along the edges, just as in fact they are seen in the distinctly typical fissure veins.—*From the Engineering and Mining Journal.*

The Lidgerwood Manufacturing Company have issued from their New York headquarters, 96 Liberty Street, a forty page pamphlet, the third of their Sketch Book series, bearing the title "Open Pit Mining." It is profusely illustrated with dainty pen and ink sketches and full of valuable and interesting facts regarding the application of the company's celebrated Locke-Miller and Harris-Miller suspension cableways to open pit mining, quarrying and construction work.

Several views are shown of the Tilly Foster Iron Mines, Tilly Foster, N. Y., the concentrating works at Edison's Ogden Ore Mills, Ogden, N. J., and the Dunnellon Phosphate Company's mines, Dunnellon, Fla., with the suspension cableways erected by the Lidgerwood Manufacturing Company at these well known localities, also views of cableways used for building the Sodom Dam, at Brewsters, N. Y., and the Austin Dam, Austin, Tex. The last named cableway is the largest ever erected, having a span of 1350 feet. The book contains as well some very strong testimonials which will be read with interest by engineers and contractors. "Open Pit Mining" is intended for gratuitous distribution.

The Lidgerwood Manufacturing Company now own or control over a dozen patents on cableways, notably those of T. S. Miller, M. W. Locke, N. C. Harris, and C. M. North.

Correspondence

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

The Editor is not responsible for views expressed in this Department.

☞ *Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.*

Speed of Fans.

Editor Colliery Engineer:

SIR:—I submit the following in reply to "C. A.," of Broadford, Pa., who asks the following question in the April issue:

"The barometer reads 29·5°, where a fan is making 40 revolutions per minute, if the barometer suddenly drop to 28·5° will the fan travel faster or otherwise, the power remaining the same?" As the pressure varies directly as the density, and as the density is decreased by the sudden drop in the barometer the fan will travel faster, that is in the proportion as 28·5° : 29·5° :: 40 : x, or 41·4 revolutions per minute at a reading of 28·5°.

Yours, etc.,
T. K.

Mt. Olive, Ill., April 12th.

Ventilation.

Editor Colliery Engineer:

SIR:—I notice in your April issue that in his answer to Question No. 2, asked by "Alberto," of Wall, All'y Co., Pa., "T. K." makes a mistake regarding the water-gauge 2,000′ farther in the mine. If the water-gauge registered 0·5 at entrance, the distance being 4,000′ in and 4,000′ return = 8,000′, then the water-gauge 2,000′ farther in, and 2,000′ back again, making an additional 4,000′ would be found by proportion.

Thus:

8 : 4 :: 0·5 : x, or 0·25 = the pressure 2,000′ farther in the mine.

In finding the pressure at any distance, everything else being equal, the rule is, if the length is doubled the pressure is also doubled, and one-half the length requires one-half the pressure.

Yours, etc.,
J. N.

Trotter Mine, Pa., April 11th.

Mensuration.

Editor Colliery Engineer:

SIR:—I submit the following in answer to "L. P. H.," of Avoca, Pa., in the April issue: As the kettle was to hold 7 gallons less than a score, the contents would equal 13 gallons. In 13 gallons there are 282 × 13 = 3,666 cubic inches. Then as the diameters are as 5 is to 3, we can solve as follows:

$$(5^2 + 3^2) + (5 + 3) \times \frac{12}{3} = 196, \text{ and}$$

$$196 \times {\cdot}7854 = 153{\cdot}9384.$$

By proportion we find the required diameters thus,—

$$153{\cdot}9384 : 3666 :: 5^2 : 595{\cdot}30801733,$$

Then

$$\sqrt{595{\cdot}30801733} = 24{\cdot}4002 \text{ inches, the greater diameter.}$$

Also

$$5 : 3 :: 24{\cdot}4002 : x, \text{ or } 14{\cdot}6401 \text{ inches, the smaller diameter.}$$

I would have worked it out in full, but did not want to use too much of your space.

Yours, etc.,
BRYCHAN.

Nanticoke, Pa., April 20th.

Mensuration.

Editor Colliery Engineer:

SIR:—Please insert the following question for answer in your Correspondence Department:

On the Fourth of July a pole was erected,
Composed of six pieces and nicely connected.
Two feet and six inches it measured around
On the place where it stood on the top of the ground.
The form was a cone in surface complete;
The height of the same was twice sixty feet.
What length of inch riband procured at the shop
Will wind round the pole from bottom to top,
And have it lay smooth and plain to be seen
By leaving a space of five inches between.

Yours, etc.,
BRYCHAN.

Nanticoke, Pa., April 20th.

Trigonometry.

Editor Colliery Engineer:

SIR:—In the December, 1891, issue of THE COLLIERY ENGINEER "R. L. T.," of Reynoldsville, Pa., asks a question which I do not think has been answered as yet, therefore I offer the following solution:

Will some of your readers kindly explain how the decimal is found for any number of degrees such as 35°? Is it by multiplying by the sine of one degree? ·017452 × 35° is not correct.

Being under the impression that "R. L. T." is situated like myself, and has to plod along the best he can, I venture to submit the following formula as I understand it in Davis' Legendre:

The sine of one degree is found thus: As there are 180° in a semi-circle, and the radius being 1, we have

3·141592+ ÷ 180 = ·017453+, the sine of the first degree, then

·017453+ × 2 = ·03489+, sine of the second degree carried out to five decimal places.

Now by Davis' rule we find the sine of the third degree thus:

·01745 : ·03489 — ·01745 :: ·03489 + ·01745 : sine of third degree.

We will illustrate this by the following example:

Sine 1° : sine 2° — sine 1° :: sine 2° + sine 1° : x, or substituting their values

·01745 : ·01744 :: ·03489 : x, or ·03486,

then,

·03486 + ·01745 = ·05231, sine of the third degree. The slight difference is caused by not carrying out the decimals further.

Yours, etc.,
BRYCHAN.

Nanticoke, Pa., April 20th.

Speed of Fans.

Editor Colliery Engineer:

SIR:—Please publish the following in reply to question by "C. A.," of Broadford, Pa., in your April issue: The barometer reads 29·5° where a fan is making 40 revolutions per minute, if the barometer suddenly falls to 28·5° would the fan travel faster (owing to diminished density) or otherwise, the power remaining the same? 28·5 : 29·5 :: 40 : x, or 41·4.

Yours, etc.,
T. K.

Belleville, Ill., May 5th.

Mensuration.

Editor Colliery Engineer:

SIR:—Please insert the following in answer to the "Kettle Problem" in your last issue: The kettle is to contain 13 gallons × 282 cubic inches = 3666 cubic inches. The depth is 12 inches and the diameters are in the ratio of 5 to 3, then the areas for the different ends will be in proportion to the ratios squared. The square of 5 is 25 and of 3 is 9 making a total of 34 parts, 9 for small and 25 for large end. Now if we divide 3666 by 12 we have 305·5 area for one end which multiplied by 2 and divided by 34 gives one part. We now multiply this by 9 which gives area of small end then

305·5 × 2 = 611 ÷ 34 = 17·970588 × 9 = 161·735292. Then subtracting 161·735292 from 611, we have 449·264708 area for large end. These areas divided by ·7854 = the squares of their diameters, the square roots of which will be the required diameters. Therefore

161·735292 ÷ ·7854 = $\sqrt{205{\cdot}93}$ diameter squared, the square root of which = 14·35 + and

449·264708 ÷ ·7854 = $\sqrt{572{\cdot}0202}$ the square root of which = 23·9169, now if we divide 14·35 by 3 and multiply by 5 we have 23·9165, being only $\frac{4}{10000}$ over the mark.

Now to prove from the areas that the kettle holds the quantity let us multiply each end by one-half the depth and 161·735292 × 6 = 970·411752 and 449·264708 × 6 = 2695·588248 = 3666 cubic inches ÷ 282 = 13 gallons.

Yours, etc.,
G. S. FORSYTHE.

Delaney, Cambria County, Pa., May 9th.

Mensuration.

Editor Colliery Engineer:

SIR:—In Nesbit's Mensuration there is a question similar to "L. P. H.'s" kettle question which appeared in your April issue. It is not worked out but the answers given for the diameters are 24·400163 inches and 14·640098 inches respectively. In working it out, however, I make the diameters 20·760 inches and 12·456 inches. What causes the difference? I cannot imagine unless it is in the value of the score. I compute a score to equal 20. By the rule my diameters give the whole quantity of inches in 13 gallons counting 282 cu. inches to the gallon.

The rule to find the contents of a frustum of a sphere, which is similar to the "Tinker's Kettle," is "To the sum of the squares of the radii of the two ends, add one-third of the square of the height, and this sum being multiplied by the height and the product again by 1·5708 will give the contents." In this instance we will let 10 x equal the large diameter and 6 x the small. The radius equals one-half the diameter, then the formula is.

$$(5\,x)^2 + (3\,x)^2 + \frac{12^2}{3} \times 12 \times 1{\cdot}5708 = 282 \times 13, \text{ collecting}$$

$$(34\,x^2 + 48)\ 18{\cdot}8496 = 3666 \text{ cu. ins.}$$

Therefore, x = 2·0760, which multiplied by 10 and 6 gives the large and small diameters respectively.

Yours, etc.,
W. J.

Dunlo, Cambria Co., Pa., May 2d.

Mensuration.

Editor Colliery Engineer:

SIR:—I send the following solution to question by "L. P. H.," of Avoca, Pa., in the April issue:

The rule for finding the contents of a conical frustum is as follows where the two end diameters are D and d and the height is H and C = contents:

$$C = \frac{D^3 - d^3}{D - d} \times {\cdot}7854 \times \frac{H}{3}$$

In the example we have $d = \frac{3}{5}$ of D; H = 12 and C = 3666 cubic inches and we have to find D.

Reducing we get $\frac{D^3 - d^3}{D - d} = \frac{3666}{3{\cdot}1416} = 1167$ nearly.

Calling D = x we get

$$\frac{x^3 - \left(\frac{3}{5}\ x\right)^3}{x - \frac{3}{5}\,x} = 1167\ ;\ \frac{490\,x^3}{250\,x} = 1167\ \therefore\ 1{\cdot}96\,x^2 = 1167.$$

Hence $x^2 = 595{\cdot}4$ and $x = \sqrt{595{\cdot}4} = 24{\cdot}4$ inches the larger diameter of which $\frac{3}{5} = 14{\cdot}64$.

Yours, etc.,
W. H. BOOTH.

Willesden Junction,
London, N. W. England, May 3d.

Ventilation.

Editor Colliery Engineer:

SIR:—As "X. Y.," of Nanaimo, B. C., does not understand my solution of "R. R. S.'s" question in September issue, I will try to oblige him by further explanation and show him where I get my formula. It is not always necessary to go to an author for one. It must be evident to any one who understands anything about friction of air in mines that the water-gauge (1·85 inches) or 9·62 pounds pressure is the frictional resistance due to the passage of the current, not for the first section of the air-way alone, but all four combined and that each contributes its part of pressure; and the relative amount due to each section will be as its rubbing surface divided by its area cubed. Now I will try and show you as plainly as I can where I get my formula. By using the equation $k\ s\ q^2 = p\ a^3$; and as we want to find p we must divide $p\ a^3$ by a^3, to get p or what is the same divide $k\ s\ q^2$ by a^3, because $k\ s\ q^2 = p\ a^3$, but in the question k and q are the same in each of the sections of the air-way those factors cancel each other so we can leave them out, and we then have

$$\frac{k\ s\ q^2}{a^3} = \frac{p\ a^3}{a^3} = \text{the relative pressure.}$$

The next formula I used was made from the same equation as above where it is found if air-ways passing the same or equal quantities with the same pressure their rubbing surfaces will vary as the cubes of their areas as can be seen thus, $k\ s\ q^2 = p\ a^3$, because after canceling we have s on the one side and a^3 on the other, hence s varies as a^3.

"X. Y." says he has tried Fairley's formula where a road of various dimensions can be reduced to a typical air-way that will offer the same resistance to the passage of the current and cannot find anything like the same pressure, viz., 16 lbs., I think he has evidently made a mistake in the working of the question as may be seen by applying Fairley's formula, which is

$$\frac{a'^3}{o'} \times \frac{s}{a^3} = l' \text{ for the typical airway.}$$

A′ and o' representing the area and perimeter of the assumed or typical air-way respectively.

Let us assume such an air-way 4 × 5 whose area will = 20 sq. ft. and its perimeter 18 feet,

Then

$$\frac{20'^3}{18'} = 444{\cdot}44$$

1st air-way, or section,

Lengths.

$$\frac{s}{a^3} = \frac{28000}{48^3} \times 444{\cdot}44 = 112{\cdot}53$$

2d air-way, or section,

$$\frac{s^3}{a} = \frac{27500}{31\frac{1}{2}^3} \times 444{\cdot}44 = 392{\cdot}44$$

3d air-way, or section,

$$\frac{s}{a^3} = \frac{30000}{35^3} \times 444{\cdot}44 = 373{\cdot}15$$

4th air-way, or section,

$$\frac{s}{a^3} = \frac{34000}{24^3} \times 444{\cdot}44 = 1085{\cdot}54$$

Total length of typical air-way = 1963·66 ft.

Then,

$$\frac{k\ s\ v^2}{a} = p = \frac{\overset{k}{{\cdot}0217} \times \overset{l}{1963{\cdot}66} \times \overset{o}{18} \times \overset{v}{648{\cdot}1^2}}{20}$$

= 16·1 lbs. pressure.

So we see that by Fairley's formula we obtain the same pressure as I found it to be before, and if "X. Y." will apply this formula to the quantity, which I gave as the answer, viz., 9·998 cubic feet, he will find it will work back to the given pressure nearly (9·62) and I think that either of the formulæ I used is easier than Fairley's, and not so difficult to understand.

Yours, etc.,
T. S. C.

Gardner, Ill., May 17th.

A Problem in the Development of Coal Lands.

Editor Colliery Engineer :

SIR:—In answer to "H. J.," of Charleston, W. Va., in the April issue, I would say that to answer his problem in detail would require considerable space. I will endeavor, however, to answer his questions so that he can draw a conclusion as to which field of coal would be the cheapest to develop.

We will first consider the coal above water level and note some of the advantages and disadvantages. As I am not informed as to the rise of the ground I would say for the benefit of "H. J." that the cost per yard for putting in a drift and timbering the same, would be $6.00 per yard without taking into consideration the cost of timbering. The opening to be 6½ feet high, 6 feet wide on top and 8 feet wide on bottom. This cost will be on the mine until the coal will be fit for market; probably twenty yards. We will say twenty yards for our calculation. Then we have:

20 × $6.00	$ 120.00
Cost of grading	1,500.00
600 ties at 10 cents each	60.00
15 tons steel rails at $30	450.00
Labor for laying the same	60.00
Splice bars, spikes, and bolts about	15.00
Rollers and brackets about	40.00
Total,	2,245.00

I haven't given the cost of rope as I don't know what size would be used, but a rope ¾ inches diameter would be the proper size for the above calculations. I will not make an estimate of the friction drum and connections, but will suppose the cost to equal the head gearing, etc., of the shaft. Steel rails to be 20 lbs. to the yard and incline to have three rails all the way except the pass-bye, which will require four rails. The ties should be long enough to reach under all the rails as they hold the road in better shape than if they were short, besides the saving of timber. If you have no timber on the tract of land the ties will cost more than 10 cents each. In a drift mine there is no trouble to get the water out of the mine, whereas in a shaft or slope mine it will be necessary to use pumps. The coal could be handled on the incline with two day hands less than with the shaft.

We will now make an estimate of the shaft work. As the shaft will be 60′ to the coal it will require 70′ to be sunk in order to give sump room. The average cost of sinking a shaft 10′ × 14′ including tools, timber, blasting material, carpenter and blacksmith work, etc., is $120 per foot, then

$$70' \times \$120 = \$8,400.$$

As there will be 100,000 gals. of water to be lifted per day it will be necessary to calculate size of pump required to perform the work, and as it will require a pump to perform the work in ⅓ of a day to allow time for packing, repairs, etc., we will calculate the size of pump to lift water in 8 hours: 8 × 60 = 480 min.

Then by using imperial gallons we have

$$100{,}000 \div 480 = 208\tfrac{1}{3} \text{ gals. per min.}$$

$$\frac{208\frac{1}{3}}{2\frac{1}{2} \times 20 \times {\cdot}034} = 11 + \text{ inches } = \text{ diameter of water end.}$$

In one imperial gallon there are 277·274 inches; length of stroke 2½ ft.; number of strokes per min., 20. Again using the U. S. standard gallon we have

$$208 \times 231 = \frac{48048}{20 \text{ (No. of strokes)}} = \frac{2402{\cdot}4}{30 \text{(length of stroke)}} = 80{\cdot}08.$$

$$\sqrt{\frac{80{\cdot}08}{{\cdot}7854}} = 10 + \text{ inches } = \text{ water end of pump.}$$

A pump of that size would cost from $1200 to $2000, or on an average of $1600, you will then need pipes and fittings, boilers, engines to hoist coal, boiler house, engine house, etc., which would not be required for the drift mine.

In case of a stoppage for want of a market for coal, or from strikes, etc., the drift mine would cost merely nothing but the shaft would require a fireman, pumper, and machinist, or engineer, besides the boiler coal used to pump the water out besides the cost of packing, lubricants, etc. A slope mine could be driven for less than the sinking of the shaft, but the coal could not be handled any faster and all other labor would be on a par with the shaft work. If a slope was put in it should be on an angle of 15° or 20°. To make it any steeper will require a carriage to convey the cars to the surface. The cost per yard for driving a slope would be about $18 for labor and standing the timber. I haven't the time to give the question the consideration it should have or I would answer more fully and perhaps some of your able correspondents will have answered the same question. If any of your correspondents wish to criticise or correct this answer, I hope they will do it in a gentlemanly way.

By discussing all such questions in the proper way in your valuable journal, we can get all, or nearly all, the good there is in a question and may get the ideas of some of our brightest correspondents, thereby making the Correspondence Department more interesting and learning some good lessons ourselves.

Yours, etc.,

PEACE.

Dunbar, Pa., April 20th.

P. S.—Would say for the benefit of "H. J." that if he adopts the drift mine and lays an incline road to the same that he may take a few hints from the following:

A good rate of speed on an incline is 8 miles per hour or 704 ft. per min. At this rate it will require 2 min. 7 sec. to make the trip, or three minutes to make the trip and give ample time to hitch and unhitch the cars. The work should be laid out so that it could be done in 8 hours.

$$\frac{600 \text{ tons}}{8 \text{ hours}} = 75 \text{ tons per hour. } \frac{75 \text{ tons}}{60 \text{ min.}} = 1\tfrac{1}{4} \text{ tons per min.}$$

1¼ tons × 3 min. = 3¾ tons per trip. The reason I took 8 hours for the time was to give allowance for breakage or accidents.

P.

Mensuration.

Editor Colliery Engineer :

SIR:—Please insert the following in answer to question by "L. P. H.," of Avoca, Pa., in the April issue: The diameters of the flat-bottomed kettle being in the proportion as 5 is to 3, make it in shape the frustum of a cone. There being 282 cubic inches in an ale gallon, the cubic contents of the kettle would be as follows:

$$282 \times 13 = 3666 \text{ cubic inches,}$$

and

$$\frac{3666}{12} = 305{\cdot}5,$$

then

$$\sqrt{\frac{305{\cdot}5}{{\cdot}7854}} = 19{\cdot}72$$

the mean diameter. Adding the top and bottom diameters; also the given proportions, we obtain the following:

$$\frac{19{\cdot}72 + 19{\cdot}72}{5 + 3} = 4{\cdot}93$$

and

$$4{\cdot}93 \times 3 = 14{\cdot}79 \text{ top diameter,}$$

also,

$$4{\cdot}93 \times 5 = 24{\cdot}65 \text{ bottom diameter.}$$

The following is a proof that the diameters are as 5 is to 3,

$$5 : 3 :: 24{\cdot}65 : 14{\cdot}79$$
$$3 : 5 :: 14{\cdot}79 : 24{\cdot}65$$

Yours, etc.,

TRACKMAN.

Mt. Pleasant, Pa., May 25th.

Specific Gravity of Gases.

Editor Colliery Engineer :

SIR:—In the May issue of THE COLLIERY ENGINEER I notice several replys to question asked by "Miner", of Uniontown, Pa., none of them agreeing. I will therefore offer the following solution to his question. He wants a rule whereby the specific gravity of any gas may be found. In the first place the specific gravity of any gas is its weight as compared volume for volume with dry air, air being taken as 1 or unity. And it requires 13·06 cubic feet of dry air to weigh one pound, then as the weight of any gas compared volume for volume with 13·06 will be the specific gravity of the gas. To illustrate the above more fully we will take the following gas for solution:

Hydrogen requires 188·53 cu. ft. per 1 pound, then 13·06 ÷ 188·53 = ·0692 specific gravity of hydrogen.

Carbon requires 15·75 cu. ft. per 1 lb., therefore the specific gravity of carbon is 13·06 ÷ 15·75 = ·8292.

Carbonic oxide requires 13·50 cu. ft. per 1 lb., therefore carbonic oxide is 13·06 ÷ 13·50 = ·9673.

Carbonic acid requires 8·59 cu. ft. per 1 lb., therefore the specific gravity is 13·06 ÷ 8·59 = 1·52.

Methane requires 26·61 cu. ft. per 1 lb., therefore the specific gravity is 13·06 ÷ 26·61 = ·559.

Yours, etc.,

T. K.

Mt. Olive, Ill., May 23d.

The Siphon.

Editor Colliery Engineer :

SIR:—In your April issue "S. U. P." asks a number of questions regarding siphons, among which is "How can a siphon be prevented from cutting off?" In reply would say, if the pipe is 2″ thick, remove a length from the discharge end and replace it with 1½″ pipe, the siphon will then run as long as there is water to supply it.

Yours, etc.,

WM. KELLER.

Irvona, Pa., May 28th.

Ventilation.

Editor Colliery Engineer :

SIR:—I notice that "N. S.," of Dagus Mines, Pa., in answering question by "A. B.," of Hanna City, Ill., gives the perimeter as 21·7′. I calculate it to be 18·3758′ and 5·817′ diameter by his rule for working the question. T. S. Cummings, of Gardner, Ill., also, objects to "N. S.'s method of finding diameter, but says he is glad that it can be worked several ways. Now, I am not satisfied with any of the answers given so far, and would like "W.," of Hornsby, Ill., to work his calculations out more in detail so that they could be better understood.

Yours, etc.,

SAGER.

Pine Knot, Whitley Co., Ky., May 28th.

"Watercracks" in Steel.

Editor Colliery Engineer :

SIR:—Please insert the following in answer to question by "Burleigh," of Nanaimo, B.C., in the May issue:

When the drills are ready to be tempered they should be dipped blood-red hot in the following mixture: 2 ounces of charcoal, 2 ounces of bone-dust, and one pint of machinery oil *thoroughly* mixed. Then made blood red hot again and tempered in the usual manner. The water used should not be too cold, as this is often a cause of "watercracks."

Yours, etc.,

JAMES T. JENKINS.

Plymouth, Pa., June 3d.

Something About Graphite.

We occasionally hear of some one complaining of graphite or graphite productions. Now and then such a person, without further investigation, will write to some mechanical paper condemning its use in places where, *if the graphite is pure and properly prepared*, it should be of the greatest benefit.

The nature of graphite, sometimes called plumbago or black-lead, is not generally understood. Eminent writers on friction have declared that it is the best natural lubricant known, and scientific and mechanical papers have advocated its use for many purposes. Incompetent, if not unscrupulous parties, have attempted to meet the demand by putting on the market graphite productions that are totally unfit for the uses specified.

Graphite is one of the forms of carbon. It is not affected by heat or cold, or any known chemical. As it comes from the mine, however, it contains from 50 to 80 per cent. of silica, sulphur, and other impurities, and the process of completely freeing the graphite from impurities requires very expensive machinery and the most skillful manipulation. Only manufacturers having such facilities can hope to produce an absolutely pure article. The impurities in much of the graphite now in the market take on the appearance of graphite by contact, and such impurities are sometimes undetected even by the expert, unless chemical tests are employed. This is especially true of amorphous graphite, commonly called black-lead, which is graphite without any particular form, and usually mixed with clay.

Pure graphite, and even black lead, is useful in many ways as will be shown by a perusal of the catalogue of the Jos. Dixon Crucible Co., of Jersey City, N. J.

To be useful in the highest degree, the graphite should be carefully selected with a view to the use intended. Graphite suitable for lead pencils is not the most suitable for lubricating, although it has lubricating qualities. Again graphite suitable for stove polish would not answer for crucibles, although it might be equally pure and stand the heat equally well. It varies greatly in its construction and usefulness, and the best results are only brought about through experience, knowledge and proper mechanical facilities.

The Jos. Dixon Co. are miners as well as importers of graphite in all its forms, and they do not use any graphite that they do not either mine or prepare. They not only have every facility in the way of machinery and chemists, but also the records and experience gained in sixty-five years in the business. They therefore know and guarantee the purity of their productions, and buyers of the Dixon products can feel assured not only of the purity of the graphite used, but also that the *proper* graphite has been used.

We have received from the Lidgerwood Manufacturing Company, of 96 Liberty Street, New York, a copy of "Open Pit Mining," which is a beautiful pamphlet of forty pages, illustrating by engravings from pen and ink sketches the use of Lidgerwood Improved Suspension Cableways in open pit mines. Among other sketches are a number illustrating the method of handling the ore at the Tilly Foster Mine, in New York, and the method of handling phosphate at phosphate mines in the South.

As an example of the possibilities of their method of handling material, the cableway in use at Austin, Texas, for the construction of the famous Austin dam, is shown. This is the largest hoisting and conveying cableway ever built. It has a clear span of 1350 feet; the main cable is 2½ inches in diameter, and the load carried is seven tons.

Among the other interesting illustrations are several showing the Lidgerwood cableways in use at Thomas A. Edison's famous Ogden Ore Mill, at Ogden, N. J.

The success that the Lidgerwood Company has met with in their business is entirely due to the superior quality and convenience of their machinery, and is attested by the fact that during the year 1890 they sold 1105 engines and 588 boilers.

"A Practical Consideration of Compressed Air," by William L. Saunders, C. E., of 10 Park Place, New York, is one of the most interesting and valuable treatises on the subject we have yet read. Mr. Saunders has given the subject of compressed air as a means of transmitting power, years of study, and has had a vast amount of practical experience in the matter. His work is therefore one that contains in a condensed form many valuable hints regarding the means necessary to obtain the greatest efficiency from compressed air, and he corrects some popular errors on the subject. The work is reprinted from the *Journal of the Franklin Institute* for May, and contains several illustrations that make clear the ideas expressed. It was originally delivered as a lecture before the Institute in December, 1891, and is now published in pamphlet shape, so as to be within the reach of all persons interested.

We have received a copy of the *Monthly Record*, Vol. 1, No. 5, published by the Edison General Electric Co., at the Edison Building, New York City. It is a very pretty 8-page journal printed on fine calendered paper, and is illustrated by half-tone engravings of superior merit. While naturally intended as an advertisement of the Edison General Electric Co., it contains a great deal of useful and interesting matter regarding the transmission of power by electricity. It is well edited, and is just such a production as would be expected from such an enterprising and progressive corporation as the Edison Co.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since Our Last Issue.

Elkhorn Mountain Gold Mining Co.,	Portland, Oregon.
The Kootenay Lake Reduction Co.,	New Haven, Conn.
Katahin Mining Company,	Spokane, Wash.
The American Flag Mining and Tunnel Company,	Fremont, Colo.
Columbian Mining and Milling Co.,	Reading, Vermont.
McAntire and McKee Mining Co.,	Joplin, Mo.
Jack Mining Co.,	Carterville, Mo.
McKinney Coal and Coke Co.,	Marietta, Ohio.
McKinley Iron Co.,	Duluth, Minn.
The North Dakota Coal and Power Co.,	Mandan, N. D.
The Miller Mining and Tunneling Co.,	Aspen, Colorado.
The Fortunatus Gold and Silver Mining Co.,	Denver, Colo.
The Colorado Enterprise Leasing and Mining Co.,	Denver, Colo.
The Captain Inca Mining Co.,	Pueblo, Colo.
The Cut Diamond Mining and Milling Co.,	Colorado Springs, Colo.
The Creede Camp Mining Stock Exchange Co.,	Amethyst, Colo.
The Home Run Mining Co.	Del Norte, Colo.
The Mountain Chief Gold Mining and Milling Co.,	Fremont, Colo.
The White Star Mining Co.,	Buffalo, Wyo.
The Refugio Mining Co.,	Chicago, Ill.
Gold Brick Mining Co.,	Portland, Oregon.
The Rochester Cosolidated Mining and Milling Co.,	Ouray, Colo.
The White Elephant Gold Mining Co.,	Fremont, Colo.
The Shenandoah Mining and Milling Co.,	Denver, Colo.
The Star of the East Mining Co.	Fremont, Colo.
The Colorado Oil and Gas Co.,	Denver, Colo.
The Copper Rock Gold Mint Mining Co.,	Denver, Colo.
The Rock Island Gold Mining and Milling Co.,	Colorado Springs, Colo.
The Juniata Mining and Milling Co.,	Denver, Colo.
The Burton Gold and Silver Mining Co.,	Denver, Colo.
The Grand View Mining, Milling and Developing Co.,	Del Norte, Colo.
The Rhyolite Mining and Milling Co.,	Denver, Colo.
The Garfield Coal Mining Co.,	Denver, Colo.
The Relief Mining and Milling Co.,	Fort Collins, Colo.
The Gold Link Mining and Milling Co.,	Denver, Colo.
The Tecumseh Mining and Milling Co.,	Denver, Colo.
Rocky Ridge Coal Co.	New Whatcom, Wash.
The Silver Queen Mining Co.,	Kettle Falls, Wash.
Merrit Nickel Mining Co.	Duluth, Minn.
Stiles Gold Quartz Mining Co.,	San Francisco, Cal.
The Guadalupe Mining and Milling Co.,	Chicago, Ill.
Middlesex Marble Co.,	Portland, Maine.
Tennessee Oil, Gas and Mineral Co.,	New York City, N. Y.
Bon Accord Placers, Limited,	Cavendish, Montana.
Portable Improvement Co.,	Camden, N. J.
Sussex Slate Co.	Newton, N. J.
The Mackinly Mining Co.,	Jersey City, N. J.
The Diamond Portland Cement Co.,	Middlebranch, Ohio.
The Evangeline Gold Mining and Milling Co.,	Chicago, Ill.
The Bonner Oil and Gas Co.,	Hartford City, W. Va.
Pride of the Mountain Mining Co.	Everett, Wash.
Chicago Improvement Co.,	Chicago, Ill.
United States Asphaltum and Development Co.,	East St. Louis, Ill.
The Tower Lode Mining Co.,	Kingham, Kas.
The Englevale Coal Mining and Development Co.,	Englevale, Kansas.
Whitaker Phosphate Co.,	Kansas City, Kas.
Cymbia Coal Co.,	Philadelphia, Pa.
The Pacific Gold and Silver Extraction Co.,	Los Angeles, Cal.
The Black Bear Mining Co.,	Telluride, Colo.
The Anchorian-Leland Mining and Milling Co.,	Colorado Springs, Colo.
The Equity Mining, Milling and Development Co.,	Denver, Colo.
The Mineral Development Co.,	Denver, Colo.
The June Mining and Milling Co.,	Denver, Colo.
The American Girl Mining Co.,	Denver, Colo.
The Woody and Silver Creek Mining and Milling Co.,	Aspen, Colo.
The Amethyst Mining Co.,	Denver, Colo.
The Mica Monarch Mining Co.,	Denver, Colo.
The Empress of Aspen Mining Co.,	Manitou, Colo.
The Needles Reduction Co.,	Denver, Colo.
The Crystal Mining and Milling Co.,	Fremont, Colo.
Rochester Medina Stone Co.,	Albion, N. Y.
Elko Mining, Milling, and Manufacturing Co.,	Randolph, N. Y.
Mechanical Gold Extractor Co.,	Jersey City, N. J.
The Evangeline Gold Mining Co.,	Jersey City, N. J.
The North Star Iron Co.,	Baltimore, Md.
Elk Ridge Coal and Coke Co.,	Elkhorn, W. Va.
Oswego Lead and Zinc Co.,	Chicago, Ill.
Empire Granite Co.,	Barre, Vt.
Eureka Mica Mining Co.,	Nashua, N. H.
The Boulder Creek Mining Co.,	Boulder Creek, Idaho.
The A. O. Jones Brick and Terra Cotta Co.,	Zanesville, Ohio.
South Fork Mining and Milling Co.,	Kalispell, Mont.
Mill Side Mining Co.,	Butte, Mont.
The Lee Gold Mining Co.,	New Brunswick, N. J.
Union Jack Mining Co.,	Spokane, Wash.
Isabella Mining Co.,	St. Louis, Mo.
Daisy Hill Mining Co.,	San Francisco, Cal.
Blue Ridge Coal Co.,	Scranton, Pa.
The McLaughlin Oil Co.,	Allegheny, Pa.
The Elizaville Natural Gas Co.,	Lebanon, Ind.
Tenta Duras Mining and Milling Co.,	Cherokee, Iowa.
Jewell Metallic Paint Co.,	San Francisco, Cal.
The Chicago and Creede Consolidated Mining and Milling Co.,	Creede, Colo.
The Free Coinage Mining and Milling Co.,	Denver, Colo.
The Princess Gold Mining Co.,	Colorado Springs, Colo.
The Colorado and Mexico Exploration and Development Co.	Denver, Colo.
The Miller Mining and Tunneling Co.,	Aspen, Colo.
The Oolitic Stone and Lime Co.,	Romona, Ind.
The Goodman Mine.	San Francisco, Cal.
The Des Moines Gold Mining Co.,	Colorado Springs, Colo.
The Riall-Collins Tunnel Co.,	Jimtown, Colo.
The Little Don Mining and Tunnel Co.,	Fremont, Colo.
Boulder Electric Power Co.,	Creighton, Neb.
American Verde Antique Marble Co.,	Milwaukee, Wis.
Bland Mining and Tunnel Co.,	Philipsburg, Mont.
Allegheny Iron Mining and Milling Co.,	Duluth, Minn.
The Steubenville Oil and Gas Co.,	Steubenville, Ohio.
The Falcon Gold Mining and Milling Co.,	Salida, Colo.
The T. E. T. Mining and Milling Co.,	Colorado Springs, Colo.
The Copper Rock Gold Mining Co.,	Denver, Colo.
The Lucky Tunnel Mining Co.	Pueblo, Colo.
International Mining Co.,	Spokane, Wash.
The Inter-State Development Co.,	Cheyenne, Wyo.
The Cheyenne Mining Co.,	Cheyenne, Wyo.
Citizens' Natural Gas Co., of Greencastle, Indiana,	Greencastle, Ind.
Yellow Run Coal Co.,	Greensburg, Pa.
Columbia Mining Co.,	Danville, Ill.
Inter-Republic Gold and Silver Mining and Milling Co.,	Las Cruces, N. M.
The Bi-Metallic Smelting Co.,	Leadville, Colo.
The Ophir Bell Mining Co.,	Aspen, Colo.
[illegible]olfax Mining and Prospecting Co.,	Denver, Colo.
The Mammoth Mountain Mining Co.,	Denver, Colo.
Mammoth Mountain Deep Mining and Tunnel Co.,	Denver, Colo.
The Bachelor Hill Mining Co.	Pueblo, Colo.
The Golden Rule Mining Co.	Denver, Colo.
The Fre: Gold Hill Consolidated Mining and Milling Co.,	Denver, Colo.
The Carson Mining Co.,	Denver, Colo.
The Iron Clad Mining and Milling Co.	Denver, Colo.
The Kootenai Placer Mining Co.,	Waneta, British Columbia.
The Seven Mile Mining and Milling Co.,	Fort Collins, Colo.
The Leghorn Mining and Manufacturing Co.,	Reading, Pa.,
Brookside Coal Co.,	Wilkes-Barre, Pa.
The Sunflower Coal and Mining Co.,	Kansas City, Kas.
Ferguson Splint Coal Co.	Ferguson, W. Va.
Berkeley Sand Co.,	Berkeley Springs, W. Va.
Out-Crop Iron Mining Co.,	St. Paul, Minn.
Trojan Mining Co.,	Tacoma, Wash.
Po-Keg E-Ma Iron and Mining Co.,	Chicago, Ill.
Menlo Gold Mining Co.,	Grass Valley, Cal.
Continental Marble Co.,	Manchester, Vt.
Capitan Mining Company of Colorado,	Jersey City, N. J.
The Golden Eagle Mining and Milling Co.,	Colorado Springs, Colo.
The Mountain Chief Mining and Milling Co.,	Denver, Colo.
The Mammon Gold Mining Co.,	Colorado Springs, Colo.
The Sweet Mining and Milling Co.,	Pueblo, Colo.
The Toronto and Montreal Mining and Milling Co.,	Denver, Colo.
The Jack Pot Mining Co.	Colorado Springs, Colo.
The Nugget Mining and Milling Co.,	Colorado Springs, Colo.
The Requa Gold and Silver Mining and Milling Co.,	Canon City, Colo.
The Decatur Mines Syndicate, Limited, London, England.	London, Eng.
The Cambria Mining Co.,	Denver, Colo.
The Stanhope Mining Co.,	Denver, Colo.
The Victor Smuggler Gold Mining Co.,	Pueblo, Colo.
The Pueblo Bell Mining and Milling Co.,	Pueblo, Colo.
The Currency Mining Co.,	Denver, Colo.
The Phil Sheridan Mining and Milling Co.,	Pueblo, Colo.
The Free Coinage Gold Mining Co.,	Colorado Springs, Colo.
The Alhambra Mining Co.,	Pueblo, Colo.
The Anequa Placer and Lode Mining Co.,	Fremont, Colo.
The Barbara-Gibson Mining and Milling Co.,	Denver, Colo.
The Windsor Mining Co.,	Denver, Colo.
The San Luis Coal and Coke Co.,	Denver, Colo.
The Gold Dust Mining and Milling Co.,	Denver, Colo.
The Monument Treasure Mining and Milling Co.,	Colorado Springs, Colo.
The Orphan Girl Consolidated Mining and Milling Co.,	Denver, Colo.
Ravenswood Oil and Gas Co.,	Ravenswood, W. Va.
American Exploring Co.,	San Francisco, Cal.
Martha Washington Placer Mining Co.	Oakland, Cal.
The Pacific Mining Co.,	Duluth, Minn.
The Kirkpatrick, Howk & Massey Stone Co.,	Joliet, Ill.
Corinth Store and Improvement Co., of W. Va.,	Baltimore, Md.
Empress Josephine Mining Co.,	New York City, N. Y.
Reed Mines Consolidated Co.,	San Francisco, Cal.
Western Star Gold and Silver Mining Co.,	San Francisco, Cal.
Osborn Gold Mill and Mining Co.	San Francisco, Cal.
Helena & Butte Co.,	Helena, Mont.
The Catherine Noble Mining Co.,	Minneapolis, Minn.
The Collett Gas and Oil Co.,	Collett, Ind.
Standard Coal and Timber Co.,	Philadelphia, Pa.
Battelle Oil Co.,	Morgantown, W. Va.
Aetna Mining Co.,	New York City, N. Y.
Diamond Developing Co.,	Cheyenne, Wyo.
Lander Coal Mining Co.,	Lander, Wyo.
Carbonate Chief Mining Co.,	Great Falls, Mont.
The Gold Geyser Mining Co.,	Cripple Creek, El Paso Co., Colo.
The Bachelor Mountain Mining and Milling Co.,	Denver, Colo.
The Mammoth Mining and Smelting Co.,	Pueblo, Colo.
The Mason Gold Mining Co.,	Colorado Springs, Colo.
The Rocky Mountain Mining and Development Co.,	Pueblo, Colo.
The Ophir Gold Mining and Milling Co.,	Denver, Colo.
Black Butte Consolidated Quicksilver Mining Co.,	Portland, Ore.
Golden King Mining Co.,	San Francisco, Cal.
The Mountain Bank Coal Co.,	New Whatcom, Wash.
The Bogie Man Mining Co.,	Kansas City, Kas.
The Curtisville Natural Gas, Oil, Light, Heat and Power Co.,	Curtisville, Ind.
The Josephine Mining Co.,	Spokane, Wash.
The Diamond R. Mining Co.,	Pueblo, Colo.
The Cripple Creek Brokerage and Investment Co.,	Cripple Creek, Colo.
The World Mining and Milling Co.,	Fremont, Colo.
The Old Dominion Mining Co.,	Richmond, Va.
The Solitaire Mining Co.,	Aspen, Colo.
The Holden Smelting and Refining Co.,	Denver, Colo.
The Colo. Cripple Creek Gold Mining Co.,	Denver, Colo.
The Lillie Gold Mining and Milling Co.,	Denver, Colo.
The Sheba Queen Mining Co.,	Denver, Colo.
The Salida Mining and Developing Co.,	Salida, Colo.
The Southern Red and Brown Stone Co.,	Sanford, N. C.
The Ten Mile Mining Co.,	Paterson, N. J.
Juneau Mining and Manufacturing Co.,	Eauclaire, Wis.
The White Cloud Copper Mining Co.,	New York City, N. Y.
Wolfe Butte Consolidated Mining Co.,	Great Falls, Mont.
The Boise County Mining Co., Limited,	Idaho City, Idaho.
Custer Mining Co., Limited,	Wallace, Idaho.
The B. V. Gold Mining Co.,	Colorado Springs, Colo.
Crystal Mills Co.,	Chester, Mass.
Rock Island Gold Mining Co.,	Rock Island, Ill.
The Graham Oil Co.,	Franklin Mills, Pa.
Enterprise Mining and Milling Ass'n.,	Riverside, Cal.
Mount George Mining Co.,	Grass Valley, Cal.
Farwell Stone Co.,	San Francisco, Cal.
The Pajaro Mining Co.	Sacramento, Cal.
The California Mining Co.,	Cripple Creek, Colo.
Cardinal Mining and Milling Co.	Denver, Colo.
The White Cross Mining and Milling Co.,	Portland, Maine.

Endless Rope Haulage Operated by Electricity.

The Leavenworth Coal Co., at Leavenworth, Kansas, is arranging to drive the endless rope haulage machinery at the foot of the shaft by electric motors. There are two separate lines of rope, one on each side of the shaft, and the length of each is about 3500 ft. Each line will be operated by a 40 H. P. Sperry electric motor. The power is at present applied to the work by a transmission rope from the surface. As the shaft is 710 feet deep and very wet, and the ropes are exposed to the influence of frost in the winter, their average life is only about eight months, while in the mine where the ropes are dry, the haulage ropes last from 3 to 4 years. By the use of the electric motors, the heavy expense of frequent renewals of the transmission ropes is overcome.

A Popular Coal Drill.

The McNelley Coal Drill, a cut of which is shown herewith, is deservedly very popular on account of its many points of excellence.

McNELLEY COAL DRILL WITH SIDE GEAR ATTACHED.

The machine complete, consists of the post, as shown in the cut, with boxing to carry the screw and auger, a steel screw for driving the auger, three steel augers, two, four, and six feet long, and side-gear for imparting the motion. The posts are made of extra strong pipe, made especially for this machine, and are made so as to telescope together, which feature is secured by letters patent. This enables the operator to lengthen or shorten the machine easily and more quickly than any post machine made; it being held at any desirable height by set-screws. The connecting parts of the posts are all made of malleable iron, strong and durable. The boxing is longer than any other used, giving it more strength, and saving wear over any other. It rests upon a slide bridge, which can be raised or lowered in the post at will. This is a valuable feature in this machine, as when the bottom is soft the post is liable to settle, and thus cause the auger to bind in the hole, often necessitating a resetting of the post. A post machine is liable to settle. In this machine all this trouble is overcome, as with the jack-screw it can at once be tightened, and the sliding bridge adjusted so as to relieve the auger from any friction, however slight. No other machine has this feature, which is also secured by letters patent.

The driving screw is made of the best steel, and also the augers which are fitted and sharpened ready for use.

This machine is adapted to all kinds of mine work, and for lifting bottom, or taking down roof, it is absolutely the best machine made, as it can be worked at any angle desired, and is so easily and quickly adjusted. For close work it is unequalled; and, the side gear can put a hole within two inches of the rib. The gear can be used on either side, or on top, or directly under the driving screw, and can be changed from one position to another instantaneously. This valuable feature is not embraced in any other machine made, and is also secured by letters patent.

The great advantages of this machine are: It will drill high or low, at any desired angle or elevation, and closer to the rib than any other, and can be more quickly and easily adjusted; is lighter and more easily moved from place to place, and can be operated by a boy as well as a man; it will do quicker and better work than any other machine made, and where in use is pronounced perfect.

It is made regularly in three lengths, as follows:

No. 0 for seams ranging from 3 ft. to 5 ft. in thickness.

No. 1 for seams ranging from 3 ft. 8 in. to 7 ft. in thickness.

No. 2 for seams ranging from 4 ft. 4 in. to 8 ft. in thickness.

Different lengths will be made on application, without delay.

The general agents for these drills are Messrs. Puchta, Pund, & Co. (Queen City Supply Co.), of Nos. 161 to 165 West Pearl St., Cincinnati, Ohio, who will be pleased to send catalogues and circulars to all inquirers.

Western Pennsylvania Mining Institute.

The next meeting of the Western Pennsylvania Mining Institute, which will be held at the Court House, in Pittsburgh, on the 28th and 29th inst., promises to be a very interesting one. The following is the programme of special papers arranged for this meeting: "The Longwall that would be Applicable to the Pittsburgh Seam," by Inspector James Blick; "Mining," by Daniel Boden, Supt. Mansfield Coal and Coke Company; "The advantages of a Slope over a Shaft for Mining Coal," by Inspector Wm. Duncan; and "The General System of Longwall," by W. S. Gresley.

The subjects for debate are as follows:

(1) Should a Miner have a Theoretical Knowledge of Mine Gases? (2) What Relative Advantages or Disadvantages has the Exhaust Fan over the Blower Fan for Ventilating Purposes? (3) In the Absence of a Physician, what Remedy is the Best to Apply for the Relief of a Miner (*a*) Burnt by an Explosion of Gas; (*b*) Rendered Insensible by Inhaling Fire-damp; (*c*) Overcome by Inhaling Black-Damp? (4) What kind of Timber is Best for Timbering the Entrance of a Mine; also What kind is Best for Propping Working places, the Cost to be Considered? (5) Does the Present Mine Law Need Revising?

This programme is one that promises to be very interesting and instructive, and should induce a large attendance of the members and others interested in coal mining.

UTILIZATION OF ELECTRICALLY TRANSMITTED POWER AT THE WORLD'S FAIR.

The potentialities of electricity become wider and more numerous as the days pass, and seems like a horizon continually receding before the advancing student and inventor. Each new day a new development is made manifest, and the public now omits its expressions of astonishment at the perusal of the wonderful evolutions of the only recently appreciated force. The electric light was received first with incredulity and surprise, while now, even an advance of 100 per cent. would call forth nothing more than a faint expression of approval, as if what had been done was only what had been expected.

Electricity, as a power, utilizable for almost every purpose to which steam has been applied, is of a later date. It sprang into favor as soon as the possibility of its economical transmission was proved. The problem has been economically and successfully solved. Manufacturers mindful of greater profits, derivable from a reduction in the expenditure for power, are adopting the ever ready motor to the exclusion of the steam engine. The long lines of shafting with the inseparable evils of copious lubrication and costly friction, heavy and expensive belting in complex systems and large and small pulleys innumerable are slowly being discarded. One of the largest engine and mining machine manufactories in this country has recently been equipped with motors, the claims of which to greater economy, reliability, and perfect safety being fully conceded; and the greatest electrical manufactory in the world, that of the Edison General Electric Company at Schenectady, employing over 5,000 men, and covering with its fifty-three buildings an area of nearly twelve acres in extent, is entirely operated by electricity generated in, and transmitted from a central power house in which are the only boilers and steam engines in the entire works.

The immense advantages which the use of electrical power offers, the freedom from dirt, oil, smells, and the many shortcomings incidental to steam power, of which loss in transmission is perhaps greatest, appeal strongly to the public, and the consequent increase in the demand on Central Stations throughout the country, for electrical power, is causing them to strengthen their facilities in order to cope with the constantly increasing load.

The engineers of the Construction Department of the World's Fair have recognized the many benefits to be derived from the use of electricity and from the first decided upon employing it to run the machinery used in the work of construction, as being the only perfect agent to perform the work as expeditiously as the shortness of the time at their dispo-al demanded. They have installed in the Fair Grounds a perfect electrical power transmission plant—one in which the conditions are of a peculiar nature on account of the long distances separating the apparatus, and the fact that this machinery is being constantly shifted from place to place as it is required. The lines had therefore, to be erected to satisfy any call for power from any particular spot in the grounds.

The buildings of the Fair, which are to be wonders of the World for the time being, are built of wood covered with stuff which will give to them the appearance of imposing marble edifices. The frame-work of the buildings is of iron. The major part of the machinery, therefore, consists of saw-mills to cut the lumber, and hoists for raising into their lofty positions the immense girders, trusses, and ponderous beams. In addition there are moulding machines, planing machines, and pulverizers for the clay. The presence of the electric motors for operating the saw mills ensures the absence of fire, from the danger of which the employment of steam-engines is no guarantee.

The entire plant consists of the generators, the line and the motors, together, with the various accessory appliances needed for the successful and economical operation of the electrical apparatus. The current of 500 volts is generated from two 100 K. W. compound wound Edison Generators, of the Edison street railway type, belted direct to two high speed engines. The duplication of the generating apparatus was decided upon in order that the machines should be continually supplied with power, and the chances of a total breakdown, obviated, one generator being capable of supplying the entire demand for a short time in case the other should be disabled. The "temporary" station in which the dynamos and engines are located, are so substantially constructed that the term is almost a misnomer. The same may be said of the pole line carrying the wires and making a complete circuit of that portion of the grounds in which the motors are located. It is of first-class construction, and of the best material. The high standard of insulation of the wires is always maintained, each circuit being subjected to rigid daily inspection and tests.

In the Manufacture and Liberal Arts Building—the largest structure in the Exposition, which covers an area of thirty acres, one of the saw-mill plants is erected. This consists of a saw sharpener, band and cut-off saws, a rip saw, and a boring machine. This compact outfit is run by a 12 K. W. Edison shunt wound machine belted to a line shaft. In the United States Government Building is another saw-mill plant run by a 15 Kilowatt Edison motor. There is still another in the Mines and Mining Building, and one in the Horticultural Building. In this last named building is an electric hoist operated by a 20 K. W. Edison motor fastened to the same frame as the base of the hoist. The hoist is of the double-drum form with two winch heads and can be used to raise two separate weights at once, while at the same time the winch heads can be used to drag material into position. It is now used to raise the immense trusses and purlins of the dome of this building, and has proved eminently satisfactory. In the Transportation Building a huge derrick has been erected for raising the trusses into position. It can be rolled to any requisite point and has a 20 Kilowatt Edison Motor erected in its base frame. In this building as well as in the Agricultural Building, are other electrically operated saw-mill plants.

The Exposition Building, facing towards the lagoon, and ornamented on the exterior with Corinthian pilasters 42 feet high, has another saw mill plant. This building has been especially arranged with a view to electrical illumination at night, which in effect will be unequalled.

Here, too, is the large clay pulverizer, belted to a 12 K. W. Edison Motor, which drives it at a speed of 1,200 revolutions a minute. In the Machinery Hall, the Illinois St te Building, the Fisheries Building, and Woman's Building are other mills and planers.

Each motor is operated by means of an ordinary starting switch and rheostat, and main line switches in series with each motor. Protection is afforded by suitable fusible cut-outs, and the motors are also sheltered from dust, dirt, rain, and accident as far as possible. These machines are let to the contractors by the Exposition Managers, the charge for their use being based upon the average daily maximum load, gauged by suitable measuring instruments. As promised by the Engineers, the result of the adoption of electricity has proved entirely satisfactory, and the advocates of the portable steam engine and boiler have been compelled to acknowledge defeat. The motors have responded to every call made upon them even to the extent of sustaining a heavy overload for a short time.

The entire plant is leased from the Edison Company and is to be returned in the same good condition as received on the 1st of January, 1893.

This transmission plant is a most important one, although only temporary, on account of its magnitude, the long distances separating the various plants, and the fact that the line is easy of access from any point within the grounds. The motors are scattered over an area a mile north and south by half a mile wide. The absolute freedom from accident or failure of any kind which the plant has enjoyed, proves that this means of power transmission is as reliable as, if not more so, than any known method.

OBITUARY.

Theodore S. Mize.

Theodore S. Mize, the genial, whole-souled and talented Eastern representative of *The Black Diamond* is dead, at the early age of thirty-eight. He was a man of most amiable disposition, and had the peculiar faculty of winning the friendship and esteem of every person thrown in contact with him.

He was an able writer, and one of the best informed men regarding the current status of the coal trade in the country. His integrity and good judgment commanded the respect of every coal man with whom he was thrown in contact, and all were ready to give him their confidences because they knew he was worthy of them and never abused the trust placed in him. In his writings he occasionally, of necessity, touched on technical matters, and when this was the case, he wrote not as a careless novice, but as one who studied the conditions, and sought information from those who were versed in the technicalities. The result was that his writings on trade topics, a subject he was most familiar with, were never spoiled by ridiculous technical errors.

There was hardly an operator or coal dealer of prominence in the East who did not know him and appreciate his pleasant disposition and noble character. Words fail to portray the sorrow caused by his early death, and the sympathy we feel toward the editorial force of our contemporary, which has lost a faithful coworker and a friend endeared by the possession of a character composed of all the attributes that go to make a gentleman.

PERSONALS

Mr. James Clayton, of the Clayton Air Compressor Works, New York, was among the passengers on the Cunard Steamer "Aurania," which sailed May 28th for Liverpool. Mr. Clayton will spend a well-earned vacation of about three months traveling through England and France, and while in the former country will for a time be the guest of his brother, Mr. Thomas G. Clayton, the superintendent of the Midland Railway. Before his departure, Mr. Clayton was presented with a handsome gold watch by his employes.

The Langcliffe Colliery, located at Avoca, Pa., was recently sold to Messrs. Brooks and Mears, of Scranton. The new organization will be known as The Langcliffe Coal Company and officers have been elected as follows: President, Reese G. Brooks; Treasurer, John A. Mears; Secretary, T. R. Brooks.

Mr. John Sweeney, of Treskow, Pa., has been made foreman of the Lehigh and Wilkes-Barre Coal Co.'s large stripping at that place.

Mr. Wm. L. Saunders, Secretary of the Ingersoll-Sergeant Drill Co., of New York, is certainly a versatile personage. He is a civil engineer, and one that ranks very high in his profession. He is the author of several valuable pamphlets on air compression and the use of compressed air, and also on quarrying, shaft sinking, and tunneling. He personally manages the extensive business of the Ingersoll-Sergeant Co., and also personally designs and compiles the elaborate and beautiful catalogues issued by that company. His most recent venture is in the field of politics, as he has recently been elected Mayor of North Plainfield, N. J., his place of residence. His energy and sound business judgement are such that it is safe to say that Mayor Saunders' administration will be both an economical and a progressive one.

Mr. Wm. Young, father of Major James Young, Superintendent of the Pennsylvania Coal Company's collieries in the Lackawanna Valley, died at his residence in Dunmore, Pa., on the night of the 20th ult., aged 70 years. Mr. Young was a native of Scotland, from which country he emigrated in 1843. With his wife and first-born child, James, he settled in Carbondale, where he resided until 1851, when he located in Dunmore, where he continuously resided up to the time of his death. Up till within a few months of his death he was employed about the collieries in various capacities, but for most of his life as a skilled miner. He was offered official positions several times, but always declined them, preferring to work as a miner, rather than to take charge of men. The cause of his death was due to a general breaking down which began with a severe attack of "Grippe" two years ago. He is survived by his wife, now 70 years old, and thirteen children, of whom Supt. Young is the eldest. Mr. Young was a man, who, through all his long life in one locality, always retained the respect of his neighbors, owing to his integrity, and many good qualities as a man.

Mr. H. C. Zacharias, late superintendent of the collieries of the Silver Brook Coal Co., at Silver Brook, Pa., has been appointed General Manager of the Peerless Coal & Coke Co., whose coal lands are at Vivian, McDowell Co., West Va. Mr. Zacharias is now at work opening out the colliery, and with his engineering skill, backed by a broad gauged management, he will soon have one of the most extensive and well arranged mines in the Pocahontas field.

Mr. Monroe Schreffler, division superintendent of the Philadelphia & Reading Coal & Iron Co.'s collieries between Big Mine Run and Treverton, Pa., has had the division formerly under the supervision of Mr. John L. Williams added to his old one. This change makes Mr. Schreffler's division include all the collieries operated by the P. & R. C. & I. Co., between the Mahanoy Tunnel and Treverton. In point of production and number of collieries, his new district is the largest in the world under the superintendency of one official.

Mr. Frank A. Hill, superintendent of the Dunbar Furnace Co.'s plant at Dunbar, Pa., has been promoted to the position of President and General Manager of the company. Mr. Hill has made a record in the Connellsville region by his business ability and professional skill, exercised under the most trying conditions, that marks him as one of the ablest men in the business, and the Dunbar Furnace Co. attests its appreciation of his services by this promotion. We sincerely wish him a continuance of his past success without a repetition of the troubles he went through as superintendent.

Mr. R. M. Haseltine, Chief Inspector of Mines of Ohio, has assumed the responsibility of making Ohio's mineral exhibit at the Chicago Exposition. Mr. Haseltine held the matter under advisement for some time, and formally accepted the undertaking last month. He is now considering the plan of exhibit and the amount of space required. The great variety of the mineral wealth of Ohio and the desire to give each product a creditable showing is quite an undertaking. He should have the hearty co-operation of all engaged in the production of minerals in the State, and he will be greatly assisted in the work if they will correspond with him in regard to the size and character of the samples they desire to furnish.

Mr. W. J. Watkins, well known in the Schuylkill coal field, where he was for several years employed as inside foreman of Suffolk Colliery, near Mahanoy City, and who made a record for bravery and good judgment as Lieutenant of the Coal and Iron Police force during the Mollie Maguire troubles some years ago is now located at New Whatcom, Wash., as superintendent of the Blue Canyon Coal Mining Co. During the past three years he has traveled from southern Oregon to Herendeen Bay, on the Behring Sea, examining and reporting on coal properties for the Oregon Improvement Co. On the first of September of last year he accepted his present position. He has purchased a fine farm of 170 acres at New Whatcom, which he has well stocked, and on which he has three large barns and a very comfortable residence.

Mr. Jonah A. Davis, fire-boss in the Boston Mine of the D. & H. Coal Co., near Edwardsville, Pa., was instantly killed on the 2d ult. by a trip of cars running over him. Mr. Davis had been a prominent resident of Edwardsville for twenty years, and was highly respected for his upright character and close attention to his duties.

Mr. George Johns, of the firm of Geo. H. Myers & Co., after 12 years active service as superintendent of the Yorktown Collieries, at Audenreid, Pa., has retired to enjoy a rest well earned, after many years of active service in both the Schuylkill and Lehigh regions. Mr. Johns ranked as one of the ablest colliery managers in the Anthracite field, and under his superintendency the Yorktown Collieries have been made one of the best paying investments in the Lehigh region. Col. D. P. Brown, superintendent of the Lehigh Valley Coal Co.'s Collieries in the Mahanoy and Shenandoah Valleys of the Schuylkill region, succeded Mr. Johns on the first inst. Under the intelligent and progressive management of Col. Brown, who is a man of long and successful experience, the record of the Yorktown Collieries will not fall from the high position to which Mr. Johns had raised it.

Mr. J. A. Haskell, President of the Mahoning Railway, and General Manager of the Adrian Coal Co.'s Helvetia Mines, in Jefferson County, Pa., will on July 1st become Vice-President of the Hercules Powder Co., of Wilmington, Del., and will remove to that city.

Hon. John W. Parker, of Mahanoy City, Pa., at one time a very prominent labor leader, died at his residence in Mahanoy City last month. Mr. Parker was a man of superior intelligence, and was the founder and editor of the *Anthracite Monitor*, a one-time prominent labor paper published, at Tamaqua, Pa., and later was the founder and editor of the *Tri-Weekly Record*, a profitable and influential journal now published by his son. Mr. Parker's first literary work was done while working at his trade as a blacksmith at a colliery near Tamaqua, and his productions were signed "The Buckville Blacksmith," a sobriquet by which he was widely known, until he became more prominent as a labor leader, when his conservative counsel, strict integrity, and wisdom of speech and writings, won for him the title of "Honest John Parker."

Mr. Parker was a labor leader but not a demagogue. When his counsel was followed the workingmen always profited, and when at times the policy he advocated was thrown aside for that of demagogues, disastrous results were always the outcome.

He was not a professional politician, but was honored in politics by being elected to the Pennsylvania Senate, from the Twenty-ninth Senatorial District in 1878, on the Greenback-Labor ticket. The district was strongly Democratic, and his opponent, Hon. W. L. Torbert, was a very popular man. He served but one term, and never sought office afterwards, but was appointed by Governor Beaver a trustee of the State Hospital for Injured Persons at Ashland, Pa.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED 1881. INCORPORATED 1890.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER,
RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
ALEX. DICK, MINING ENGINEER, ASSISTANT EDITOR.
THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

***Remit** by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.*

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed

THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Scranton, Pa.

Cable Address—"Retsof. Scranton."

Vol. XII. June, 1892. No. 11.

For Table of Contents see page vii.

NOTICE.

The editorial rooms and business offices of The Colliery Engineer Company, have been removed from the fourth floor of the Coal Exchange Building to Rooms 14, 15, 16, 17 and 18 on the third floor of the same building, with the entrance at Room 17. The School of Mines will occupy, in addition to its old quarters, the rooms formerly occupied by the editorial and business rooms, and the instructors can be found there.

THE NECESSITY FOR TECHNICAL EDUCATION.

NEVER in the history of American mining, was the necessity for technical education on the part of all persons connected with the industry more apparent than at the present time. The extraction of a limited portion of the mineral in the ground at a heavy expense, and with great liability to accident will not be tolerated in these days of enlightenment and progress. While the development of the mining industry of the United States has advanced with most prodigious strides during the past few years, the methods of development and working have naturally also advanced to a higher and more successful plane. This advancement will continue. Every day new difficulties and obstacles present themselves to the mine [illegible]l and working miner. They must be overcome, [illegible]here is but one way to overcome them. That way is by the application of intelligence and skill.

Competition has been a strong incentive to this raising of the standard of intelligence on the part of mining officials and miners; and as this competition, not only between different districts producing the same mineral, but between different mines in the same district, increases, there will be greater necessity for increased technical ability.

That region, which, by reason of natural advantages possessed by it, or the superior skill of the men employed therein, can produce a mineral at the least expense is naturally the one that prospers most. The first of these advantages cannot be regulated by man, but the second and equally important one depends upon the personal exertions of each man employed, to store up in his mind the principles regulating the forces of Nature, which, when intelligently directed, are most potent for good, and which when ignorantly dealt with frequently cause disaster.

Even where the advantages bestowed by nature are greatest, brains are necessary for success, and many regions with less natural advantages, but with intelligent and skilled labor working under intelligent supervision, are more prosperous than those possessing great natural advantages and less skilled labor.

Employers as a rule have learned by experience that by the employment of skilled labor, the production is increased and there is infinitely less danger to life and property, than when ignorant labor is employed. Several of the State legislatures have also recognized this fact, and have wisely passed laws compelling mine officials to prove, by strict examinations, that they possess sufficient technical ability to superintend and direct the work of miners in a safe manner. Similar laws will eventually be enacted by other States, and it is safe to predict that within ten years, there will not be a State in the Union, in which mining is a prominent industry, that will not require mining officials to show their ability by qualifying before a board of examiners.

Therefore it is evident that the mining official who desires to advance must keep up with the times, by systematically studying the principles involved in the art of mining that he may be able to apply his knowledge in such a way as to produce better results than his neighbor. If he will do this, advancement is sure and speedy. If he does not do it, he is sure to retrograde, and by ignorance of certain principles in an emergency, he may be directly responsible for great loss of property and possibly of life.

Ambition to rise above the position in which he is placed by force of circumstances is inherent in the American miner, and it is commendable. Family ties and affections are just as strong among American workmen as among any other class of men, and they naturally desire a higher position in life for their children than they themselves hold, and they should be ready to grasp any means by which this ascension in wealth and the social scale can be secured. Education is the most potent lever to effect this rise, and systematic study is the only proper way to secure the necessary education.

There is also a moral obligation resting on both mine officials and miners to secure a technical education. It is their moral duty to not only protect their own lives, but the lives of their fellow workmen as well. This they cannot do, if they do not study the principles regulating the mighty forces of Nature, so as to direct them aright, and make them assistants rather than cruel and death-dealing masters.

The miner or mine official who neglects his opportunities to study these principles is untrue to himself, for he not only toils more than is necessary, but he is a constant menace to his own life and that of his fellow-workmen, because his ignorance may be the primal cause of a disastrous accident.

WHAT IS THEORY?

THERE is no word in the English language more abused than "theory." It is a word that is as a rule used in an entirely wrong sense. The majority of men believe it to mean something entirely opposite to *practice*, when in reality it is closely allied to it. There never was a practical man who was not a theorist. If he did not understand the theories involved in his business, he could not put them in practice.

The meaning usually given to the word *theory* properly belongs to *hypothesis*. A theory is an exposition, or explanation, of the general principles of a science, and not an improved supposition advanced merely for argument as an hypothesis is. The introduction of organization among the facts or data of a science is theory. Thus, the practical and well proven facts and data observed by different men at different times, in the production of certain results, when collected and organized, form the theories that explain what forces produced those results, and how much each force was exerted. Thus, we know that the pressure required to produce a certain current of air in a mine depends upon the resistance due to friction and also upon the sectional area of the air course. We know also from experiment that the resistance due to friction is so much per square foot of rubbing surface, and this amount is known as a fixed quantity or co-efficient. We also know that the friction increases with the square of the velocity, which is a fact that has been proved by both calculation and experiments. Now, having these facts firmly established, we combine or organize them and find that the pressure required to produce a certain current is equal to the product of the co-efficient multiplied by the number of square feet of rubbing surface, and the square of the velocity of the air current, divided by the number of square feet in the sectional area of the air course. This is theory. Establishing the current by producing the required pressure is practice. Or, it is a theory that a box four feet long, by four feet wide and four feet high, contains sixty-four cubic feet. If a carpenter who is told to construct a square box to contain sixty-four cubic feet does not know and understand this theory he cannot build the box, and is therefore not a practical man. The miner or mine foreman who is told to produce a certain amount of ventilation in a mine, to do it quickly, successfully and economically, must understand the theory of ventilation. If he doesn't he can't fulfill his duties, and he is not a practical man.

HOW A WORKINGMAN CAN EDUCATE HIMSELF.

THERE are three ways by which a workingman can educate and fit himself for advancement. The first is by purchasing text-books and studying them at home; the second is by attending a night school; and the third and best way is by taking a course in a good school in which tuition is by correspondence, and each student studies when and where he pleases, and recites his lessons when learned, by writing out the answers and mailing them to the instructors at the headquarters of the school.

The first method is one that rarely proves successful though some very eminent men secured their educations in this way. In the first place the choice of text-books is a difficult one. Some excel in one branch, some in another, and a few, owing to the authors giving hypotheses for theories are worthless. In the second place the cost of all the text-books necessary to pursue the study of any science is necessarily high. The author of each, assuming that the student has been educated to a certain standard, begins with formulæ and statements that are Greek to the uneducated man. Before he can understand the books specially designed to teach the principles of a science, he must have at least a good common school education. Few workingmen are fortunate enough to possess this advantage, and the result is that if they desire to study a science they must start with elementary school books and gradually work their way up. In doing this, unless they are carefully directed and advised by competent persons, they lose a great deal of valuable time studying branches or parts of the school books that have no relation to the subject they desire to master; and, by misconstruing the language of a single rule or principle they find themselves hopelessly entangled in a mass of formulæ, and they give up, completely discouraged. Their time and money having been spent in a great measure, for nothing. As we stated before, some few men have educated themselves in this way, but they were exceptions to the general rule. Few men have the natural talents that Hugh Miller and Henry Wilson possessed, and few men can hope to educate themselves as they did.

The plan of securing an education by attending night school, while possessing many excellent features, is not free from disadvantages that make it almost impracticable. In the first place, it is difficult to establish a night school, and when it is established it is impossible to secure a teacher, who combines practical knowledge with ability as a teacher, for the limited compensation, offered. In many cases the teacher, from lack of experience in the sciences taught, confuses hypothesis with theory, and thus lays a faulty foundation for future study. It must also be borne in mind that while the workingmen are in point of education, children, they are not children when natural responsibilities are concerned. They must labor to support themselves and families, and in the natural course of their labor, they must at times neglect the school, owing to other engagements, or they find that when night comes they are too tired to supplement the day's muscular toil with several hours of mental labor. The result is that the classes in the night school are composed of men, some of whom, being naturally bright and with few family cares, are able to push forward rapidly, while others, owing to no fault of their own, are slower. This causes the first class, to be retarded in their studies, or it causes the second class to be pushed forward without a clear understanding of the principles gone over.

There is but one way in which a night school can be successful. It must be located where the number of students is sufficiently large to enable the employment of a competent instructor. Every student must be regular in his attendance and must have an equal educational start to keep up with his associates. Bad weather, illness, business or social engagements, must not prevent attendance, or the student will fall behind and will be unable to catch up. To comply with these requirements is hard enough when the pupils are children without responsibilities, but when the pupils are men with heavy responsibilities it is impossible to fulfill them and make this system a success.

By the correspondence system of tuition the difficulties of the two former systems are overcome. When the student joins he is taken in hand by a competent instructor and he is drilled in the very elements of the science he desires to learn. He is not advanced beyond the elementary lessons until he fully understands them. He is not limited in time, and takes such opportunities for study as are most convenient for him. As he finishes one lesson he is led by easy steps to the next. His text-books are furnished him free, and they are specially prepared with the idea of making them as simple, clear, and brief as possible, so that the student works only on such principles as bear on the particular science he desires to master. If two men start the course on the same day, and one is either naturally brighter, or has more time to study than the other, the second is not expected to keep up with the first. If the first finishes a lesson in a day or two, and the second requires a week, he is given a week, or longer, if necessary. He is under no obligation to keep up with the first student. All that is required of him is that he sticks at the lesson until he thoroughly understands it, and is able to answer the questions given him. In this way he is made as proficient as the first. Distance of residence from the headquarters of the school does not affect its work. A man may live three thousand or even ten thousand miles away from it, and enjoy equal facilities with those living in the same town. The school, naturally having a very large number of students, gathered from all sections of the Continent, can afford to make its terms reasonable and at the same time employ a large force of able specialists as instructors. The system of studying the lessons, and then answering the questions by writing them out, drills the student in composition, and trains him for experience with an examining board. It improves his penmanship and spelling, and drills him in the art of letter writing. In case he does not understand a principle or formula, he does not have to pass it over or show other students his inability to comprehend a principle that may have seemed easy to them. A short note to the school asking for explanation is treated confidentially and all necessary explanation is given. No student can join the school and not receive its full benefit, unless he purposely neglects the advantages given him in his scholarship. The system is not a new one. It has been in successful operation for years both in America and in Europe, and is conceded by all who understand the plan to be the only successful medium by which an education can be secured by men of limited means who cannot afford to neglect their daily toil.

THE SUCCESS OF THE COLLIERY ENGINEER SCHOOL OF MINES.

THE necessity for some practical means whereby the standard of technical education among mine officials and miners, could be raised has been for years apparent to the management of THE COLLIERY ENGINEER. While the necessity was thus apparent, the means of meeting it, and successfully filling the want was not so clear, and much time and thought was bestowed on it. The outcome of all this was the establishment, on November 1st, of last year, of THE COLLIERY ENGINEER SCHOOL OF MINES. It was expected that a school in which the elementary principles of the sciences connected with mining, would be taught by correspondence, would be popular enough to warrant us in calculating on from two hundred to three hundred students in the first year of its existence, and that with that number of students it would pay to furnish a simple elementary course of lessons, which would enable the student to pass successfully an examination for a mine foreman's certificate of competency. As soon as the organization of the school was announced, and its plan of operation was explained, it became exceedingly popular, and many requests were made to have its scope so widened as to give the students a complete practical education in the principles of mining. As the number of students increased, we saw our way clear to comply with this idea, and the scope of the school was accordingly enlarged. This naturally made it even more popular, and as a result there are now over seven hundred and fifty students enrolled. They reside in various parts of the Continent, and there is hardly a mining district from Mexico to Nova Scotia, or from the Atlantic to the Pacific that has not representatives in the School. The list of students embraces all classes, from executive officers of companies and superintendents down to day laborers, and also includes a number of prominent mine inspectors. Every student who has fairly entered the course has voluntarily expressed his gratification with its plan and features. Hundreds of letters have been received from students, in which their approval of the course is expressed in the highest terms, and there has not been a single complaint against it. The plan and treatment accorded students has been so highly appreciated that we find that each student advocates the advantages of the school among his associates.

This gratifying state of affairs has made necessary an enlargement of the force of instructors, and of quarters, and has enabled us to carry the student further along in the various sciences connected with the art of mining than was at first contemplated.

Among the new features added are facilities for those of the students who desire to come to Scranton, to have practical work in surveying and mapping, and to enjoy a number of practical illustrated lectures on mining topics. Other features equally as advantageous to all students, are detailed in the new prospectus, which is a handsome volume of sixty-five pages, and which will be sent free to all enquirers. It explains in detail the work of the School, and the advantages offered to every man, who can read and write, to secure a complete mining education at a small outlay of money, that will enable him to fill any mining position. The only requirement is that students can read and write, no matter how poorly. This prospectus contains many valuable hints to miners, and also a large number of testimonials from students in the School. Those who wish to take advantage of the course, and do not, for various reasons, desire to have their names published in the list of students, will always have their wishes respected.

EDITORIAL NOTES.

NOTWITHSTANDING the exertions being made by interested parties to break the combination of the Anthracite coal roads, President McLeod and his subordinate officials are quietly going on with the work of opening up new markets for the coal, and of advancing prices gradually until they shall reach a point, that while not oppressive, will guarantee to the miner fair wages and more steady work, and to the operator a fair profit on his invested capital. Notwithstanding this work has been in progress for some time, we can authoritatively state that up to present writing neither Messrs. Pulitzer, of the N. Y. *World*, or Bennett of the *Herald*, have been compelled to raffle off their cook-stoves on account of their inability to purchase fuel for them.

FOR the benefit of mine owners, superintendents, inspectors, and others, who do not desire to take a course in THE COLLIERY ENGINEER SCHOOL OF MINES, but who do desire to possess the lesson papers used, which constitute a text-book of over 1,000 pages, we have arranged to sell the complete set of papers at the same price as a complete scholarship. The papers embracing the text used in partial scholarships will be sold at the same price as the corresponding scholarship. These papers will only be sold subject to the same conditions as are required of students, and cash must invariably accompany the order. They will not be sold on installments.

IN the nominations of Judge John Dean, of Hollidaysburgh, for Judge of the Supreme Court, and of Genl. Wm. Lilly, of Mauch Chunk, for Congressman at Large, the Republican party of Pennsylvania has diverged from the usual plan and given the great coal industry of the State the recognition it deserves. The nominations are practically equivalent to election, and we will shortly have on the supreme bench, a man who not only ranks high as an able jurist, but one who also has a thorough knowledge of the coal business; and we will also have as a representative in Congress, an able, practical business man whose integrity is unquestioned, and whose experience in the practical working of collieries, and whose knowledge of the necessities of the coal trade in the way of legislation is equal to that of any other man in the State.

IN our April issue, in "Easy Lessons for Beginners," the answer to Question 39, under the heading, "Surface Arrangements" unintentionally omitted the Diescher Washer, manufactured by the Scaife Foundry and Machine Co., Limited, Pittsburgh, Pa., from the list of best jigs.

This washer has proven its superiority by actual work in many portions of the country, and its simple construction and method of operation commend it to all practical men.

It is a rigidly constructed jig, having a stationary screen four feet square with a reciprocating plunger placed directly below the screen, and an automatic slate box or discharge at the front end of the screen. The location of the plunger or piston immediately under, and of equal size, with the screen, ensures a uniform action of the water over the entire screen surface, while the construction and arrangement of the slate discharge effect the continuous and most efficient separation and discharge of the coal and impurities respectively.

The Anthracite Trade.

The Anthracite trade, while dull, is in excellent condition. It is now between seasons, and not much demand is expected. The demand and consumption during the Spring was large, and as a result, stocks are very low. Restriction now restricts, and prices, which have been again advanced 25 cents per ton on Western shipments, and 15 cents per ton on chestnut coal for shipments Eastward beyond the Capes, are rigidly adhered to. There has been no change in prices to line trade. The Summer and Fall trades promise to be active, and good prices will be obtained for coal. The prices realized for coal last month were such as to fix the rate of wages paid the Schuylkill miners, for the last half of May, at 6 per cent. below the basis, an increase of one per cent. over the wages paid in the first half, and an increase of three per cent. over the wages paid immediately before the Reading deal was consummated. While the increase is not a large one, it is a welcome one to the miners, and is evidence to them that the new order of things means greater prosperity in the future than they have enjoyed in the past days of restriction that didn't restrict, and circular prices that were not adhered to.

The output for June has been fixed at 3,000,000 tons, which amount is expected to meet the requirements of the market. Suits to secure legal interference in the Reading, Lehigh Valley, and Jersey Central combine are multiplying, but they do not seem to cause much uneasiness on the part of the Reading managers. The latest suit has been begun by Lehigh Valley stockholders in Northampton County, Penn'a. It is evident to all familiar with the history of the Anthracite trade, that the only means by which it can be lifted out of an unprofitable condition, is by some such means as contemplated by the combination of the coal roads. To continue in the old way means only loss to operators and miners, and enormous profits to retail dealers in the large cities, who for years have been getting all the plums. If the journals that claim to oppose the deal in the interest of the poorer class of consumers will display as much activity in exposing the true sources of extortion under their very noses, by showing up the methods of the average

ANTHRACITE COAL STATISTICS.

Statement of shipments of Anthracite coal for month of April, 1892, compared with the corresponding period last year. Compiled from the returns furnished by the Mine Operators.

The stock of coal on hand at tide-water shipping points, April 30, 1892, was 714,842 tons; on March 31 1892, 821,023 tons, decrease 106,181 tons.

retail dealer, they will more nearly consummate the end they profess to desire and will to a small extent, at least, become something more than journalistic fakirs.

The Bituminous Trade.

The Bituminous trade is dull and featureless. Contracts made early in the season are being filled and large quantities of coal are being moved from the mines. New orders are few, and are for comparatively small amounts. Prices are weak and fluctuating.

The Coke Trade.

The iron trade continuing exceedingly dull, and prospects for the future not being bright, makes the demand for coke very light. In the Connellsville region only about two-thirds of the ovens are in blast, and they are not running full time. In fact, there has been no change of any importance since our last report, and prices remain the same.

SUMMER TOURS.

The Latest Publication of the Pennsylvania Railroad.

The 1st of June is a date looked forward to by the thousands who make their preliminary plans for summer outings, and their main guide is the Summer Excursion book issued yearly by the Pennsylvania Railroad Company, which regularly appears on that date. Advance copies for the season of 1892 are fresh from the press and certainly excel anything of like character ever published by this progressive railroad company.

It is not only a compendium of all the rates prevailing over its own and connecting lines to the principal resorts of the land, but it is equally as valuable as a guide-book, with full and explicit information as to how trips may be made, and as to what desirable variations may be utilized to enhance their pleasure and profit. Nearly five hundred resorts, ranging from Prince Edward Island to the mountains of Western North Carolina, from the southern extremity of New Jersey to the wild lakes of Canada, from the mineral springs of Virginia to the great inland lakes, are described at length, and over fifteen hundred routes, representing a stock of fifteen hundred special forms of tickets, are set out clearly and intelligibly within its pages.

In arranging these routes care has been observed in making them read over lines that present the greatest number of interesting points, and in every case there is a wide field for choice. They also provide for a return trip by a different direction, so that the tourist may find his outing a continual succession of changing scenes.

It is so comprehensive that one could hardly ask for a ticket to an Eastern resort of any prominence and fail to find it ready-made by a variety of routes. One hundred and thirty railroad and steamboat lines are represented in the coupons of these tickets, every one of them connecting directly or remotely with the Pennsylvania system.

The cover to this handsome edition represents one of the famous Pennsylvania Railroad Observation Cars artistically executed. The illustrations are the finest style of half-tone work, on as high a grade as the popular magazine productions.

Application of Electricity to Mining Operations.

It is a mistaken idea to suppose that the number of electric plants at mines is so small as to keep the application of electricity as a means of transmitting power still in the experimental stage. It is also a mistake to imagine that the application, of electric power is confined only to two uses, haulage and coal cutting. While it is true that these two branches of the work have received the most prominence in literature treating on applications of electricity to mining it was simply because they were the ones that most needed the application of an improved method of transmitting power. However, while the electricians and mining engineers were wrestling with the problems that presented themselves when these branches were under consideration, they did not neglect the others, some of which were very simple propositions, while others presented just as large a field for the application of inventive faculties as either of the two first mentioned branches. The Thomson-Houston Electric Co. was the first to enter the field of mining on a large scale, and after securing the best available engineering talent, they expended large sums of money, and an amount of patience and perseverence that seems almost incredible, to secure the best designs of electric machinery capable of performing the work in a perfect manner, and their enterprise has been rewarded, by the possession of patents that enable them to turn out machinery designed for haulage either by locomotive or rope, and for coal cutting either by chipping or scraping, solenoid drills or rotating drills. They have also succeeded in sucessfully applying electric motors to hoisting machinery, ventilating machinery, triplex, duplex, and centrifugal pumps, diamond drills, etc., etc. They have also produced the VanDepoele electric percussion drill for rock work, that is so arranged on a universal joint tripod or adjustable tunnel columns, that it can be operated in any position.

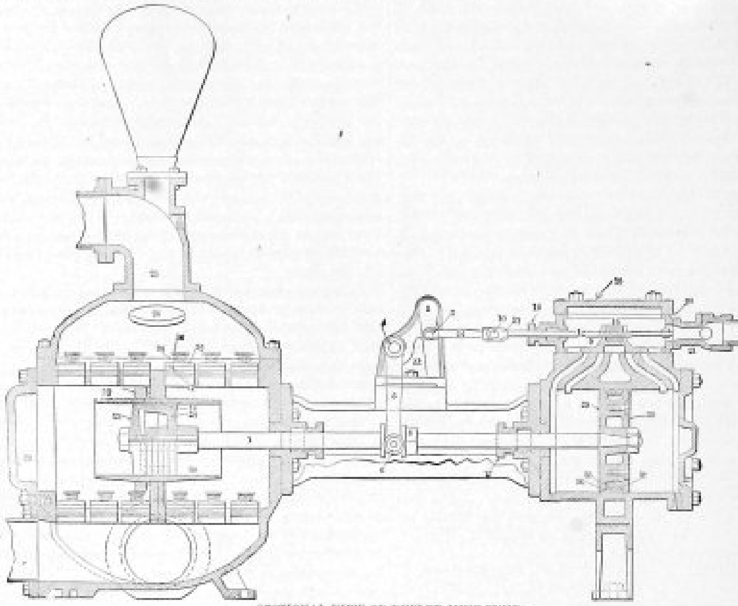
Plants embracing all types of the machinery mentioned run by Thomson-Houston motors, and supplied with power generated with Thomson-Houston dynamos are in operation in mines in all parts of the country, and a number of them are superbly illustrated in the handsome catalogue just issued by the Thomson-VanDepole Electric Mining Co., which controls all the mining work of the Thomson-Houston Co. This catalogue is composed of 200 pages containing fine illustrations and a large amount of interesting [illegible]luable text. We advise all our readers who [illegible]t already secured a copy of this work to send [illegible] once.

STEAM PUMPS.

We herewith present sectional views of The Laidlaw and Dunn Co.'s Duplex Mine Pump and Duplex Boiler Feeder. These pumps have won an enviable record for efficiency and durability, and are specially constructed in a manner to ensure a continuance of their high reputation, and the consequent large volume of business being done by their manufacturers.

These pumps are made with removable and interchangeable brass water cylinders and plungers, with bronze piston and plunger rods to resist the action of acidulated mine water. The cast brass cylinders are heavy enough to be bored out several times, before it cup leathers, or metallic packing, in accordance with the kind of water to be pumped.

The boiler feed pumps manufactured by the Laidlaw & Dunn Co., are also fitted with heavy removable cast brass interchangeble water cylinders showing the flanged ends. They are held in by the water cylinder heads. The advantage of having pumps constructed in this manner, lies in the fact that when the water cylinder becomes worn, it is not necessary to send the pump to the repair shop to be rebored, because, by simply taking off the water cylinder heads, the old or worn cylinder can be removed, and a new brass cylinder can be pushed into its place in a few minutes. This advantage will be apreciated by all steam users.



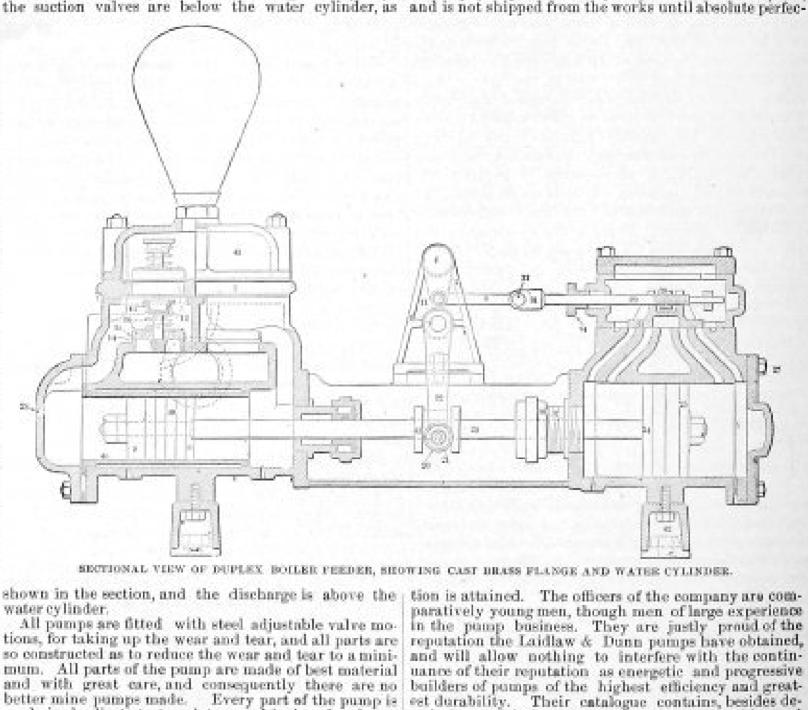
SECTIONAL VIEW OF DUPLEX MINE PUMP.

is necessary to renew them. They are fitted to the main body of the water end with ground joints, and are held in place by a heavy flange. They are also fitted with brass valve seats, which are screwed into the valve deck with a fine tapering thread. The valve stems are of best brass, and screw into the valve seats in a similar manner.

The water ends of these pumps are provided with large hand hole plates, so that every valve in the suction and discharge of the pump can be removed without dismantling the pump. On the large mine pumps the suction valves are below the water cylinder, as

The smaller sizes of these pumps are all fitted with brass followers in the packing glands. The bearings are large and long, thus ensuring least wear and tear. They are also fitted with steel adjustable valve motions, brass valve seats, brass stems and springs, and composition or brass valves, as may be desired. They are guaranteed for hot or cold water. As in the mine pumps, all parts of these pumps are interchangeable. They are made of the best material, and the best workmanship is used in their construction.

Every pump is carefully inspected in all its parts, and is not shipped from the works until absolute perfec-



SECTIONAL VIEW OF DUPLEX BOILER FEEDER, SHOWING CAST BRASS FLANGE AND WATER CYLINDER.

shown in the section, and the discharge is above the water cylinder.

All pumps are fitted with steel adjustable valve motions, for taking up the wear and tear, and all parts are so constructed as to reduce the wear and tear to a minimum. All parts of the pump are made of best material and with great care, and consequently there are no better mine pumps made. Every part of the pump is made in duplicate to templates, and is therefore interchangeable, and can be duplicated without any trouble. The ports in the water end are made large, so that, if necessary, the pump can be run at a high speed. The water plungers are packed with square packing,

tion is attained. The officers of the company are comparatively young men, though men of large experience in the pump business. They are justly proud of the reputation the Laidlaw & Dunn pumps have obtained, and will allow nothing to interfere with the continuance of their reputation as energetic and progressive builders of pumps of the highest efficiency and greatest durability. Their catalogue contains, besides descriptions of their various styles of pumps, tables and data of value to all pump users. It will be sent free to all colliery owners or colliery officials. The address of the manufacturers is The Laidlaw & Dunn Pump Co., Cincinnati, Ohio.

COLLIERY IMPROVEMENTS.

Colliery Owners, Superintendents, Mining Engineers, Contractors, and others are respectfully requested to inform us as early as possible of all improvements contemplated at their mines. We desire to make this department as complete as possible.—*Editor.*

*** The Coahuila Coal Company, Hondo, Coahuila, Mexico, has the following improvements in course of construction under the supervision of Mr. E. G. Tuttle, Superintendent:

At their new mine they are sinking a three-compartment shaft, which is 10 ft. 10 in. x 21 ft. 4 in. Each compartment will be 6 ft. x 8 ft. in the clear.

At their Hondo mine, they are erecting a new tipple with Mitchell dump alongside of their 600 ton washer. This new tipple will weigh and screen the coal before it passes to the washer.

They have also erected a 22" by 20" air compressor at the same mine to furnish power for a Harrison Coal Cutter.

*** The Leavenworth Coal Company, of Leavenworth, Kansas, Mr. J. E. Carr, General Manager, is erecting one 115 H. P. generator, and one 60 H. P. generator to operate 6 Sperry mining machines, a 25 H. P. power pump, with a capacity of 80 gals. per minute and a lift of 710 ft., and two 40 H. P. motors to drive their inside endless rope haulage machinery. They will also use other smaller motors for various purposes around the mines. The electric machinery is all being erected by the Sperry Electric Mining Machine Co., of Chicago.

*** Messrs. John Ingle & Co., of Evansville, Ind., are making sweeping improvements at their Ingleside colliery at Evansville, and propose to have the most complete coal handling appliances in the State. They have ordered new first motion Brazil winding engines of latest type, from Messrs. Crawford & M'Crimmon, of Brazil, Ind., and are putting in new boilers, pumps, etc. They will also begin the erection of a new tower at once and put in a new outfit of screens of the most approved construction. They are also sinking a prospecting shaft from the present level, which has reached a depth of 100 feet from the surface.

*** A number of improvements will shortly be introduced at the Milnesville colliery under the superintendency of Mr. J. I. Hollenback, of Hazleton, Pa. A new locomotive has been added to the plant, and an electric light plant will be added, so that the work on the extensive strippings can be prosecuted both night and day.

*** The Mill Creek Coal Co., New Boston, Schuylkill County, Pa., will shortly sink a new slope 900 ft. long in the Buck Mountain seam to the basin, and will open the overlying seams by tunnels. They will also erect a new breaker to prepare the coal from this new opening. All the improvements contemplated will be under the supervision of Mr. T. D. Jones, general superintendent.

*** The Reynoldsville Coal Co., of Reynoldsville, Pa., is opening a new mine near Sandy Valley, Jefferson County, Pa.

The D. L. & W. R. R. Co. have made preparations to sink shafts and erect two breakers in the vicinity of the Badman and Gomer farms in the suburbs of Nanticoke, Pa. They will be fitted up with the latest and most improved machinery for the preparations of coal for market, and will be called the "Bliss" and "Auchincloss" after Directors of the Company.

*** The Vesta Coal Co., under the superintendency of Mr. R. A. Drum, has a large force of men at work opening up a new mine at Allenport, Washington County, Pa., near the old American Mine, which they are now operating to its full capacity. The narrow work in the new mine is being pushed forward as rapidly as possible. The entire structural work of the tipple, etc., will be of iron, and it will be one of the finest on the Monongahela River. A rope haulage plant is being placed in the new works which will handle the coal from both the old and the new mines. Both mines will be ventilated by a 25-foot fan, which is nearing completion at the old mine.

The Vesta Coal Company is composed of members of the Jones & Laughlin Iron and Steel Company, and the products of the two mines will be largely used at the mills and furnaces of that company at Pittsburgh. At the new iron tipple, a large crusher will be operated for crushing the coal, which will be loaded in barges and taken to the coke ovens near the furnaces. It will be so arranged that when the river is too low, the coal can be loaded on cars and run down by rail. This plant promises to be one of the largest and steadiest running mines in the upper pool of the Monongahela.

New Mine Inspection Districts in Ohio.

Chief Mine Inspector R. M. Haseltine, of Ohio, has redistricted the State for inspection purposes, in compliance with the law as amended at the last session of the Legislature. The state will now consist of seven districts, instead of five, as formerly. The first district comprises the counties of Hocking, Vinton, Jackson, and Scioto, containing seventy-nine mines that employ more than ten men and forty a less number.

The second district is composed of Washington, Athens, Meigs, Gallia, and Lawrence, containing sixty large and thirty-eight small mines.

The third district, embracing the counties of Muskingum, Perry, Morgan, and Noble, contains seventy large and eighty small mines.

The fourth district, composed of Monroe, Belmont, Guernsey, Coshocton, and Holmes, embraces sixty large and eighty small mines.

The fifth district covers Harrison, Jefferson, Carrol, and the southern portion of Columbiana, and contains thirty-seven large and sixty-seven small mines. This district was made smaller than the others in order to allow more time to each, owing to the number of mines in it which generate fire-damp.

The sixth embraces Tuscarawas, Stark, and Wayne, and has sixty-three large and one hundred and nineteen small mines.

The seventh, Summit Medina, Portage, Mahoning, Trumbull, and the northern portion of Columbiana, containing fifty-four large and seventy-seven small mines.

The records in the Mining Department show nine hundred and twelve mines in operation. Of these four hundred and twenty-three employ more than ten men and four hundred and eighty nine, a less number. The average to the district would be sixty large and seventy small ones. In making the division, three small mines were considered the equivalent of one large one and the districts will contain 92, 93, 87, 61, 100, and 79 average mines respectively.

Engineering Association of the South.

The regular April meeting of the Engineering Association of the South was held at the Association headquarters in the Cumberland Publishing House, Nashville, Tenn., on the evening of the 14th inst.

Vice-President F. P. Clute, of South Pittsburgh, Tenn., presided, with the following gentlemen in attendance: Messrs. Hunter McDonald, J. Biddle, J. S. Walker, H. M. Robert, W. N. McDonald, R. L. Johnson, C. E. Bright, W. B. Ross, William Leftwick, William Whorley, and Frank Ross. In the absence of the Secretary Mr. W. B. Ross was appointed Secretary *pro tem.*

The minutes of the last meeting were read and approved.

Messrs. Hunter McDonald, and J. S. Walker, the tellers appointed to canvass the ballots for membership reported the election of the following gentlemen: As members: William W. Carson, Prof. of Civil Engineering, University of Tennesse, Knoxville, Tenn.; Henry L. Collier, partner and engineer of the Lithonia Granite Quarries, Atlanta, Ga.; Chas. E. Hamlin, Engineer and Manager Southern Office of the King Iron Bridge Co., Chattanooga, Tenn.; Benjamin M. Hall, member of firm of Hall Bros., Civil and Mining Engineers, Atlanta, Ga.; Arthur G. King, Practicing Engineer Atlanta, Ga.; Henry M. Robert, Lieutenant Colonel of Engineers, U. S. A., in charge of Cumberland and Tennessee Rivers Improvement, Nashville, Tenn.

As Juniors: Philip H. Porter, Post Graduate Student and Fellow in Engineering, Vanderbilt University, Nashville, Tenn.; Arch T. B. Somerville, Engineer for the King Iron Bridge Co.; Chattanooga, Tenn.

A communication was read from President A. V. Gude, Atlanta, Ga., stating his intention to be present at the Fifth International Congress of Internal Navigation to be held at Paris, France, beginning July 21, 1892. On motion President Gude was appointed a representative of this association at the coming congress, and the Secretary was directed to forward a notice of his appointment to Mr. Gude and to the Secretaire General at Paris.

The paper of the evening entitled "Municipal Engineering in Chattanooga," by Mr. James A. Fairleigh of Chattanooga, was then read by the Secretary *pro tem*, in the absence of the author.

The paper presented the system of organization and control of the department of public works and engineering of the city, giving also the amounts of appropriation and expenditures in the city during the past two years, together with the amount of asphalt, granite block, brick, and block asphalt streets in use, with the cost of same and an exhibit of the mileage and cost of the sewers of the city, of which there are nine miles of brick and thirty-three miles of pipe sewers. The paper was discussed by Vice-President, F. P. Clute, of South Pittsburgh, Tenn., Col. H. M. Robert, of Nashville, Tenn., and Mr. Hunter McDonald, of Atlanta, Ga.

The Illinois Mining Institute.

The newly organized Illinois Mining Institute seems to have made an auspicious beginning at its first quarterly meeting held at Springfield, Illinois last month. The attendance was large, and there were fifty-seven applications for membership. Mr. J. C. Simpson, General Manager of the Consolidated Coal Co., of St. Louis, is president of the organization, and Hon. John S. Lord, Chief of Bureau of Statistics, Springfield, is secretary. Papers were read by the president, Mr. Simpson, on "The Purposes of the Organization;" by Inspector Walton Rutlege, on "The Water-Gauge;" by Thos. Stockett, chief engineer of The Consolidated Coal Co., on "Coal-Cleaning Apparatus;" by Inspector Hudson, on "Mine Inspection;" by Mr. Murray on "The Mine Manager;" by Mr. Rollo on "Fire-damp in Illinois Mines;" and by Mr. Ramsay, of the Braceville Coal Co., on "Drainage in Wet Longwall Mines." The reading and discussion of these papers occupied the greater part of two days, and the published proceedings of the meeting will doubtless afford interesting and instructive reading to all engaged in mining coal.

The Roslyn Disaster.

The explosion that occurred at the Northern Pacific Coal Company's Roslyn No 2 Mine, on the 10th ult., was the most disastrous accident that ever occurred in the Pacific Coast coal industry.

The mine is the largest one of a group of three mines known as Roslyn Nos. 1, 2, and 3, and is located in Kittitas County, near the center of the State of Washington. Its capacity is 2,000 tons per day. It has two openings for the drawing of coal (independent of the traveling way for men and mules), called respectively, the Water Level and the Main Rope Entry. The mine is a very extensive one, and consists of a dip entry, first level, second level, third level, fourth level, third east, second east, and first east; the latter being worked out, but used as an intake for a separate split of air. The second east was also used as a separate intake. The water level and manway were also used as intakes, making four in all. Ventilation was produced by a ten-foot cyclone fan, and the Inspector's report for 1891 shows that the quantity of air displaced by the fan was 57,600 cubic feet per minute.

On the day of the explosion, gas was reported in the sixth west entry and in the sixth east. All this gas was removed by Foreman John Shaw before the men were allowed to commence work. At noon the mine was reported free of gas, and the air current circulating was about 45,000 cubic feet. The explosion occurred at 1.45 P. M., and 43 men were killed. All the men were working with naked lights, except in the sixth east gangway, where three men were using safety-lamps. The cause of the explosion is not known positively, but Mr. John Kangley, the general manager of the company supposes that a sudden outburst of gas occurred which suddenly filled the workings and was ignited by some man's lamp.

The mine was supposed to be in an excellent condition and the ventilation was considered by the workmen and the mine inspector as first-class.

Taking into consideration the excellent ventilation, the comparative freedom from gas in the past, the analysis of the coal, and the fact that one small pump effected the drainage, the following deductions as to the conditions existing previous to the accident can be drawn:

(1). The mine was a dry one.

(2). The coal contained 39·29 per cent. of volatile hydro-carbons.

(3). There was a strong current of fresh air sweeping through the workings.

(4). The explosion extended over a very large portion of the mine.

These deductions show that all the elements necessary to cause an explosion of dust, ignited by gas, were present. It is a settled fact that the dust of coal containing as much as 25 % of volatile hydro-carbons is exceedingly explosive, and the presence of a small percentage of gas increases the danger.

Owing to the location of the mine and the badly mixed and untechnical press dispatches, intelligible detailed accounts of the explosion are unobtainable, but by taking the facts of the explosion, and the last published report of the State Mine Inspector into consideration, we are justified in the opinion that coal-dust was a more potent factor in the explosion than gas.

Fatal Mine Explosion.

An explosion of gas in the lower lift of the West End Coal Co.'s Colliery, at Mocanaqua, Luzerne Co., Pa., on the morning of the 31st ult., resulted in the death of two men, John Pretheroe, mine foreman, and John Walters, a miner, and the fatal injury of three others, Wm. Hooper and two Poles, names unknown. Besides these six others were more or less seriously burned.

No person is able to tell the exact cause of the explosion, as mine foreman Pretheroe, whose lamp ignited the gas, was instantly killed. It is supposed that a body of gas had accumulated in some spot not visited by Pretheroe earlier in the morning, as was his custom, and owing to the comparative freedom of the mine from gas, he took chances. He carried a safety-lamp, either of the Davy or Clanny type, and it is supposed that either the gas ignited in the lamp and burst it, or that the lamp was accidently broken, and ignited the gas. At this colliery the foremen acted as fire-bosses in connection with their other duties, and in this instance Foreman Pretheroe neglected the usual precaution of an examination previous to the entry of the miners, and he paid the penalty for his neglect with his life.

One of the neatest specimens of typography that we have ever received in the shape of a catalogue, is the New General Catalogue of the Henry R. Worthington pumps. It is beautifully illustrated, as are all the Worthington Company's catalogues, and should be in the library of every operator and colliery official. Several new special catalogues are in preparation that will show Worthington pumps of many different designs, for special work. The particularly high standard of excellence of the Worthington pump, together with the enterprise of the company in securing every real improvement in pump construction, make these catalogues a medium through which pump users can be kept posted regarding the most modern types of steam pumps.

The H. C. Frick Coke Co. is having made a complete model of its Standard mine and coke works on a scale of one twentieth of an inch to the foot. The model will be an exact reproduction of the shaft and inside workings and coke plant. It will show the headings and rooms, inside haulage machinery, the shaft timbering, hoisting machinery, transfer trucks, coke ovens, larries, etc., etc. The machinery will all work just as the larger machinery does at the mine. Coal will be hoisted and handled, and the coke ovens will be in blast, but instead of burning coal they will be fired by gas, and asbestos blocks will represent the coke in process of burning. It will be an unique and interesting exhibit.

Messrs. J. E. Carr & Son, of Leavenworth, Kansas, in a recent letter inform us that they have just shipped six of their patent cable gripe to the Pana Coal Co., of Pana, Ill., and that with the assistance of their advertisement in THE COLLIERY ENGINEER they are selling large numbers of them to collieries in all parts of the United States and British Provinces. The experience of Messrs. Carr & Son, can be duplicated by all manufacturers of mining machinery, if the same means are used to secure business, viz., by manufacturing first-class goods, and then by making their goods known to purchasers through the columns of THE COLLIERY ENGINEER.

We have received from the Goulds Manufacturing Company, of Seneca Falls, N. Y., advance sheets from their handsome special catalogue of "Efficient Power Pumps and their Application." The pages received contain a large amount of valuable data regarding the merits of Gould's Triplex Power Pumps, one of which is in successful operation at the Pancoast Colliery, near this city. Its motive power is electricity, and the operators of the colliery are highly pleased with it. The Goulds pumps are constructed to run by either electric or steam power, and we advise our readers to look into these many superior points, by sending for and reading their catalogue.

THE BABCOCK & WILCOX AS A COLLIERY BOILER.

We illustrate in this issue a boiler recently erected by The Babcock & Wilcox Co., for the Summit Branch Railroad Company at Williamstown, Pennsylvania, and reference to our advertising columns will show to what extent these boilers have already been introduced into collieries. The reasons for adopting these boilers are economy of fuel, durability, small cost of repairs, and the fact that excessively high pressures may be carried with perfect safety. Where steam has to be carried long distances, as it does at many collieries, this latter reason is often times an all-important one.

The question of economy is one that until within a comparatively short time has not been thought worthy of much attention at Anthracite mines. Now however that the finer grades of coal are being utilized operators are finding out that the coal they burn is valuable to sell, and lately at many collieries the boilers are charged on the books at the regular market price for all coal burned. Where this is done it is easy to see that the old practice of plain cylinder boilers is a very expensive one. As a matter of curiosity we have made some estimates as to the probable saving that could be effected by a change from cylinder boilers to the more improved type. The mine inspectors report about 8,000 boilers in the Anthracite Districts of Pennsylvania. If these average only 30 h. p. each, there is a total of 240,000 h. p. Suppose the running time averages 12 hours per day for 200 days per year and that the saving in coal is only 2 pounds per h. p. per hour. The total annual saving will then be 528,000 tons of coal worth on board cars an average of about $1.00 per ton, or $528,000.00 per annum.

The economy secured by the use of the improved type of boilers, however, covers a good deal more ground that the market value of the coal saved. It means a reduction in the number of men required to handle the coal and ashes. It also includes wonderful saving in wear and tear. To fire the 8,000 boilers referred to not less than 1,000 men are required, while the same h. p. in Babcock & Wilcox Boilers can be fired by at most 400 men. This great reduction in the number of employes is due to the smaller amount of fuel handled, and to the fact that the boilers are usually put in larger sizes, one 125 h. p. boiler taking the place of four cylinder boilers. If the saving in labor be 600 men at $300.00 per year, the aggregate economy in labor and fuel will amount to considerably over $700,000.00 per annum, or about $3.00 per h.p. per annum. If the Babcock & Wilcox Boilers cost when set from $4.00 to $8.00 per h. p. more than the plain cylinder type, the difference will be paid back in from two to four years, after which the saving is a continual source of profit to the operator. In addition he has a boiler that will last many times as long as the cylinder boiler, and carry high pressure steam with safety. We are glad to know that so many collieries have already taken this view of the matter. It is a branch of colliery engineering that has had entirely too little attention paid to it in the past.

Gettysburg.

The New York Commercial Advertiser says in a recent editorial:

"There is no spot in this country so attractive to those who have patriotic emotions, and who honor heroic deeds, as the quiet little town in Southern Pennsylvania, known as Gettysburg, which the great battle of the Civil War has made historic for all time. Unlike Waterloo, this field is marked by monuments which tell every detail of the struggle. Nearly four hundred of them mark the spots where the Federal forces fought and won everlasting glory. Many of these monuments are genuine works of art. In fact, this famous battlefield is a *grand out-door National Gallery of Art*—heroic Art. Nothing like it can be seen on either hemisphere. Twenty miles of roads have been laid out on the field, and a million dollars' worth of bronze and marble may be seen in a day. As an object for Summer Excursions there is no such spot on the Continent. The scenery about Gettysburg is beautiful and full of repose. Its hotels are good, its people hospitable and appreciative, and the Reading Railroad has made the journey thither comfortable and even luxurious.

A Convenient and Accurate Transit.

The transits manufactured by Mr. Herman Pfister, 195 West Fifth St., Cincinnati, Ohio, are models of convenience, accuracy and good workmanship. They are all made under the personal supervision of Mr. Pfister, who carefully tests and adjusts every instrument, before it leaves the shop. Among the special features of this transit may be mentioned the following:

The telescope plunges both ways over the compass box, even when extended its greatest length. The graduation of the compass box and sliding plates are especially distinct and easy to read. The shifting plate for moving the head of the transit on the tripod is entirely independent of the leveling screws. The leveling plates and screws are not detachable from the instrument proper, and are packed in a walnut case, exposing nothing but the tripod to dust and dampness. The vertical angle is read from a full circle, and not from an arc only. The eye piece as well as the object glass is adjusted by rack and pinion movement; and there are spring tangent movements for both upper and lower plates. The instrument is constructed in such a manner that is not easily put out of adjustment, but if such a thing should happen it is readily and easily adjusted. The prices for the different types of instruments are reasonable, and catalogues will be sent free on application.

The new catalogue, just issued by the Lunkenheimer Brass Manufacturing Co., of Cincinnati, is a book that should be in the hands of every mine owner, and colliery official, or other person using steam power. It is a beautiful illustrated volume, bound in flexible cloth, and illustrates the many types and styles of brass and iron valves, fittings, etc., etc., for steam, water, gas, or oil, manufactured by the Lunkenheimer Co. This company was founded over thirty years ago by the late Frederick Lunkenheimer, who won a high reputation for the excellence and efficiency of his brass and iron specialties, and his sons who have succeeded him have demonstrated the fact that they can perpetuate this reputation, and are doing it by turning out only first-class goods at reasonable prices. Every product of their large works bears the name "Lunkenheimer" stamped prominently on it, and every valve, gauge, lubricator, etc., is tested before it leaves the factory to ensure its bearing out the reputation ensured it by the name it bears.

A New Culm Separator.

Mr. James Pollock, mechanical engineer, of Wilkes-Barre, Pa., has been granted a patent on a culm separator that promises to be very successful in practical operation. It consists of a water tight tank about eight or nine feet deep, having a rectangular form five feet by fourteen feet at top with sides converging to a small square opening at the bottom. In this opening at the bottom a gate valve is located which can be opened and closed at will, through which the sediment can be removed. The tank is filled with water to within a few inches of the top, and seven inches under the surface of the water is located a perforated plate of one-eighth of an inch round the mesh. In its operation the coal or culm enters the tank at one end and is conveyed over the surface of the perforated plate and under the surface of the water, washing the material as it moves through, allowing all the particles which are too small for burning purposes to drop to the bottom where it can be drawn off through the gate without materially affecting the water in the tank. The material washed is conveyed through the water until it approaches the opposite end of the tank, at which point the perforated plate is inclined upward with the conveyor, carrying the material out of the water and depositing it into a chute, which carries it to a screen to be meshed into marketable sizes. This arrangement enables the water to remain in the tank and to continue washing the coal without an overflow. The sediment, which settles under the perforation, is drawn off through the gate valve at the bottom into a car and deposited on the dirt bank.

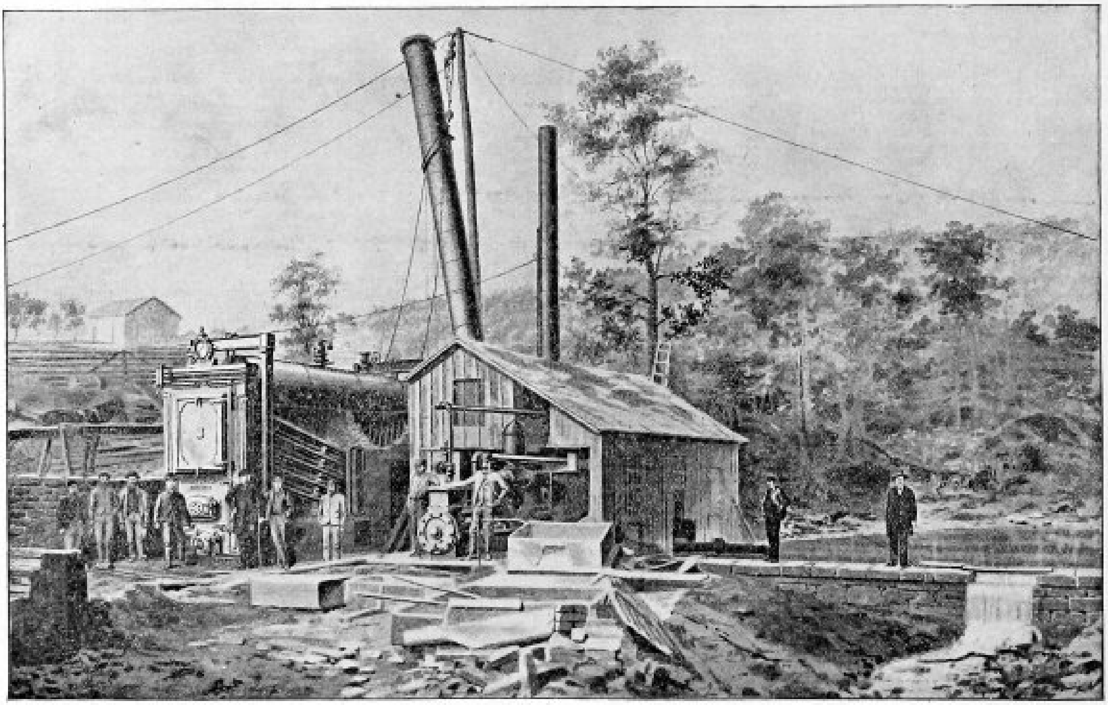
The idea was originally intended for washing the small dirty coal in breakers, but the capacity of the machine is large and it has been found to be suitable for washing the material in culm banks, for which purpose it seems very well adapted.

The American Institute of Mining Engineers.

The Sixty-second Meeting of the American Institute of Mining Engineers, which was announced for June 21st has been postponed for one week, and will begin Tuesday evening, June 28th.

This change of date has been made in consequence of the offer of the manager of the magnificent Hotel Champlain, situated at Bluff Point, about three miles south of Plattsburgh, to open the hotel in advance of the regular summer season, for the special entertainment of the Institute, provided the date of June 28th could be substituted for the earlier date first announced, at which time it would be impossible to have the hotel open. The superior comfort and enjoyment assured to members by this arrangement need not be argued to any one knowing, by reputation or personal experience the Hotel Champlain. Headquarters will therefore be established and sessions will be held in this hotel. The usual rate of $5 per day will be reduced to $3.50 for members and guests of the Institute, and the reduced rate will be continued until July 6th for the benefit of such as may desire to remain at Bluff Point over the Fourth of July.

This meeting promises to be one of exceptional interest and pleasure. Communications and inquiries concerning local arrangements may be addressed to A. L. Inman, Esq., Plattsburgh, N. Y., Acting Chairman of the Local Committee.



THE BABCOCK AND WILCOX BOILER AT WILLIAMSTOWN, PA.

EASY LESSONS FOR BEGINNERS IN THE STUDY OF THE ART OF MINING AND THE SCIENCES RELATED TO IT.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the theory of mining and to learn how to answer the questions in ventilation, mine surveying, and mechanics which are asked at the examinations for mine manager's and mine foreman's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine manager's and mine foreman's certificates and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and the calculations are worked out at length for the benefit of those who are not familiar with figures.

PENMANSHIP.

The capital Y consists of a capital loop similar to that employed in making the letter V, a right curve which is connected with the loop by a short turn, and an extended inverted loop which has its straight line made one space longer at the top than usual. The inverted loop should extend below the line two-thirds of the height of the capital loop above the line. It is shown in the right proportions in the first letter at the left of Fig. 46. The second letter from the left is faulty in that the right curve is on the wrong slant and the

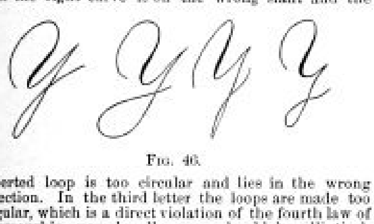


Fig. 46.

inverted loop is too circular and lies in the wrong direction. In the third letter the loops are made too angular, which is a direct violation of the fourth law of Penmanship, namely, all curves should be elliptical. In the fourth letter the right curve is too short which destroys the symmetry of the whole letter; also, the inverted loop is out of proportion to the rest of the letter, and it is terminated below where the line would be.

The first letter in Fig. 47 shows the capital Z written in conformity with the four laws of Penmanship. It consists of a capital loop, an inverted loop and a small loop, which is made in joining the inverted loop with the capital loop. As in the letter Y the inverted loop, is two-thirds the length of the capital loop, or if the whole length of the letter was divided into five parts, the capital loop would be three parts high and the inverted loop two parts. In letter 2 the capital loop is too angular, and the inverted loop is

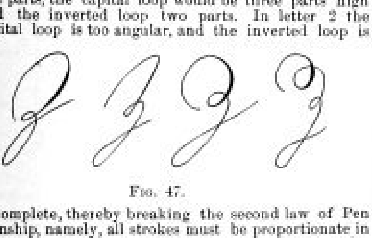

Fig. 47.

incomplete, thereby breaking the second law of Penmanship, namely, all strokes must be proportionate in distance. The capital loop of the third letter is circular instead of elliptical, and shows how any divergencies from the correct elliptical arrangement produce deformities. This is a common error to be guarded against in writing both letters Y and Z. In the fourth letter the capital loop is drawn too far to the left producing a manifest deformity. Also the inverted loop is contracted and out of all proportion to the rest of the letter.

GEOLOGY

In its Relation to Coal, Iron, Oil, Gas, and Ores.

70. What is the ore of iron?

The several ores are all varieties of the compound of iron with oxygen. They are called hematite, limonite, or magnetite.

71. Where are they found?

In the sedimentary rocks between the strata, like coal; and often very thick.

72. How were these beds formed, like coal?

Not exactly like coal but yet very similar, in that water and vegetable and organic matter have had a great deal to do with the deposit.

73. What is the process?

We judge only by what is going on now. Taste the waters of a bog as they ooze from the soil. The taste is inky. The water is colorless. A chemist would tell you that there is iron in it. Where did it come from? I will tell you. Where are the iron bogs seen? Anywhere and everywhere. Do you remember my saying that pyrites was a very common mineral? It is everywhere. In coal, in clay, in sandstone and in nearly all the rocks. Water is a great and powerful solvent. It can leach out of any rock some of the matter it contains. Well, it will dissolve, or wash away pyrites which naturally accumulate in the marshes.

74. But we do not find pyrites there?

No you do not for the moment, wet pyrites comes out into the air it rusts (that is it takes oxygen from the air) and you will notice a scum floating on top of the water. That is iron rust. Bye and bye the rust sinks to the bottom and as more of it is washed in here, a layer of iron mineral is formed.

75. Why it is just like coal formation.

Yes, this bog iron ore forms in pools like coal but there is a difference. It seems that organic matter is important in this work. Decaying plants and animals seem to hasten the process which otherwise would be slow.

76. Are all the varieties of iron formed in the same way?

Practically the same. The varieties differ in the amount of oxygen contained with the iron. This difference causes some iron ores to be reddish, like ochre, and others metallic.

77. Are iron springs the same thing you have been describing?

Yes, they are. You will see them near the place where coal-beds come up to daylight. Indeed one way to find some coal blossom is to be on the lookout for these iron springs or iron bogs.

78. You told us of the effect of heat on coal, does it ever change the iron ores?

Wherever a bed of iron ore has been heated by having lava near it or where it has been squeezed badly in the disturbances of the rocks, the soft limonite iron ore was changed into the hard shiny "magnetite" or "hematite."

79. In what geological formations does iron ore occur?

Most of the English iron ore comes from the coal measures. Alabama iron ore is also from near the coal seams. The Silurian contains much of the iron ore.

80. Does an iron bed have fossils in it as in a coal seam?

Yes, but the fossils are always of fresh water plants and shells.

81. How much iron is there in the ores?

Magnetite is nearly three-fourths pure iron; hematite or specular ore has nearly as much; bog ore has a little over one-half iron.

82. Where are these ores mined?

In almost every state of the Union. Some ores are purer than others, but the Lake Superior region, Cornwall of Pennsylvania, and Virginia, are turning out large amounts of iron ore. Michigan stands first in mining nearly 6,000,000 long tons of an average value of $2.70 per ton. Alabama and Pennsylvania come next with 1,500,000 each.

83. Do all kinds of iron ore produce the same kind of iron?

No. The red hematite is the most desirable iron ore.

84. How much iron ore have we in the United States?

We produced 14,518,500 long tons last year. The consumption is 15,733,465 (according to the census). Each long ton of ore is equal to about 1200 pounds of pig iron.

85. Have any figures been given as to how long the iron ore supply will last?

It is predicted that we have only sufficient iron ore, now discovered, to furnish the United States, for 110 years assuming that the consumption doubles every 13 years as it has done during the last 10 years.

86. How thick are the iron ore beds?

Like coal, they may be found up to 50 feet thick, though the purest seams are only about 4 feet. Like coal, also, the seam is underlaid by clay

87. From what you say of iron and coal, the plants and animals must play a very important part in Nature?

They do, and though we are exhausting the coal beds and iron mines, they return to the earth again. When we burn up coal, it goes up into a gas, that is called carbonic acid gas, what miners call choke-damp. That gas feeds the plants now living and they take the carbon out of the gas, put it into the grass or wood which soon decays and goes through the same process. So it is with iron, when it rusts it falls into the soil and is washed back into some pool and we have iron ore again.

88. Does anything else depend upon the plants?

Yes, natural gas and petroleum. They are the products of decay of wood and vegetation. Some claim that petroleum, or mineral oil, was made by the decay of organic matter, perhaps of animals.

89. Why is that so thought?

Because big caves have been found containing bitumen, the solid remnant of petroleum and with fossils. In one place there has even been a cave solidly full of fishes that have been changed into oily tar. At least the geologists are all agreed that petroleum was made from organic matter that lived in *salt* water.

90. What is the objection to the belief that the oil came from trees and plants?

Because petroleum rarely occurs in strata that have been heated.

91. What is natural gas?

It is a gas accumulated in the subterranean chambers. It was discovered while drilling for oil wells. All oil wells may yield gas, but gas wells do not give petroleum.

92. How was it produced?

Do you remember Q. 8 in which it was shown that the movements of the rocks in the earth heated and changed the character of the coals from peat or lignite to Bituminous and from the soft coals to the hard coals? In this process, the most of the carbon remained in the coal as the table in Q. 2 showed, while the oxygen and some hydrogen forming water was carried off while the remainder of the hydrogen and some of the carbon, combined as a gas or in different gases (see page 287 July, 1892, number of The Colliery Engineer), escaped into the strata where it was collected in the pores or in cavities.

93. Is the natural gas, then a remnant of the coal changes?

Yes, it is, and is found in the vicinity of the coal regions. A few geologists believe that fishes furnished the oil.

94. Does the gas cover a large territory?

It is found in a greater area than that of oil. And by the finding of new wells the district is extending. There are 500 gas-wells in the oil country and its vicinity and these produce 100,000,000 cubic feet per day.

95. At what depth is gas found?

The depth is 2200 feet or so, though of course it varies.

96. Is there any connection between the gas and oil?

Yes, Mr. C. Asburner who is the authority says they are the same in a Geological sense. (See also p. 145, February, 1892, number, also the illustrations.)

97. Where does the gas occur, geologically speaking?

It is found in the flat or nearly flat beds of three different sets of strata. The most productive wells are in the Devonian sands. (See Q. 18 Geology). It is found in the lower Silurian limestones. It is in the Bradford and Sheffield sands and 1500 feet below the Pittsburgh coal. In no case, however, does it occur where the rocks are broken up badly or where the strata are not porous. We find oil and gas in the Cretaceous in Colorado.

Fig. 14.

98. Why is the oil in a given stratum?

Because the rock B is porous and has a floor A of clay. If now the rocks above are so badly cracked as to allow the oil to flow in from above, the oil will accumulate in just the same way as the artesian well waters do, Fig. 14. When a hole is drilled to the porous stratum, the oil, gas, or artesian water, according to the region, will flow out.

99. Does the natural gas occur in the same way?

The stratum is there overlaid by a roof or cover of impervious material like clay, and the rocks below are broken or porous enough to let the gas rise as high as it can.

[TO BE CONTINUED.]

METHODS OF MINING.

Shaft Sinking—Tunneling—Systems of Working Coal and Metals—Timbering in Mines.

68. What is the best method of supporting the roof besides timbering?

The important one is by filling the excavation with rock waste.

69. What is this method called?

The name varies with the other conditions. For example, coal, clay, and ore may be mined by "Longwall", which you shall see, is one variety. Then the iron mines of Lake Superior and many lead mines in the old country are worked by a method called "caving," or one called "filling." Then in silver vein mining, the methods include a kind of filling. So no one name can be given to it.

70. What is the idea?

In "Longwall" and in "caving" the idea is to break and "hew" ore over as large a face as it is safe and then to let the roof cave behind the miner as much as it would. No effort is made to support it. These methods require a bad roof and a brittle hanging wall.

71. Suppose the roof is strong?

If the roof or hanging wall is strong and will not break, then these methods will not do. Unless the roof caves you cannot work by "Longwall" with any degree of safety.

72. What is the "filling" method?

That is where the roof is too firm to break and cave and rock is quarried above and lowered into the mine to fill up the rooms as fast as the ore is mined out. It is cheap and very safe.

73. What is the method in silver mines?

It is not often that the vein carrying an ore of silver has only silver minerals in it. For then the silver would be as plentiful as coal, for example. But a vein which is about four feet wide will have in it a streak or two which may not be over a few inches thick. All the rest of the four feet is filled with quartz, or spar; and they are worthless. Now, we shall see that in vein mines then, only a little of the mineral is taken away and hoisted to the surface, while all the rest is left. Sometimes it is all shot off and broken to be left on the stulls (see Question 39), for support between the walls. Or sometimes if the vein does not happen to have enough of this waste rock to fill up the rooms that are mined out, the hanging wall is shot down to help fill up.

74. Then the only idea is to so use the waste rock as to save timbers?

Yes, even in the pillar and bord method, you throw the waste rock behind you and try to pack it into a place so as to hold up the roof. The waste is called gob in coal mines and gangue in metal mines.

75. What are the methods of mining and upon what do they depend in making a choice?

The choice between the various methods of mining depends upon the thickness of the vein, the dip of it and the strength of the roof and ore. A hard ore, whether thick or thin may be mined by any method almost, but a soft ore can only be mined by caving or by square setts (see Q 64). Otherwise the method of mining depends upon the dip and the thickness of the vein. A very steep vein, and thin, can be mined only by overhand method—the underhand method is no longer used. A very steep vein, that is also thick, may be mined by "filling" and by square setts. A vein of moderate dip and medium thickness may be mined by the bord and pillar. A quite flat vein of not over 6 feet thick can be mined by "Longwall," while a vein over 6 feet thick and flat may be mined by bord and pillar. Panel working is used for coal seams that have much gas.

76. Is the vein worked all over at the same time?

Oh no. It must be "blocked out". That is the vein is divided into sections, or lifts. And one lift is worked at a time. After the shaft has reached the vein, or where a slope is on the vein, gangways are driven along and in the vein for some distance. In coal mines they are always in pairs. One is the return air-way and the other is a haulage way. In metal mines they do not drive any return air-ways, so there is only one gallery, which they call a drift.

77. How far apart are these galleries?

If the dip is steep, they are about 100 feet apart. If the vein is quite flat they are several hundred.

78. What fixes the distance between them?

The thicker the vein, the nearer together these may be. In large steep iron mines, the drifts are about 60 feet apart. In thin coal seams that are quite flat, the gangways are as much as 600 feet apart.

79. What is the distance between these called?

The part of the vein between the two drifts is called a "stope" in metal mines and a "lift" in coal mines. So stopes are from 60 to 100 feet high and lifts are 300 to 600 feet.

80. How many of these lifts or stopes are laid out?

If you run out the galleries very long, you need not block out more than two lifts at a time. For you will have enough of vein to work out for a long time. Of course you work on both sides of the entry. If the drifts are not run out very long then you must sink the shaft or slope deep enough to drive several galleries on each side.

81. Why do you drive them so long or so numerous?

To open up enough of the vein to have "reserves" for changes in the market demand. When the price is good you will be ready to turn out a great deal. So in veins. As you may know under "Geology" questions, the metal-ore changes very much in value and in purity. By opening up much of the vein, you will have a variety of ores to supply the market with as the demand varies.

82. How long are the galleries driven?

That depends upon the kind of haulage systems to be used. Tramming would not pay if it was over 500 feet. But if you put in a tail rope or an endless rope or even a locomotive you can make the gallery even a mile long. But a mile is as long as will surely pay to haul the coal unless the shaft is very deep. It may be cheaper to sink another shaft further on, than to haul all the coal a mile, or more, to one shaft. When a mine becomes large the entry may not be large enough to allow all the coal to be raised from the ground a mile on each side. Then the operator must sink a new shaft or entry to help out the first one.

83. What is the size of these galleries?

They are made only large enough for the purposes they are to serve. In coal mines they may be wide enough for two tracks and a space for a man to travel along without being struck by the cars. Sometimes the gangway has a row of center props to hold up the cap of the timbers and so support the roof. But this is an exceedingly dangerous and barbarous practice because of the numerous accidents that come from it. A gangway has to do service for a block of vein that is one lift of 300 to 600 feet high by perhaps a mile long.

In metal mines the width of the gangway is only enough for a car track. Usually the width of the gangway, or drift, is fixed by the distance between the walls of the vein. A drift here only does service for one stope of 60 to 100 feet high and rarely over 1000 feet long.

Along metal mine drifts the haulage, or tramming is by hand; while along coal mine gangways, cable rope or even locomotives may be the source of power.

The height of gangways in coal mines is fixed by the thickness of the seam. It can hardly be less than 4 feet for mules or men and need not be over 7 feet. If the roof is good it may not be objectionable to rip into it to get height sufficient for tramming. If the roof is poor it is not usually cut into. In some few cases the floor may be cut away. Generally, however it is best to avoid cutting either roof or floor, if one can. In metal veins the height of the drift is about 6 feet 6 inches because there is no objection to cutting into the vein matter.

84. Is a vein or seam ready for attack when it is divided in this way?

Yes. To review, we have reached the vein or seam and driven out a number of galleries, quite horizontal, which have between them blocks of mineral ready for mining. A metal mine has several stopes opened out, (see Q. 81) but coal operators do not run out more than one lift at a time, because the coal is so even in nature and value that "reserves" are not needed and besides the keeping up of several galleries is expensive. So the next lower lift is not started until the one above is exhausted.

[TO BE CONTINUED.]

POWER IN MINING.

The Elementary Principles of Mechanics—Steam—Boilers—Engines—The Machinery Employed in Mines.

How does the fusee or conical drum work?

It is an arrangement for making the work of the engine as uniform as possible. It is used single where the object is merely to equalize the engine work. In Fig. 14 is a side view of a conical drum, from the small end of the drum the rope A and its load is hanging. Then the leverage is the radius of the small end: if the rope weighs q pounds per foot, the cage and car weighs c and the load weighs W, then the weight hanging from the small end, down the full length, D, of the shaft is $c + W + q D$.

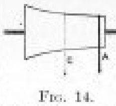

FIG. 14.

This multiplied by the lever arm, r, gives the moment of the weight. To make this constant then this product must be constant for any position of the cage in the shaft. But the length of rope is decreasing. To balance that, the lever arm must increase so that when the cage is at a point half way down the shaft we have

$$(c + W + q D) \text{ times } r = (c + W + q \tfrac{1}{2} D) \times R.$$

So, R, the radius of the drum at that time (C, Fig. 14) is known, when the weight of your cage, load, and rope are fixed upon.

64. What then should be the size of the drum for a one inch rope with a cage and car of 2,500 pounds?

A one-inch steel rope weighs about 1·6 pounds per foot. Assume a shaft 600 feet deep, then the rope, weighs, q D, 960 pounds. A car usually holds about twice the coal that it weighs. So that the weight to be hoisted is 2,500 + W + 960 pounds. Now the smallest allowable diameter to a drum is 40 times the diameter of the rope. That is the drum cannot be less than 40 inches across at its small end. This makes the radius of the drum 20 inches.

(3460 + W) × 20 must balance the rotational power of the steam on the crank arm. At the other end of the drum, the lever arm of the weight is R, from it are hanging only the cage car and load, or 2,500 + W, so

$$(3460 + W)\ 20 = (2{,}500 + W)\ R$$

and if W is a ton of 2,000 lbs., R becomes 24·3 inches The deeper the shaft, the larger R must be for a balance.

65. How would you proceed to calculate the power of a hoisting engine?

Always calculate the least power the steam has on the crank arm for the engine may stop on any point of its revolution, see Question 34, and it must be capable of starting from that same position. As a single cylinder would be unreliable the double cylinder is used as in Question 56. Then you must calculate the smallest power of the double crank arrangement as in the table given below.

66. Please explain the table.

The first column has the amount of cut-off which the engine valves are set to. For example a cut-off of

TABLE OF ROTATIONAL POWER OF STEAM UPON THE CRANK PIN.

(Including 7% clearance and excluding compression.)

Ratio of apparent expansion.	$l = 4\frac{1}{2}\ r$		$l = 5\frac{1}{2}\ r$		$l = 7\ r$	
0, no cut-off.	·5615	·3974	·5600	·3974	·5589	0·3974
⅞, cut-off.	·4964	·3553	·4606	·3288	·4586	·3096
¾, cut-off.	·4380	·2172	·4365	·2499	·4353	·2350
⅝, cut-off.	·4256	·1878	·4193	·1923	·4124	·1966
½, cut-off.	·3926	·2469	·3818	·1473	·3736	·1542

Co-efficient given is to be multiplied by $P k^2 s$

½ means that the steam only enters for ½ of the stroke when the supply valve is closed until the piston reaches the end of its stroke to return.

The other columns are in pairs. The first pair are for a connecting rod 4½ times as long as the crank, the second where it is 5½ times, and the third pair where it is 7 times the crank length. The first column of each pair gives the greatest steam power that the crank arm receives while the second column gives the least power and the one you must figure for.

The co-efficient is the same, for any boiler pressure or size of cylinder. So you must multiply that found in the table by $P k^2 s$ where P is the pressure of the steam as it enters the cylinder, k is the diameter of the cylinder in inches and s is the length of the stroke in feet.

For example, a ½ cut-off engine, 80 pounds of steam, duplex cylinders 16 × 20 having a connecting rod of 70 inches long will give a co-efficient from the table of 0·4124 as a maximum and of 0·1966 as a minimum (the connecting rod is 7 times the length of the crank, 10 inches.) These two give us therefore

$$0{\cdot}1966 \times 80 \times 256 \times 1{\cdot}666 = 6710 \text{ pounds.}$$

$$0{\cdot}4124 \times 80 \times 256 \times 1{\cdot}666 = 14076 \text{ pounds.}$$

On a conical drum directly connected having (as in Question 64) radii of 20 inches and 24·3 inches, the engine could in the weakest position raise a weight, W, = 566 lbs. from the small end and of 820·8 lbs. from the large end, because (reducing 20 inches to feet)

$$6710 = (3460 + W)\ 1{\cdot}666$$

Whence

$$W = 566 \text{ and } 6710 = (2500 + W)\ 2{\cdot}02$$

Whence

$$W = 820{\cdot}8$$

67. That is a small load is it not?

Yes, the case results in a small load, but it shows forcibly the influence which the dead weight of the rope, cage, and car has in the effective work of the engine. These should all be very light and then properly proportioned to the weights to be carried.

68. What would be the difference if there were two such conical drums on the same shaft arranged so that while one is hoisting the other is lowering?

The result in that case would be very beneficial. Assume just the case mentioned. Then, while the (3460 + W) has a lever arm of 1.666 feet, the load (2500) is hanging from the 2·02 radius of the drum to turn the drum with the effort of the engine and thus assist it. This leaves for the engine to do only (3460 × W) 1·666 − 5050 = 716 + 1·666 W.

So that the engine could start, even from its weakest position, a weight of 3,600 pounds. So you can see the benefit of a balance like some of those mentioned in Question 58.

69. How is it with reels?

They are only used for flat ropes, where the first coil winds on the small axle of the reel and after that each successive turn winds the rope on its predecessor. The result is that the lever arm of the weight at the start is small, but increases with each revolution of the reel until at the top, the weight is winding on a big circle. It is practically the same as with a conical drum. (See also page 115, of December, 1891, number of THE COLLIERY ENGINEER.)

70. Is that the object of the flat rope?

Partially so. It saves a long drum, and is safer to wind. But it gives trouble by slipping off its coil and down between the other coils and the arms, where it wedges tight and often breaks.

71. Are engines measured in any other way?

Oh yes, you will hear them spoken of as so and so many horse power. Long ago Watts set a number of horses to lifting weights by means of pulleys and averaging up their work, he found that a horse could raise 150 *pounds* at the rate of 220 *feet* a minute. It was also found that with other machines a single horse would lift, each minute, 1,000 pounds at a speed of 33 feet a minute. Tested by various appliances, the result was always the same that the weight lifted multiplied by the speed was 33,000. So 33,000 foot-pounds was called the work or power of a horse. Any machine or appliance that gives 33,000 foot pounds in a minute is said to give one horse power, sometimes written H.P. No matter how slow, or how fast, the product of the speed and weight measures the work. A given engine, machine, or animal may, by suitable arrangements hoist fast, but the load is correspondingly less. Remember what was said in Question 23. What held true of the "balance" of moments is also true of the equilibrium of work. The general principle is known as that of the conservation of energy.

72. How does this apply to the example in Question 19?

There 50 pounds at B balanced 150 pounds at C. The work done by the lever was to raise the weight. Now if that weight is lifted 2 inches or ⅙ of a foot, the work done is ⅙ times 150, which is 25 foot pounds; expressed as ft. lbs. To perform this work, the force of 50 pounds at the other end had to pass through ½ foot. The measure of the work of the force is 25 ft. lbs.

73. Is the foot pound, (ft. lb.) the unit of measure of work?

Yes, it is called also a dynamic unit. (See page 163, of the February, '92, number.) In this unit all work is expressed, sometimes the work is also measured in time; for example, the work done would be the same no matter how long it took you to raise the weight. If you did it in a minute, you are stronger than one who required 3 minutes to lift it. So in comparing power it is necessary to refer the work to some unit of time—a minute is the standard.

74. Will you cite some instances of powers?

The average man on a windlass can, in a minute, do 5,300 ft. lbs. of work, a horse on a canal averages 28,000 ft. lbs. per minute, a mule hauling cars gives the same work.

A trammer is capable of about 3,240 ft. lbs. per minute. A water-wheel may give out as much work as is equal to the weight of water used multiplied by the height of the fall.

[TO BE CONTINUED.]

ANALYSES OF COAL, ORES, ETC.

Instructions in Sampling and in Making Analyses to Ascertain the Quality and Value of Coal, Ores, &c., &c.

The Amount of Carbonic Acid in Air.—This may be found, approximately, by putting into a glass stoppered bottle, one-half an ounce of dilute lime-water, tinted with phenolphthalein, and if on opening the bottle in the room, the color remains as it was, there is less than ¼ of one per cent. of the choke-damp. If the color disappears rapidly, there is more carbonic acid than 1 in 400 of air.

The only other method that is simple consists in filling a bottle that will hold about a gallon (its volume must be carefully measured) with the air to be tested. Pour into it 100 c. c.* of lime water and shake up for some time; add phenolphthalein and it will color the solution so long as there is any hydrated lime present. Now add of a standard solution of oxalic acid till the color is gone and note how much solution it requires. Every 1 c. c. of the solution corresponds to 0·012125 grain of carbonic acid.

So that if it required 108 c. c. of the solution there were 1·31 grains of carbonic acid.

Now take another 100 c. c. of the same lime water as used before, and add the same amount of phenolphthalein. Also proceed as above to add of the standard oxalic acid solution till the color is gone. Note the amount and calculate as before. Suppose it required 70 c. c. of the solution. Then that corresponds to 0·848 grain of carbonic acid.

The difference between the two readings, (0·462), gives the amount of carbonic acid in grains which when multiplied by 48·4 gives the number of cubic inches of the gas in the given bottle. For greater accuracy this should be reduced to the zero of temperature and normal pressure of 30 inches of barometer.

Having now the number of cubic inches of gas in the known volume of the bottle it is a simple matter to

*All measuring flasks and burettes (dropping tubes) are divided up into French measure instead of English measure. A c. c. is a cubic centimeter, that is, a cube whose sides are the one-hundredth of a meter in length. A meter is 39·37 inches long. So a cubic centimeter is 0·0610 cubic inches.

determine the percentage of gas in the given sample of air.

Assaying of Ores.—Just as the analysis of coal proceeds in miniature as does a coke oven to ascertain the fixed and volatile compounds, so assaying similarly treats ores to ascertain their behavior in the smelting furnace as well as the amount of silver, lead, etc., that they will produce when melted. We distinguish the terms analysis and assay from one another by embracing in the latter term all methods which require the high heat of a furnace. Analysis is a term the chemists use for the wet processes, or those involving filtering and the use of liquids.

An ore contains several metals of iron, silver, lead, copper, etc., the amounts of which may be determined by the dry (or fire) method, or, with greater accuracy, by wet methods. The former is preferred because it is quicker, and resembles the smelting process. There are in the main two fire methods, one employing a crucible and the other a scorifier shown in Figs. 7 and 7*a*. These receptacles are both of clay but the crucible is coarser and heavier than the scorifier which is a soft smooth fire-clay receptacle, not as deep but broader. The crucible is of sand, in form round or triangular, and of sizes from those 2 inches high holding, perhaps, 2 ounces to those holding a gallon. These crucibles are sometimes called "Hessians."

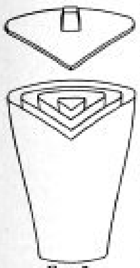

Fig. 7.

Fig. 7*a*.

In the crucible the operation of assaying follows the principle of smelting the contents to metal which is then weighed. In the scorifier the operation is rather one of roasting—that is driving off all the volatile substances. It is broad and shallow exposing a large surface of the molten contents to the action of the air. All the operations of assaying the metallic value of an ore are conducted in one or other of these dishes.

The assayer must be provided with a suitable furnace within which to perform the fusion. Fig. 8 shows the three veiws of the best form of assay furnace. It is made of common brick, with fire brick lining at the places, exposed to the flame. As seen, it is merely a brick shaft having a fire grate, *c* near the bottom opposite to which is a door, *a*, for feeding coal, an opening for the "muffle" and a vent *d* connecting with the chimney. The draught ought to be strong—at least 10 feet of chimney; soft coal may be used. Upon the ledges marked *b*, *b*, the "muffle" rests. This furnace can be built for \$25.00.

Fig. 8*a*.

A muffle is a fire clay cylinder about 14″ long and having a cross-section the shape of a capital ⌂, Fig. 8*a*. One end is open and faces the front while the other is closed except for a small vent. The crucible or scorifier is placed inside of the muffle which is kept red hot by the flames of the coal burned below. A muffle 8 inches wide × 14 inches long is the best size for all around work and will allow 3—2½-inch scorifiers to stand side by side. A muffle with care will give a month's service.

When the muffle, *m m*, is placed on the supports and in position there should be at least a 3-inch ledge in front, the space between the muffle and the brick is stopped up with a cement made of fire-clay 4 parts, sand 1 part, and some water.

The tools required by the assayer are: 1 pair crucible tongs, Fig. 9.

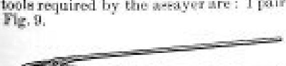

Fig. 9.

2 pairs of scorifier tongs, Fig. 10.

Fig. 10.

2 pairs of cupel tongs, Fig. 11.

Fig. 11.

1 small shovel scraper, Fig. 12.

Fig. 12.

The latter is an emergency tool for sprinkling sand upon the muffle floor when a scorifier has been upset or eaten through; and also for scraping off the fused mass as soon as possible.

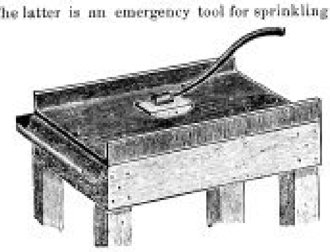

Fig. 8*b*.

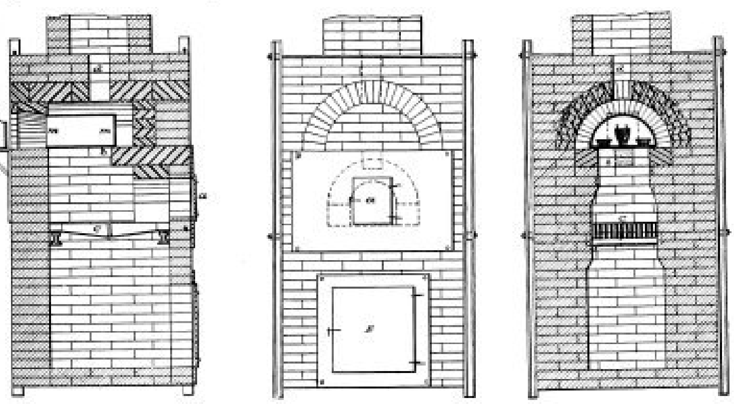

Longitudinal Section. *Rear Elevation.* *Cross Section.*

Fig. 8.

For grinding ores, a mortar and pestle might be used but the most rapid crusher is the combination of a large heavy cast-iron plate 18 x 24 inches 1 inch thick and a cast iron grinder about 5 inches square and about 3 inches thick, Fig. 8*b*. The lower face of the box is convex. A handle is set into an eye at the top. The ore to be ground is broken into small pieces and then the grinder, held by the left hand and the handle by the right, is rubbed over the smooth surface of the plate and pulverizes the ore quickly and easily.

The ore is always sifted through a sieve with 100 holes to the inch. The sieve in two parts is preferable, that is a tin box about 8 inches diameter, into which fits a tin cylinder with a sieve bottom. The ore is thus sifted through the sieve into the box below without dust or loss, Fig. 13.

Fig. 13.

The assayer should also have an iron mould receiving scorifications. This is a heavy casting into which are several cup-shaped cavities, Fig. 14.

Fig. 14.

With a supply of the articles mentioned the assayer is ready for business, though there are several other articles to be purchased. These will be suitably discussed in place.

[to be continued.]

VENTILATION IN MINES.

Including a Description of the Gases Met With in Mines and the Atmospherical Conditions Necessary to be Known to Understand the Laws of Ventilation.

47. Suppose the case of a furnace in a 400-foot shaft and the mine drag is 2 inches gauge, how hot must it raise the air?

2 inches gauge = 10·368 pounds pressure between the two columns of 400 feet each. The difference in weight per cubic foot must therefore be 0·02592. Air at 60° F. weighs 0·0766 pound. So the light air must weigh 0·0507 pound per cubic foot. To attain this the air must be at a temperature of 320° F.

48. Is that the same method of figuring as with a fan?

Yes, you know the difference is only one of pressure, not of temperature. For example, in the formula given in Q. 45, *t* is 60° Fahrenheit usually. Then W becomes 0·002553 B and the difference between the weights of a cubic foot of downcast and a cubic foot of upcast air would be equal to 0·000186 times *g*, the gauge reading. A fan producing an exhaust equal to 2 inches (it is also called a depression of the water-gauge of 2 inches), makes the upcast air lighter than that in the downcast by 0·000372 pound per cubic foot.

49. Is the difference in the weights of the air in the two shafts the only cause producing draught and ventilation?

Yes, that is all. The product of the depth of the shaft by the difference between the two weights is called the motive column,—that which causes the draught.

50. Is not there a natural method of ventilating, which requires no machinery?

Yes, by having the two outlets at different levels and depending upon the difference in weights of the warm mine air and the air outside, but it is not reliable nor safe. This plan is only used in the metal mines, and not in the coal mines.

51. Does it furnish as good ventilation?

No. The current is not always in the same direction; and in mines having bad gas this would be dangerous. One time the air from outside would come down the entry and then go along the workings to the upcast. At another season the air would be in the opposite direction and go along the workings first. In the spring and autumn there would be no current.

52. Would it make any difference which way the air moved?

Yes, it would, because at one time the goaf gases would be swept into the mine by the current; at another they would go out and give no trouble.

53. Is the air good in metal mines?

There are no coal gases to spoil the air, but then there is very little fresh air taken into the mine. The air in the metal mines is more impure than in coal mines because no current is supplied and the dead air is not washed out.

54. What do you mean by dead air?

Air is composed of two gases, called oxygen and nitrogen. If air contains no oxygen it cannot support life and nothing can live in it. It is dead air.

55. Is there much oxygen in it?

Under any conditions and in any place you gather it, pure air has 21 parts of oxygen and 79 parts of nitrogen.

56. What is oxygen?

It is a colorless, tasteless gas that is essential to the burning of fuel and to life of any animal.

57. What is nitrogen?

That is a gas that simply has no influence upon life, one way or the other. It appears to act only as a dilutant—to prevent the air being too rich.

58. Then air is good or bad according as it has much or little oxygen in it?

Yes, that is true to a certain extent. But the air may be bad if it has other gases in it. When you step into a room you say its air is bad when you may mean that there are other gases in the room besides oxygen and nitrogen.

59. What are the other gases?

There is always some carbonic acid (choke-damp) and there may be some sulphureted hydrogen. In coal mines there is also more or less marsh gas (fire-damp).

60. What is carbonic acid?

It is a gas that weighs more than air and is the product of all decomposition. We breathe it out from our lungs, so do animals. Timber and coal, while rotting, give out the same gas. It is the gas that comes out of the stove from burning fuel. You will always find it near the floor or in the bottom of old workings. As this gas is very poisonous, no one should go into it. Only a small amount of it in the air will poison a person. You never feel it if you are breathing it until it is too late to help yourself. It makes you very weak and finally kills. Old workings should, therefore, never be entered until they have been tried by a candle. If the candle or lamp will not burn in it, keep out of the place until the place is ventilated. If you want to test the air in another way, do this: Fill a bottle outside with water. Go into the room, turn the bottle upside down and as the water runs out, the gas will bubble up into it. Cork the bottle and when you get up above, pour into the bottle some clear lime water. If the fluid becomes milky, then carbonic acid is present.

61. Will carbonic acid only gather near the floor?

Yes, so long as it is undisturbed. If a current of air be swept through the place the carbonic acid will float off with the air.

62. What is sulphureted hydrogen?

A heavy gas that has a rotten egg odor and is very poisonous. It comes from the pyrites, or mundic, that you find sparkling in the coal, like gold, some call it fool's gold. This gas cannot be produced unless there is also some heat. So if ever you smell it, be sure that you do not breathe it long and also be careful that the goaf or room in which it is be thoroughly ventilated. If it is not ventilated, the heat may start a fire in the slack.

63. Is this also found near the floor?

Yes, the two I have mentioned are the only two heavy gases produced in a mine.

64. What are the light gases?

Some say there is formed a little carbonic oxide that you call "white damp" but the main gas of collieries is the fire-damp.

65. What is fire-damp?

If you remember Q. 8 under Geology, I spoke of the miasma of swamps, that is called marsh gas. The marsh gas collected in swamps, some later, gathered in the rocks and is now called natural gas and some stayed in, or near the coal and is called fire-damp. This fire damp also comes off from the burning of coal and produces the chimney smoke. (See page 66, October, 1891, number.)

66. Is there much of it in coal?

Underground, it is found in big caves or chambers that suddenly burst into the mine; it collects in the pores of the coal or in crevices. The amount can never be estimated. It is always found in the coal mine, and is always feared because you never know when a great deal of it might be thrown out.

67. Is it poisonous?

Yes, it is not wise to breathe it but there is a still more serious objection to it. It explodes.

68. Where is it most often found?

Near the roof, and always at the upper portion of any cave or nook. Just under the platform it collects, too, so that it must be watched for everywhere.

69. How may we know of its presence?

Sometimes it comes out from the coal continually with a low hiss as a "blower." At other times, there is no sound at all. The several ways of testing for fire-damp is by the way a candle or lamp flame behaves in it. If there is very little gas, the flame does not show it but as the amount is large, the flame will become long and the cap of blue grows long too. When the flame is all blue and can hardly be seen, there is a very dangerous amount of gas in the air. When you find the lamp flame shows blue, *don't blow it out*, but first lower it slowly toward the floor and leave the room. (See page 163, February number).

70. What does the blue cap mean?

That there is enough gas in the air to take fire and almost enough to explode.

71. What causes the production of gas?

It is always escaping from the coal. A little would not be very serious, but it is the sudden production of gas that we fear. The falling or sqeezing of a part of the roof, the creeping of the floor, the crushing of a weak pillar or the falling of the barometer outside will force a great deal of gas into the workings.

72. Is there no means of preventing this?

None whatever. There is no prevention, but there is a cure, and only one—a very strong ventilating current.

73. Is not the use of the safety-lamp a good cure?

It is a partial cure. That is, a mine not using safety-lamps is very likely to have more accidents than one using them. But still, even in the latter case, the only remedy is to have a very powerful pressure and plenty of good air.

74. Why is the safety-lamp not good?

Because, first, none has yet been invented that gives a good light and also prevents the air current from blowing the flame against the iron wire gauze. Secondly, because there is no lamp that can be locked so that a miner can not open it. Thirdly, because the miners themselves will insist upon prying it or breaking it open. The first trouble has been nearly perfectly remedied. The second has not been and the third will not be until the fool-killer's work is done. I do not blame a miner for wanting a good light to watch the roof and to protect himself against falls but too many open the lamp to light a pipe. A perfectly secure lock on the lamp or a light so arranged as to go out if pried open are the only safe-guards against the men who risk the mine and all their fellow laborers for the pleasure of an hour's smoke.

[TO BE CONTINUED.]

SURFACE APPLIANCES.

The Preparation of Coal and Ores for Market.

71. Why must the ore be broken so fine?

The lead, zinc, or silver minerals occur in such small crystals and all scattered through it. So the rock must be broken up fine enough to release all the material. This will give you clean broken quartz or galena free from quartz. Coal is not broken any finer than the demands of the market require, but here we must separate, by crushing, the different minerals from one another.

72. Then does the size of the minerals in the rock fix the fineness of the crushing?

Precisely, and this is accomplished better as the rock is softer. Quartz is so very hard that we can not get a perfect separation. The loss of mineral sticking to the lumps of quartz is what makes the process less perfect than coal washing.

73. Is the sizing done in the same way as in coal?

Yes, the broken mineral is raised by an elevator to a hopper in the top of the mill or else, if the site allows it, the mineral goes down a chute to the screens (see Q. 30). In any event, the broken stuff is now screened just as I explained in Q. 32. Only the screens are not cylindrical, Fig. 5, but conical, Fig. 6.

74. What is the advantage?

The screens must be inclined so as to deliver the coal freely at the bottom. Now, a cylindrical screen can not get this without bevel gearing or a chain of some sort. This additional machinery is wasteful of power and is expensive. A conical screen may have its shaft level and, so, can be directly connected with the line shaft. But in the metal mines we use conical altogether.

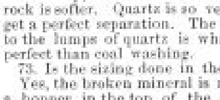

FIG. 5.

FIG. 6.

75. Then is the rest of the process the same as with coal?

Yes, but a little more complex, as explained in Q. 54. The screens give a more, or less, imperfect sizing of the stuff. Each screen delivers to its own jig and each jig treats a certain sized stuff. The jig, Fig. 1, (April number) will clean the stuff which is continuously delivered on the sieve B. The heavy stuff collects on the bottom of the sieve while the light is forced to the top. Here, however, it is the waste which is the lightest and which is washed off at the tail board. So the quartz is cleaned off from the metallic ores, while the heavy is collected, at A, Fig. 1.

76. Do not you separate the lead ore from the zinc ore, and that from silver?

Oh, yes. This is done by repeated operations in this way. As pyrites is heavier than slate, and slate heavier than coal, you could, if you wanted to, not only separate the clean coal but also, afterwards, separate the slate from the pyrites by similar operations. But the last two do not pay so of course no attempt is made to separate them. The same is true with those you mentioned. Quartz is lighter than pyrites, and pyrites does not weigh as much as zinc blende: Zinc blende, or black jack, is lighter than lead ores (galena, for example) and galena is lighter than silver ores. Now, as explained in Q. 42, the more water, you use, the more stuff it will carry off. So we could use a great deal so as to carry off all but the silver ores, or we could carry off all the material that is lighter than the lead. Then afterwards we could separate the lead from

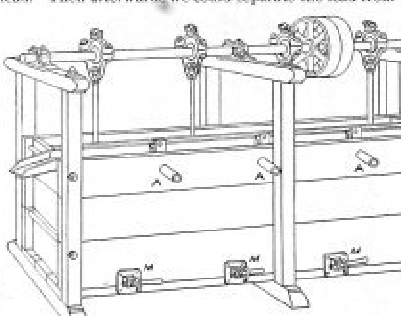

FIG. 7.

the silver and also in other machines, the zinc blende from the pyrites. That is what they do in the old country. Separate all the minerals from each other because they are all salable. Here, it would hardly pay. So we draw the line at the lead ore.

77. Then you mean that you arrange the jig so as to collect all the lead and the silver on B, Fig. 1, and wash off the tail board all that is lighter than the lead?

Yes. But remember these are not perfect machines so that we can not collect *all* the lead and silver for some does escape. Some floats off, being exceedingly fine, while more is lost by sticking to the quartz and pyrites. Most of it is caught, though.

78. Are the lead and silver discharged at A, Fig. 1, like the pyrites from coal?

Very much like that. There are many schemes for removing the "concentrates," as they are called as soon as they are made. The tailings are washed off into the jig next alongside as was mentioned in Q. 53. In that they are again treated and some lead is recovered, but of course it is not much. Sometimes even the third jig gets some of the lead.

79. How is it that the third or even the second jig can get any thing out of the tailings which are already washed?

Because usually the pistons of the others are set a little slower so as to get what had escaped with the quicker piston of the first jig.

80. Does any of the zinc ever collect in the first?

No, generally the object is to get very clean lead. The second jig has considerable zinc blende, or "jack" but little pyrites. The third will have hardly any galena, less zinc, and much pyrites. The fourth jig has a bad mixture of them all. That which escapes off the tail board or the fourth, is very poor, but has some valuable mineral in it. In Fig. 7 is an illustration of the four jigs with their discharges shown at A for the coarse and at M the fine concentrates.

81. Is this variety of jig used for any variety of ores?

Practically any mixture of mineral may be concentrated by jigging, provided there is sufficient difference in the specific gravities of the various minerals. The effectiveness of the separation depends upon the cleanness with which the various minerals break. If the ore can not be crushed perfectly enough to free the galena from the blende and the pyrites, there must be some of the valuable material lost because of its adherence to large particles of the quartz or spar, which washes away.

82. What becomes of the tailings?

They are re-treated by being subjected to another, and finer crushing to further liberate the adhering particles of valuable mineral after which washing is effected upon another variety of machines similar in principle to those aleady mentioned.

[TO BE CONTINUED.]

The Ingersoll-Sergeant Drill Co., of No. 10 Park Place, New York, has opened a branch office under the firm name of Parker, Melcher, and Ingraham, at 100 to 104 West Washington St., Chicago, Ill., where a complete outfit of machinery manufactured by the company, such as Air Compressors, Channelers, Rock Drills, and all Mining, Tunneling, and Quarrying Machinery with duplicate parts will be kept in stock.

Economy at the Steam Plant.

There is no portion of an American colliery where there is more waste and consequently more money lost than at the steam plant. Many operators and superintendents pay no attention to this waste, as they think it is entirely a waste of fuel, which is naturally cheap at the mine. But this is not the only waste, though it is bad enough, because every ton of fuel burned has a market value, and all burned in excess of actual need is loss. The waste also includes long lines of steam pipe of larger size than actually needed, and either more boilers than are needed, or loss from delays caused be lack of steam power at the point of utilization, even though the boiler plant is large enough. The waste is entirely due to the condensation of the steam between the boilers and the point of utilization. There is no excuse for this waste, because there is an efficieny remedy, and one that is really not expensive when properly considered. This remedy is a good non-conducting steam pipe covering which can be easily and quickly applied to the pipe, such as the Carey Standard Asbestos Removable Covering. It is one of the most perfect sectional removable coverings made, and is unexelled in its efficiency and convenience.

It is composed of Asbestos fiber and a very light cementing compound, thoroughly intermixed, after which it is moulded into sections 3 ft. long, and to fit any size pipe from ½ to 12 inches in diameter. It has a firm and hard exterior, while the interior is filled with minute air cells, which confines the air within the body of the covering. This is the most practical way of accomplishing the best results of an air space or air-chamber and forms the best non conductor and heat-retainer known. It is first wrapped with woolen felt cemented to the outer surface, and then covered with a heavy canvas, the whole forming a most excellent covering, complete and ready for use. It combines all the qualities essential in a good pipe covering. It retains heat, excludes cold, prevents condensation of steam, is light and durable. It is both fire and water proof, and is easy to apply. It will not corrode, eat, or injure iron surfaces, nor will it shrink or warp out of shape, and thereby leave openings for the escape of the heat. It is also absolutely indestructible by heat. As it is necessary at all collieries working below water level, to carry steam to pumps, and other machinery, often situated many hundreds of feet from the boilers, a good pipe covering is not only a good investment, but is an actual necessity. For by its use dry steam can be conveyed to the pump or other engine with sufficient expansive power to do the work required, and the covering by keeping the heat where it belongs, in the steam pipe, will protect timbers from rot, and the roof from disintegration.

A few of the advantages resulting from the use of this covering may be summarized as follows:

You can convey steam or hot water to any point no matter how far distant from the boilers.

You work dry steam in your engine cylinders and thus avoid all risks of accidents or breakdowns.

You save wear and tear on your boilers, etc., by avoiding the necessity of excessive firing to keep up the requisite amount of steam.

Your grates will not require renewing as frequently as formerly.

Your engine will run nice and smooth and give better results in developing power.

The cost of keeping your steam plant in good repair will be decreased.

It increases the efficiency, insures the safety, and decreases the expense of operation of any steam plant.

This covering is manufactured by the Philip Carey Manufacturing Co., 117 to 125 Gilbert Avenue, Cincinnati, Ohio, who also manufacture special coverings for ells, tees, crosses, and globe valves, though an asbestos cement, which they make is also frequently used for covering fittings, as it makes a very neat and complete finish. It will pay all steam users to write to the manufacturers for catalogue and descriptive circulars.

Important to Prospectors for Coal or other Minerals.

The diamond bit rock drill that furnishes a core of the material through which it bores, is naturally the best machine for prospectors' use, and is the only machine that will furnish information on which positive statements can be based. Most types of diamond drills, however are expensive and require steam, compressed air, or electricity to work them, and the question of, power is a serious one when the prospectors means are limited, or when the hole to be bored is not very deep, and the land owner or prospector does not care to expend a large sum of money for the desired information. To meet the requirements of such persons, the Hasenzahl Portable Diamond Bit Rock Drill, for hand or other power, was designed. It is simple, durable, cheap, and portable, and can be operated by any person of ordinary intelligence. It has been in use in all parts of the continent for several years and has everywhere given perfect satisfaction. The inventor and manufacturer, Mr. Wm. Hasenzahl, 135 West Second St., Cincinnati, Ohio, will cheerfully send descriptive circulars containing complete descriptions of the drill, with price-list, and testimonials from users to any person desiring to purchase a drill, with a capacity up to 500 ft. of depth of hole. Mr. Hasenzahl, has also associated with him an expert geologist and chemist of national reputation, and they are prepared to take contracts for prospecting any kind of mineral lands, and for furnishing chemical analyses and assays of any cores.

How to Live

How an Athlete Trains.

The objects which the athlete usually has in view when he begins to train are:

First—To get rid of all tissue, the loss of which will not impair the strength—in a word, the "dead weight" of the body.

Second—To improve the "wind."

Third—To develop the particular sets of muscles to be used in the actual contest, to the highest degree possible.

The first step toward the removal of fat is in a judicious regulation of the diet. The athlete, particularly if he is inclined to take on weight rapidly, diminishes the amount of fat-producing foods. He avoids fat meat, sugar, starch, and butter, and limits his liquid food to a minimum. His bill of fare consists chiefly of lean meat or mutton, varied by poultry, eggs, or fish, stewed vegetables, greens and fruit and jelly or bread pudding for dessert. The bread used should be about twenty-four hours old. For drink weak coffee or tea, the latter iced, and with a little lemon juice added, is best.

Such a diet in itself will ordinarily reduce the weight somewhat, but, by exercising and rubbing, the fat is removed more quickly. If the athlete is so heavy that he must train off a good deal, he wears a heavy "sweater," or jersey, while exercising, in order to induce perspiration. He must then be very careful not to drink much, else he will regain in a few minutes the weight it took hours of hard work to get rid of.

By "wind" we mean the power of the heart and lungs to do their work properly in spite of continued exertion. Everyone is familiar with the distressful feeling occasioned by unusual and violent exercise. This distress arises simply from the inability of the lungs to supply the proper amount of oxygen to refresh the blood and to get rid of the poisonous carbonic acid gas, the production of which is greatly increased by muscular work, and from the inability of the heart to circulate the blood freely.

It is necessary for the athlete therefore, no matter in what branch of sport he intends to compete, to take as part of his training, exercise that will develop the power of these organs. Running is by all means the best method of developing the wind, and for this reason is practiced not only by the runners themselves, but by oarsmen, boxers, and football players as well.

To develop any particular set of muscles, those muscles must be given a great deal of work. The athlete begins by exercise well within his powers, and then, by gradually increasing the demands made upon the muscles, they become accustomed easily to preform work that before would have been impossible.

He is expected to keep regular hours, to get sleep enough without becoming lazy, to avoid unusual excitement, to get plenty of pure air and sunlight, and is if he is a smoker, to give up tobacco.

A word as to the alleged dangers of training. "Athletes die young," is a warning I have often heard. Of course they do, if after training they plunge into all manner of excesses. But it isn't athletics that kills them.—*Philadelphia Record.*

The Best Exercise.

A celebrated London physician told the great Dr. Punshon, of oratorical fame, that he could extend his life ten years at least by walking a short distance every day.

Looked at from its *physical side* alone, walking is the prince of gymnastics of any kind. We do not mean, however, that rush of fury, that artificial pace which the characteristic impatience of the times has introduced, but the regular, gentle motion of a natural gait, calling many muscles into play, giving the body just occupation enough to leave the mind perfectly free for thought, aerating the blood through expanded lungs, causing the million pores of the skin to breath forth their moisture, the whole organism to glow with health, and discharge its many functions with comparative ease and lightness.

Take that exercise, and you return home with a keen zest for food or work or play, or whatever awaits you, the weary, jaded feeling gone. At night you retire to unbroken dreams, to sleep, deep and refreshing as an infant's.

If some Koch or Brown-Sequard were to discover an elixir half as virtuous as a regular walk every day in the open May air, he would become the blessed of thousands of thousands of grateful hearts. His concoctions would command their own price, and his name would encircle the civilized world; yet here is Nature's own remedy, and, like all else provided by her, free of cost and only needing a persevering trial to insure its own reward.

Again: Walking is not only healthy physically, but mentally. The distractions of the city cease as you move out to the rural scenes surrounding it. Nature instructs you that it was God who made the country, and only man made the town. Her hidden beauties, never seen by the man who rushes through them in an express train, are discovered in rich and rare splendor all around. Distant hills draw near, undulating valleys reveal their lovely hearts. Trees are companions; the grass beneath our feet is instinct with every form of life. We go back, amid the music of the birds and the rushing of the brooks and the murmuring of the winds, to quiet seclusion and peaceful thought.

Thus it is that men's best, grandest, purest moments come to them when they take their walks abroad; but whether, like Dr. Johnson, you prefer the busy city streets, or, like ourselves, the country retreat, your exercise will still be profitable to the entire being.—*New York Ledger.*

Overeating vs. Overwork.

An abuse that tends to the injury of brain-workers is excessive eating. A writer in the *Medical Mirror* recalls to mind several active brain-workers who suddenly broke down, and fancied that it was due to brain fatigue, when, as a matter of fact, it was due to overstuffing of their stomachs. The bodily furnace connected with their mental machinery became clogged up with carbon in various shapes and forms, and as a result disease came, and before the cases were fully appreciated a demoralized condition of the nervous systems was manifested, and they laid the flattering unction to their souls that they had indulged in mental overwork. Hard work, mental or physical, rarely ever kills. If a mild amount of physical exercise be taken, and a judicious amount of food be furnished, the bowels kept open in the proper manner, the surface protected with proper clothing, and the individual cultivates a philosophical nature and absolutely permits nothing to annoy or fret him, the chances are that he can do an almost unlimited amount of work for an indefinite length of time, bearing in mind always that when weariness comes he must rest, and not take stimulants and work upon false capital. The secret of successful work lies in the direction of selecting nutritious food, taken in proper quantities, the adopting of regular methods of work, and the rule of resting when pronounced fatigue presents itself, determining absolutely not to permit worry.

The Treatment of Croup.

To begin with, croup is that terror of all parents whose children are subject to this malady. The mother who has once been roused by the hoarse barking cough so unmistakable in its warning is never likely to forget the thrill of terror which seemed to make her very heart stop beating. No matter whether it be true or false croup, the alarm at the moment is the same, and in neither case is there any time to be lost. If the cough does not seem very tight, and is not accompanied by strangling, begin giving syrup of ipecac in doses of fifteen drops every twenty minutes. Continue this until the child's breathing is relieved, or until he vomits. But should he awake with symptoms of choking and great difficulty of breathing, administer at once a teaspoonful of the ipecac into which has been stirred a good pinch of powdered alum. Should this not cause vomiting in fifteen minutes, repeat the dose, and assist its action by making the child drink a cupful of warm water. Place him in as hot a bath as he can bear—about 100 degrees—and keep him there *at least* ten minutes, spreading blankets over the tub to prevent the water cooling. He should be supported in a reclining position, so that as much of his body as possible may be under water. When he is taken out roll him at once in heated blankets, and put him to bed in a warm but well-ventilated room. He may sometimes be relieved by inhaling steam. If possible get a doctor immediately.

Take great care the day after croup that the child is not exposed to cold. There used to be a comforting theory current that no child ever had croup after midnight, but, alas! time and experience have proved this a pleasant fallacy.—*Harper's Bazar.*

An Easy Way of Giving Cod Liver Oil.

Cod liver oil is a substance that is largely and very properly used in treating lymphatic conditions in delicate and rickety children. It is both a foodstuff (on account of its oil) and a medicine (through the iodine and other elements which it contains). Unfortunately its disagreeable taste prevents its administration, and this taste can be only partially concealed by mixing it with syrup of coffee, Malaga wine, orange juice, or by giving, as soon as it has been taken, a mint drop or some other aromatic preparation.

A process that is quite efficacious, but that is difficult to realize in children, consists in moistening the mouth with a little strong wine, in bolting down the oil, and in ending up with a glass of the same wine, which carries down the remaining portions of the oil.

Attention, however, has now been called to a means which seems to be a good one, and which had already been used by druggists in making emulsions of cod liver oil. It consists in mixing the oil with an equal amount of medicinal lime water. In this way an odorless liquid is obtained, of milky appearance, very like a syrup, to which can be added any aromatic essence, such as mint, lemon or anise-seed as a corrective. Cod liver oil, saponified in this way, has a taste that is almost agreeable, does not adhere to the walls of the mouth, and does not give rise to the rancid and repugnant after-taste that is so disagreeable in the plain oil. The preparation can be kept for a long time, can be easily assimilated by delicate stomachs, and has, furthermore, the advantage of being relatively low in price.

Useful Information

Musical Instruments.

Apollo was the old god of music, and his favorite instrument, the lyre, was invented by Mercury. When the latter was four hours old he found the shell of a tortoise, and made it into a lyre with nine strings, in honor of the nine Muses. This instrument Mercury gave to Apollo, who became a wonderful player upon it. The lyre was used by the Greeks in olden times, and from it was fashioned the harp.

The old time viol was the first instrument of its kind, and furnished the plan for the modern violin, which, however, is seven hundred years old. It is said that Charles II. introduced it into England. One of the finest makers of violins was Stradivarius, of Cremona, who existed in the early part of the eighteenth century. Violins made by him are worth thousands of dollars now, and highly esteemed by collectors and performers.

The flute is very old in its origin, but the flute of to-day is different from that of the ancients. It has been improved upon from time to time, and the old people would probably fail to recognize it now. The flageolet, which is somewhat similar, is credited to Juvigny, about 1581.

The first trumpet was a sea-shell and was used by very old nations. Trumpets were well known in the days when Homer lived, and a Jewish feast of trumpets is spoken of in the Bible, nearly 1500 B. C. Alexander the Great is said to have used a speaking trumpet 335 B. C.

The harp, which was suggested by the lute, is ascribed to Jubal, 3875 B. C., and was King David's favorite instrument. The harp was used by the Welsh and Saxons, and also by the ancient people of Ireland. One of the oldest harps in existence is in the Dublin College Museum, and originally belonged to Brian Boroihme, King of Ireland.—*From Harper's Young People.*

Ventilation.

The healthy atmosphere in a room is one in which the air is changed to the extent of 3000 cubic feet per hour per adult inmate. The air admitted need not be cold; warmed air, so long as it is fresh, is of course preferable to cold air in winter, but in some way the air must be brought in if we are to continue in health. There are various ways of doing this. One is by admitting cold air so that it is directed upward toward the ceiling, where the air of the room is at the highest temperature; the cold stream is then heated in its passage as it falls to the lower level for breathing. But in large rooms, to utilize at its best this current, there should be in the skirting outlets communicati g with a heated upcast flue, which will draw away the heavy air near the door. In cases where there is heating by hot water coils, the cold air may be brought in at or near the floor level and passed through the hot water coils—the outlet for vitiated air being in or near the ceiling—to a heated up-cast flue. In larger rooms or buildings for public assemblies it may be necessary with either of these systems to use a fan, either to propel fresh air into the room or to draw away the vitiated air.

The great desideratum in the admission of fresh air is to cut it up into very fine streams something in the way water is cut up in passing through the fine rose of a watering can. It has been found that air admitted through a tube or orifice of equal sectional area throughout enters as a cold draught; but if the inlet be through a series of small truncated cones, the smaller section outward, the larger inward, with a wire gauze on the inside, the current is so cut up and diffused that the draught is not felt. By analogy, a mass of water entering through a narrow canal drives all before it and cuts a channel for itself, but the same quantity passing over a large surface of ground gently irrigates it. Another important point is not to let the passage of the air be at too great a velocity, the gentler the flow the better.—*Contemporary Review.*

A Bridge of Salt.

The natural wonders of Death Valley have probably been more minutely and extensively described by professional writers than any other spot they never saw, but one wonder there has in some way escaped these untraveled scribes. In 1883 some borax works were built on the east side of the valley, a couple of miles or so above the mouth of Furnace Creek canyon. The road thence to the railroad led down the east side of the valley for several miles, and then had to cross over to the west side because no drinking water can be had on the east side below Furnace Creek. Moreover, the land on the west side lies much better for a road. But how to get the wagons across the valley was a problem. From end to end the center of the valley is one long salt marsh, and in some places it is so soft and wet that even a man would need snow-shoes to insure his safety. Elsewhere, however, the ooze has been crusted over. This crust is in places very thin and treacherous, and only in one locality does it seem to be firm. Wherever this crust has been cut through a thin, slimy salt mud has been found to be of unmeasurable depth—unmeasurable with any line or pole. Dr. C. Hart Merriam's corps of scientists cut through in one place and easily shoved a pole down fifteen feet. There is no guessing how much deeper the slime was.

However, a road must be had, and so the workmen went about over the marsh where the crust seemed to be thickest and sounded it with sledge-hammers. They found the crust was a mixture of salt and sand, and eventually a route was decided upon. The road was then to be graded, and probably for the first time in the world a road the length of this one was graded exclusively with sledge-hammers.

Here was a stretch of solid salt some eight miles across. In a sense it was level—there were no hills or valleys. In another sense there was scarce a level square inch on the whole bed, for the salt crust had probably, through the influences of heat from above and of moisture from below, been torn and twisted and thrown up into the most jagged peaks, pyramids and crisscrossed ridges imaginable. They were not high—none more than four feet—but there was not level space even for a man's foot between them. Every step made was on a ragged point or edge of some kind. The nearest approach to anything like that I have ever seen was on the ice on Lake Erie, where two fields had been jammed together by the wind and held so by the frost. The ragged ice masses were somewhat like these salt masses. They were larger, but they were not so sharp or in any way so difficult to cross.

Judging that the crust would sustain the weight of the wagons the workmen swung the sledge-hammers day after day until they had beaten down these pinnacles into a smooth way six feet wide. It was perhaps the most laborious engineering work ever done in the country, for the climate and the location, far from civilized habitations, combined to retard the efforts of the workmen. The roadway, when completed, led over what may be properly called a naturally formed bridge of salt eight miles long—the only bridge of the kind in the world.

As one enters the easterly end of this road two unmarked graves are seen in the salt crust near the track. They are graves of unknown men who died there from the heat, and, after the fashion of the country, were buried where they fell. They were covered over with pieces of salt broken from the pinnacles near by. The crust was too hard to warrant digging into it. One must travel a long time to find two more graves like these, if, indeed, two more can be found in the world.—*New York Sun.*

A Relic of the War.

The following is a copy of a bill, written in lead pencil on coarse yellowish "war paper," for second-hand crockeryware sold at auction in Raleigh, North Carolina, January 7, 1864. The war was still nearly a year and a half from its close, so some idea may be gained of what prices rose to in the last days of the Confederacy.

2 Waiters, each $4 00	88 00
1 Sifter	5 50
2 Stone crocks, each $2 25	4 50
6 Cups and saucers	78 00
6 Teacups and saucers	65 00
12 Plates, each $6 25	75 00
1 Glass mug	6 25
2 Steak dishes, each $15 00	30 00
2 Steak dishes, each $23 00	46 00
Teapot, bowl and cruet	85 00
2 Pickle dishes, each $4 50	9 00
6 Salt-stands, each $2 00	12 00
1 Soup tureen	38 00
1 Gravy dish	10 00
1 Gravy dish (cracked)	2 00
5 Dinner plates, each $6 25	31 25
2 Vegetable dishes, each $18 25	36 50
Total	$540 00

—*From Harper's Weekly.*

Practical Uses of Geology.

Though the practical value of geology has been, and still is, well demonstrated, there is a certain class of well meaning persons who, from want of due consideration or lack of information, fail to see any direct benefits from the study of stones. Appended are a few hints regarding the worth and results of geology. As a statement, geology is the sum of all the sciences, the foundation, the support, the very anchor that holds the rest, for it treats of our own earth, of its birth, rise, progress and the present state. Properly studied, it embodies the complete story of life, the great history of creation, the narrative of our very existence, the record of our own planet, our present home. To be a competent geologist, one must study everything useful and economical to explain causes and effects, reasons and results. As he journeys he involuntarily studies thoroughly the country he passes through—the botany, entomology, chemistry, zoology, mineralogy, and compares them with the silent wonders he saw sculptured in the rock that lived, flourished, and died thousands of years ago. Astronomy is consulted as to the formation of this earth and its companions and visitors. From the little diatom, resplendent under microscope, to the huge reptiles 75 feet long, in stony silence petrified, the boundless, natural realm of mysteries opens wide its gates. All have a wonderful tale to tell—a story often beyond the grasp of man's puny intellect. But proofs are constantly carried around with you of the uses of mineralogy and geology. The metal buttons on your clothes, the knife in your pocket, your keys, not to mention the countless array of hardware everywhere, owe their cheapness to work of the persevering follower of science. This assertion is true. It cannot be denied. There are belts and lodes of mineral in the earth that have certain limits, sure and certain manner of occurrence and regular deposition. Here the mineralogist and geologist steps in and defines them, toiling away until the rocks tell their own story of hidden treasure. By deductions, the geologist locates mineral belts, natural gas, oil, marble and minerals. It is not to be forgotten that his theories have to be tried in the crucible of experience.—*Mining Industry.*

ELECTRICAL PROGRESS

The Electric Current and the Human Body.

A recent discussion in an engineering society on the trolley brings up again the subject of what currents are dangerous. Notwithstanding the amount of matter published regarding the resistance of the human body and the current which would kill, the subject still seems to be greatly misunderstood by many, partly because numerous persons interested are not sufficiently well posted in electrical matters to understand the statements made, and partly because such statements often appear contradictory, making the whole subject look mysterious. There are, for instance, about as many figures given for the resistance of the human body as there are authorities for such statements. Furthermore, the question is often asked, "How many volts will kill?" It is stated by some that 30 or 40 volts will kill a horse, while others ask how it is that Tesla is not killed when he takes many thousand volts if 3,000 volts has been known to kill in a number of cases. The writer himself, on top of one of the Alpine peaks in a storm, has had lightning pass through his body to an extent sufficient to make a loud cracking noise and to produce long blue streams of sparks from the fingers, representing probably many millions of volts, without any effect on the body other than to induce him to descend without delay. Others report having taken "the full current of a 1,000 volt alternating current machine through their body" without fatal effects, while in still other cases flesh has been burned to the bone without proving fatal. These apparently contradictory statements make it seem to many that little is known about this subject. This is not the case, however. Although there is room for more definite knowledge, a good deal is known; it requires only to be properly stated. It reminds one of the old story of the color of the chameleon; all three of the observers were right in their observations but wrong in their conclusions. Regarding the resistance of the body it is well known that this resides chiefly in the skin. If the skin is very dry and thick, as on some workmen's hands, it is almost an insulator; while if it is moistened with perspiration, or water, or better yet with caustic potash, which penetrates the pores as it dissolves the fatty substances, the resistance of the skin becomes very low. The condition of the skin and the size of the electrode in contact with it are therefore the most important factors in measuring the resistance of the body, if the electrodes were placed in incisions made through the skin the resistance would doubtless be exceedingly low. A horse is easily shocked through shoes because the nails penetrate into the moist part of the hoof, thus making a good contact through the insulating horny substance; besides this, his hoofs are often wet with mud. The current necessary to kill depends very much on the contact with the moist parts of the body and it therefore cannot be said that a certain number of volts will or will not kill. Furthermore, the quantity of the current actual traversing the body is also an important factor. In Tesla's machine the quantity of the current is small and insufficient, as the body is capable of taking care of it rapidly enough to prevent danger. The source of the current must therefore be great enough to develop a sufficient quantity of current as distinguished from the voltage alone. In all electric light and power circuits there is always sufficient quantity. It would appear from this that the number of amperes might be a better gauge than the number of volts, but the time is also of importance, as the same current is no doubt more dangerous if it continues to pass for a longer time. One author states that one tenth of an ampere for one second is sufficient to kill. This, though more rational than merely the number of volts, is still not sufficiently definite, as in many cases a great enough number of amperes has been taken locally to burn and char the flesh without producing death. It appears, therefore, as Prof. Houston pointed out, that a current, to cause death, must pass across the body; that is, through some vital part, of an arm or a leg. A comparatively large current passing in at the hand and out at the shoulder would not necessarily cause death directly, but if it passes through to the other hand, thereby passing through the heart, it would doubtless prove fatal. To summarize, it is therefore not rational to speak in general of the definite resistance *per se* of the human body, not to say that more than a definite number number of volts is fatal, except between very wide limits. The nature of the contacts must first be considered, then the number of amperes, and the duration, and finally the question of the current through the body in relation to the vital parts. The voltage must then be great enough to send that current through that particular resistance of the body, according to Ohm's law, and the source must generate a sufficient quantity of electricity to keep this current flowing. Finally, there appears to be also a counter electromotive force in the body, which must be considered, and there is besides doubtless a difference between the alternating and direct currents. A direct current probably decomposes the tissues by electrolysis and a high potential discharge may act in the form of rupture of the tissues.—*Electrical World.*

Weaving by Electricity.

That decentralization in industry which some economists expect to grow out of the development of electricity as a motive power seems to be already in progress at St. Etienne, France, according to a recent report of our department of state. The industry at that place is the manufacture of silk ribbon, and most of the large output of some $24,000,000 a year is the product of house industry. Generally the weavers own their own looms and operate them by hand in their own homes. There are 18,000 looms thus distributed about, while the steam-power factories have only 5,000 looms. Now the city of St. Etienne intends to set up a large electric-power plant and distribute power to the looms of the house weavers and supply light as well. The cost of the undertaking and the conversion of the hand looms into power looms will be borne in the first instance by the city, and a charge will be imposed of seven cents a day per loom for the use of current and motor. The plan is regarded with great favor by the hand weavers. That they have been able so long to stand against the factory system with its cheaper processes of production is to be explained apparently by the fact that their ribbons had obtained such a reputation for superiority in the general market as to be able to overcome the drawbacks of higher cost of production and prices. No doubt the supply of cheap power to the house looms will now firmly establish the weavers in their industrial independence. The experiment is a most interesting one and before very long will be given a trial, without question, in many parts of the United States.—*Electric Power.*

Electricity as an Aid to Moral Suasion.

It appears that electricity is not confined to electrocution as a means of punishment as it has been found to be effective in cases of minor criminals at the Newark City Home.

This institution is a temporary retreat for the incorrigible youth of Newark, for many of whom, by reason of long practice, the rod and switch have lost their terrors.

Dr. Whitehorne, of Verona, is the regular physician of the place, and is credited with the adoption of a medical battery for administering reproof.

A boy named Rafferty, tried to stab one of his companions during the play hour one day and the Superintendent determined to try the electrical punishment on him. He was taken into the Superintendent's private room which was darkened to befit the solemnity of the occasion, and Rafferty was requested to remove his coat and roll up his sleeves. The Doctor was in attendance and adjusted his battery which gave forth an ominous buzzing sound.

The proceedings so far were unusual, and the boy commenced to get frightened. One electrode was placed at the back of his neck, and the other, in the form of a brush with wire bristles, was rubbed over the boy's arm. With a yell of terror the boy broke away from the chair and stood shivering in an agony of apprehension. He was forced back, however, and the Superintendent continued dusting the wire electrode over the boy's arm and face. The current was increased and the boy after being nearly paralyzed with fear, was finally released in an exceedingly limp condition and a very penitent frame of mind. For several days he remained in a spiritless condition, and after he recovered, not understanding the nature of the punishment, he spread the report that he had been pricked with bunches of red hot needles and subjected to the most awful tortures.

The method proves itself effective, however, as in no case where it has been tried, has the offender given cause to require a second application. The authorities of the institution consider it an entire success in subduing the vicious tendencies of their youthful charges.—*Electricity.*

MECHANICAL NOTES

Rolling Rails.

The process of rolling railroad rails of Bessemer steel, as practiced in Germany, says *Machinery* is declared to be one of the most perfect mechanical operations in the world. The steel is cast in blocks which contain sufficient material for two or three rails, these blocks, while still red hot, being carried to the preparatory rolling mills, by horses which have been trained to work in the midst of this fire and noise; here they are kept hot, in special furnaces, and are rolled into longer blocks having a square cross-section. After being thus prepared, they are taken to the rail rolling mills, which consist of two complete rolling mills, with all the appurtenances in one apartment, and the blocks which come from the preparatory mills are heated again and then passed between the rollers, of which there are three placed one above the other, so that the rails are rolled during the backward as well as the forward motion without requiring a change in the direction of rotation of the rollers. The rails have to pass back and forth between the rolls 13 or 14 times, and each time that they come from the rollers they are caught by the workmen on the short, bent ends of long levers which run on rollers on movable carriers. Each time the rail passes from between the rollers it is longer, and its cross section narrower than after the former rolling, until it finally stretches itself out like a gigantic fiery snake. It is then taken to a circular saw, which cuts through the glowing metal with perfect ease, dividing the long bar into two or three rails. The cold ring is now put under presses, by means of which the slightest irregularities are removed, and then the holes are bored, the end surfaces evened, etc.

The Great Bells of the World.

The Russians and the Chinese are behind the rest of the civilized world in many things, but bell-founding is not among the number, for the bells manufactured by both nations are not only the largest, but among the best of those made by any nation. It is said that before the great fire by which Napoleon was driven out of Moscow, there were in the churches of that city 1,706 bells, each of which exceeded 15,000 pounds in weight. The capital of Pekin, China, has a bell 18 feet high and 15 feet in diameter, and weighing 120,000 pounds. The giant bell of the world is in Moscow; it is poetically denominated the King of Bells is 19 feet 3 inches high, and its circumference around the rim is 60 feet and 9 inches. Its weight can, of course, only be estimated, but, by the least calculation, it is 443,732 pounds, and its value as old metal exceeds $300,000, not considering the gold and silver, of which there is a considerable quantity, which enter into its composition. This bell, when sung required forty men to ring it, the clapper being swung by means of two long ropes, with twenty men at each. It is now cracked and useless and rests upon its rim on the ground. The great bell at St. Ivan's in Moscow, is 40 feet, 9 inches in circumference, its thickness just above the rim is sixteen inches, and its weight is computed at 127,830 pounds. The great bell of Vienna weighs 40,200 pounds. After these are many smaller, yet of considerable size. A bell of Olmutz, Bohemia, and a bell in Rouen, France, are about equal in size to the Vienna bell; the bell of St. Paul's, London, weighs 38,470 pounds; the bell of Westminster, 30,350; that of St. Peter's, in Rome, 18,600. Several of these bells are sounded only on important occasions. The St. Paul bell, the Vienna bell and the bell of St. Ivan's are tolled only at the death of royalty; the bell of St. Peter's tolls at the death of a Pope.

ENGINEERING

The Squadron of Christopher Columbus.

At a time when preparations are making in Europe and America to celebrate with brilliancy the fourth centenary of the discovery of the new world, everything relating to Christopher Columbus and his memorable voyages assumes a great interest and has a right to attract the attention of the public. We propose to make known to day some studies that have recently been made on the little vessels, the *caravels*, by means of which one of the greatest navigators ever known discovered the new continent.

The *Revue Maritime Autrichienne*, of Pola, has recently published a very interesting article giving the result of all the investigations that have lately been made, particularly in Spain; for the purpose of ascertaining what was the exact type and maritime value of the three ships that the illustrious admiral of Castile commanded in his search for the new world, starting from Huelvas on the 3d of August, 1492.

We know that these vessels were called caravels; but the result of the latest researches has taught us that this term was applied to no particular class of vessels. The Spaniards used the word *Carabela*, borrowed from the Francic language and derived from the Greek word *karabi*, to designate ships very unlike one another in construction and sails.

The investigations have brought together all the data that the writings of the admiral (especially his log-book), the sketches made upon his published maps by his pilot, Juan de la Cosa, and the ancient publications on this subject, were capable of furnishing; and they have given Rafael Manleon, the marine painter, the means of making an aquarelle representing Columbus' three ships.

The three ships were named the *Santa Maria*, the *Nina* and the *Pinta*. The first of these had the following dimensions: Length of keel, 62 feet; between perpendiculars, 75 feet; greatest width, 23 feet; depth 14½ feet; burden, from 120 to 130 tons. As the crew never exceeded 90 men, the ship was capable of carrying quite a large supply of food and water. The admiral's log mentions that his pinnace was 30 feet in length, but the same document speaks only superficially of the armament. It mentions, for example, that on the 26th of December the admiral fired *una lombarda y una espingarda*. The latter of there arms is well known; the former was a gun of small caliber that originated in Lombardy.

The suit of sails of the *Santa Maria* was that of a small three masted-vessel, with five sails only: a jib, foresail, mainsail, topsail, and a lateen. The mainmast was provided with a top, which the sketch represents as round and basket shaped, and which was capable of affording shelter to firers of grenades. The general form of the hull was that of the round ships of the period. There was a large poop and a small forecastle. The free board was very low amidships, and the deck was here open.

The nautical qualities of the *Santa Maria* were excellent, as the admiral's log proves: "This ship behaved very well in bad weather, and had the speed of a good sailer." The same was the case with the two other ships, and the log often mentions a speed of 15 Italian miles an hour equivalent to 11 nautical miles—a very good speed for vessels sailing as consorts. The *Revue Autrichienne* cites, moreover, as an example of the high speed reached by ships of this epoch, a journey of 600 Italian miles made in 36 hours by a caravel commanded by Vincente Lago, which visited in succession the Canaries, Madeira, Port Santo, and Gambia in 1444.

The dimensions of the two other ships commanded by Columbus are not indicated. The *Victoria* celebrated for having made the tour of the world for the first time had a capacity of but 85 tons.

The *Nina* resembled the *Santa Maria*. The *Pinta* carried lateen sails on her three masts, at least at the beginning of the voyage; but the admiral's log tells us that at the first stop (at the Canaries) this set of sails was replaced by square ones, in order that the ship might be placed in the same condition as the two others.

These three ships sailing as consorts, flew the flag of Castile at the mainmast and that of the admiral at the mizzen. The first was divided into four squares, two red and two white. The latter each bore a lion and the others a castle. These were the arms of Castile. Those of Arragon were excluded by the orders of Queen Isabella, the government of that country having refused to participate in the expenses of the expedition. The admiral's flag was a white pennant with a green cross between two crowned letters F and I—the initials of the names of Ferdinand and Isabella, who had given these arms to Columbus. A cross was painted on the sails of the ships, according to the custom adopted by the Spanish and Portugese in order to distinguish their vessels from those of the infidels. Such is a summary of the data furnished by the article in the *Revue Maritime* of Pola.

There still exists in the museum of Madrid a picture of the first voyage of Chistopher Columbus. It is due to the artist Brugada, and represents the admiral's fleet coming into sight of San Salvador on the 12th of October, 1492.—*La Nature.*

Great Dam in Australia.

Official details of the great dam at Beetaloo, Australia, corrects some of the previously published statements and figures, and the immensity of such a piece of engineering work may well challenge a comparison with anything of the kind in that part of the world. The structure is of concrete, 110 feet high from the bed of the creek to the top of the dam and 580 feet long, being curved in the plan of a radius of about 1400 feet; the width of the top is fourteen feet, the profile of the section being designed in accordance with Rankine's rules and the width of the section at the foundation 110 feet; the crest of the bywash, which is 200 feet wide, is five feet below the crest of the dam, and the reservoir behind the dam at its full one and one fourth miles long, with an average width of eight chains. The capacity under these conditions, is 800,000,000 gallons, for the supply of a district covering an area of 1700 square miles, including eight separate townships, etc. The quantity of concrete used was 60,000 cubic yards, the net time occupied in construction being about two and one-half years. Special machinery was used for mixing the concrete and depositing it in place, and the whole work is regarded as a most creditable achievement.

PULLEY BLOCK.

No. 471,519. Philip Freund, Brooklyn, N. Y. *Patented March 22d, 1892.* The casing is formed in two parts which are duplicates. The halves are fastened together by rivets or bolts at B and H, and by a center pin R. The central part of each side is drawn inward, forming circular shoulders L. The sheave K is a ring having a groove N around its outside for the rope, and having two grooves Q

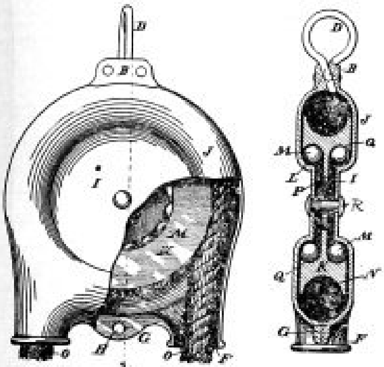

Fig. 1 Fig. 2

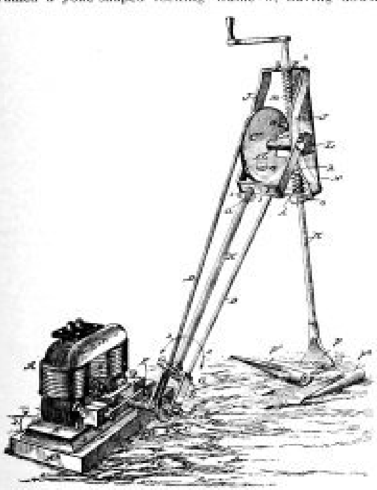
as shown, to receive two sets of balls M. These balls roll on the shoulders L of the casings and thus form circular ball bearings for the sheave. The casings may be castings, or they may be pressed into shape from sheet metal, thus making a light, cheap and serviceable pulley block. Friction is reduced to the lowest possible limit. The sheave can not bind in the casing, as the balls confine it laterally as well as centrally.

ELECTRIC MINE DRILL.

No. 472,444. John Fish, South Bend, Ind. *Patented April 5th, 1892.* This is a new mining machine, which may be used as a pick or drill, in any position where electricity is available. A is the electric motor, of any type. B is its armature, whose shaft is extended outside the motor far enough to receive the pulley C, that carries the driving belt D. The electric motor is mounted upon a base A^1 and this is mounted upon and secured to a sub-base A^2 by a strong pivot having a vertical axis that permits the motor to be swiveled as shown by the arrows 1 1. This permits the drilling to be done in any direction without changing the position of the sub-base of the motor. Upon the extended armature-shaft is hung the forked frame E, whose branches are arranged upon opposite sides of the driving-pulley C, and are retained upon the said shaft by means of collars F F. The frame E has parallel guide pins G for the belt D, and said frame is rigidly attached to the long arm H, that carries at the outer end the drilling mechanism. The forked frame I is attached to the arm H by a swivel joint so that it can be turned in any direction. At the upper ends of the forked frame I is fulcrumed a yoke-shaped rocking frame J, having down-

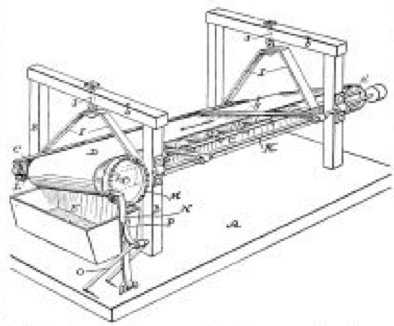


wardly-curved side bars. This frame is fulcrumed upon a pin or shaft that extends through both the branches of the forked frame and the yoke shaped frame. The large pulley C' is set to one side of the frame I in line with the arm H by means of a sleeve *d* and carries upon its inner face one or more laterally-projecting pins or tappet-lugs *e*.

In the rocking frame J, in suitable bearings in its ends there reciprocates the drill-rod K, whose angle may be changed by the adjustment of the frame about its fulcrum as shown by arrows 4 4. This drill-rod has attached to it a collar or anvil *k*, and between this collar and the end of the frame J is a spiral spring *l*, encompassing the drill-rod. On the opposite side of the collar and sliding on the drill-rod is a hammer-block L, and between this hammer-block and the opposite end of the frame is a long spiral spring *m*. Now as the pulley in this rocking frame revolves its pins or lugs force back the hammer-block against the long spring *m*, compressing the latter until the pin passes the block, and the spring forcibly drives the hammer-block against the anvil or collar on the drill rod and imparts thereto a blow, which is repeated in such rapid succession as to give a very effective cutting action to the drill-point or tool-carrier at the end of the rod.

ORE CONCENTRATOR.

No. 471,319. James Tulloch, Angels Camp, Cal. *Patented March 22d, 1892.* The pulp mixed with water is fed upon the endless belt or apron D. This is made of rubber, canvas, or other suitable material. It is supported on carrying rollers C^2, a tail roller C^1, and a head roller C, all of which are carried in a swinging frame C C. The frame, together with the rollers and the belt, is suspended by hangers I and eye bolts J to the cross sticks *b*, of the main frame. Vibratory motion is imparted to it by the cranks K and rods *k*. The head roll is provided with a ratchet M on the end of its spindle, and a pawl N is arranged to engage the ratchet and turn it one tooth at every swing of the frame. It is claimed that a decided advantage is gained by suspending the belt, etc., from the over-head frame work instead of supporting it on rocking ports, as commonly done.



This motion is advantageous, in better spreading the material over the surface of the belt, and in keeping it worked away from the sides thereof and toward the center, resulting in a more perfect concentration.

MINING MACHINE.

No 472,177. Charles O. Palmer, Cleveland, Ohio, *Patented April 5th, 1892.* The cutter wheel 43 is made like a spur gear, the back of each tooth being shaped to act as a gear tooth, and the face of each tooth is shaped to act as a cutter, or is provided with detachable cutters. The cutter wheel is driven by a pinion 28 which is keyed to the same spindle that carries the grooved pulley 32, the arms of the wheel are flush with the under edge of the rim, and are of less thickness than the rim, the carrying arm 27 is off set downward just inside of the rim of the wheel, so that the portion which enters the kerf made by the cutters will lay below the top edge of the wheel rim. The inner end of the arm has a hub which turns in the boss 25 of the machine frame and is retained in place by a ring or collar 30.

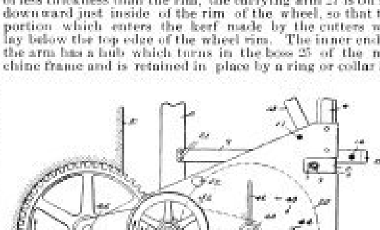


Fig 1
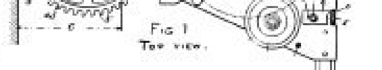
Top view.

Fig 2



End view

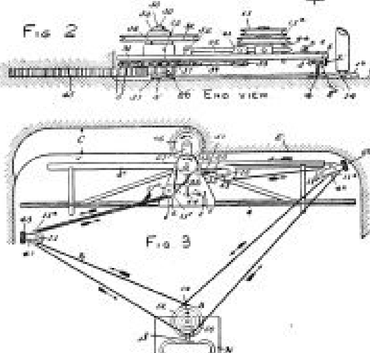


Fig 3

A sprocket wheel 37 is attached to the hub of the arm, and serves to swing the arm and cutter wheel around the center pin 35. It is connected by a chain 39 to a sprocket pinion 38, which is turned by a four-armed handle 42. The cutter arm is swung into or out of the cut by turning 42, and it is fastened in position by a stop pin 44, which may be inserted in holes 45 in the top plate of the machine. The machine slides on a stationary frame composed of two rails 4 and 4' suitably braced together as in Fig. 3. It bears on three points only—one being the head 31 of the center pin 35, and the other two points are the clamps 2. The machine is fed along the ways by the same rope which drives the cutters. The arrangement of driving rope is shown in Fig. 3. The motor N, S, drives a double pulley 10 and 12, of different diameters. The pulling strand of rope from the machine pulley 32 to the motor—runs on the small pulley 10, while the slack or returning strand runs off the larger pulley 12. Both strands run beyond the motor, around guide pulleys to a sheave 15, which is hitched to the machine.

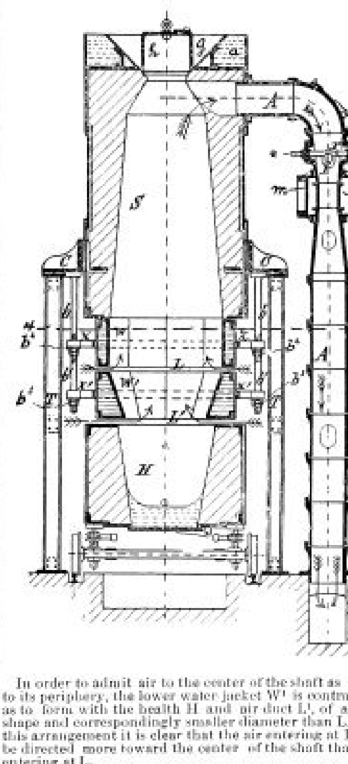
The two lines or "runs" of the driving-rope, which extend from the driving wheels 10 and 12, respectively, to and around the driven pulley 32, constitute the "driving circuit," while the opposite lines or runs, extending from said driving wheels to the pulley 15, constitute the "feed-circuit" of the driving system. The operation of the differential wheels 10 and 12 when operated in the proper direction, as indicated by the arrows in Fig. 5, is to pay off the rope to the driving-circuit faster than it takes back the rope from said circuit, the difference being taken from the feed-circuit, thereby shortening the same. The lengthening of the one circuit and the shortening of the other is compensated by the drawing forward of the mining-machine on its track toward the right hand in Fig. 5, the rate of said movement depending of course on the relative sizes of the two wheels 10 and 12, which sizes may be made of a proportion suitable for any required rate of feed.

CUPOLA FURNACE.

No. 468,306. Carl Sahler, Cologne, Germany. *Patented February 2d, 1892.* This smelting-furnace, which is operated by the suction of a steam jet or a ventilator, is used for smelting ores and resmelting the resultant metallic products.

The furnace consists of the shaft S and the water-cooling jackets W and W', the portable and adjustable hearth H, and the exhaust A with the steam-jet I. The shaft S is provided at its top with hopper *g* and bell *h*, surrounded by a water-jacket or other suitable casing *a*. The shaft S is carried freely by means of the columns T and the supporting-ring C, or the ring C is supported upon double T-standards.

The water-cooling jackets W and W' are carried by bands Z and Z', which are supported by bolts *b b'*, secured to the ring C. By means of the nuts b^2 b^3 the water-cooling jackets W and W' may be raised and lowered. By this arrangement two ring-shaped adjustable air-ducts L and L' are formed, one between the hearth H and the lower cooling-jackets W and the other between the two jackets W and W'. As soon as the jet I is in operation in the exhaust A air enters the ducts L and L' to assist the combustion.



In order to admit air to the center of the shaft as well as to its periphery, the lower water jacket W^1 is contracted so as to form with the health H and air duct L^1, of annular shape and correspondingly smaller diameter than L. From this arrangement it is clear that the air entering at L^1 must be directed more toward the center of the shaft than that entering at L.

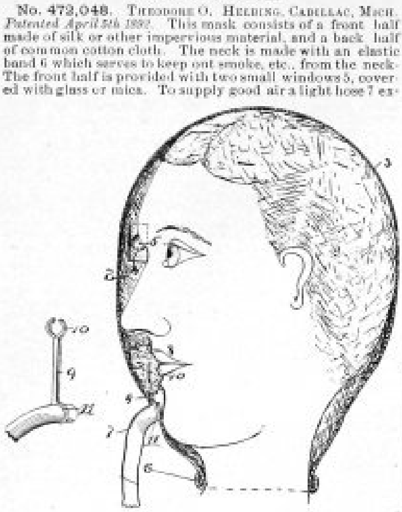
In smelting more or less pulverized ores the part R of the air-injector is apt to become clogged, and therefore it must be readily interchangeable during the working. The removable pipe section R is surrounded by the casing *m*, having closed ends, as shown, to form a tight joint and hold the parts in position, as the section R is removable.

In order to prevent overheating of the steam-pipe *r* in the exhaust, the steam is admitted at both ends *e* and e^1, and thus the whole pipe is continually filled with steam. The jet-pipe *r* is made in one piece, and is removable and interchangeable. The jet *r* is regulated by means of nuts *m* and m^1.

In order to make the furnace serviceable for distant and mountainous regions, it is made to be taken apart in pieces of not over two hundred pounds weight, so as to be transported on the backs of mules. For this purpose the sheet metal of the casing is not riveted together, but is put together with bolts, and further, the water-cooling jackets W and W^1 are each made of eight sections of water boxes, and the exhaust A is made of a series of sleeves which fit each other, while the standards T are made of two U-shaped beams screwed together and provided with base and cap pieces.

FIREMAN'S MASK.

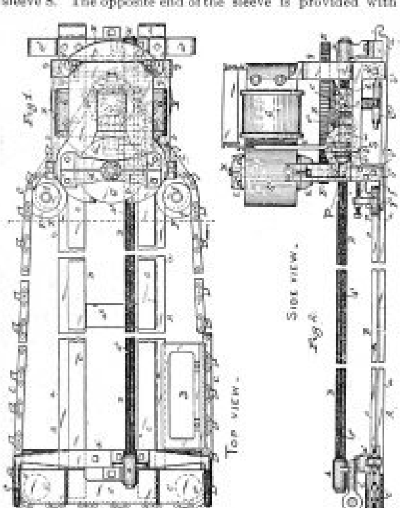
No. 472,048. Theodore O. Helding, Cadillac, Mich. *Patented April 5th 1892.* This mask consists of a front half made of silk or other impervious material, and a back half of common cotton cloth. The neck is made with an elastic band 6 which serves to keep out smoke, etc., from the neck. The front half is provided with two small windows 5, covered with glass or mica. To supply good air a light hose 7 ex-



tends nearly to the floor where there is usually a layer of air free from smoke or fumes. The top end of the hose is provided with a spring clip 9 shown separately in detail, which serves to hold a sponge against the mouth and nostrils of the fireman—thus enabling him to breathe in a room where the smoke would otherwise suffocate him.

MINING MACHINE.

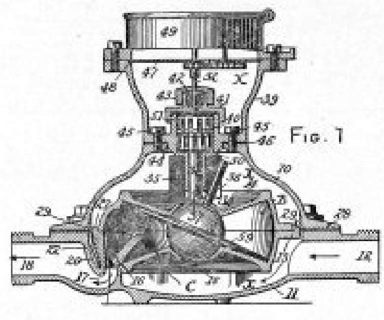
No. 472,503. Adam Kiel and Anton R. Westerdahl, Pittsburgh, Pa. *Patented April 5th, 1892.* This machine employs an endless chain having cutters attached to each alternate link. The front end of the frame is composed of two flat bars C' which serve to support the chain links while they are engaged in cutting coal. The chain is driven by a sprocket wheel C' on the lower end of the shaft of the large spur gear E. Power is supplied by an electric motor G' and G which is mounted on standards attached to the main slide or carriage b. The driving pinion E' is on the lower end of the armature shaft, and gears directly into the wheel E. The sides of the chain are supported on rollers F which have a wide flange on the lower edge to furnish a good bearing. The stationary frame A is composed of flat bars a, united by cross bars a^1, a^2 and a^3. This frame lays directly upon the floor. The feed screw D is journalled in brackets d d' which are bolted to the cross bars as shown. The screw is grooved as shown, to suit the feather in the driving sleeve 8. The lower end of the armature shaft carries a worm which drives a worm wheel P which runs loosely on the screw D, and has clutch jaws on one side to engage similar jaws on the sleeve 8. The opposite end of the sleeve is provided with

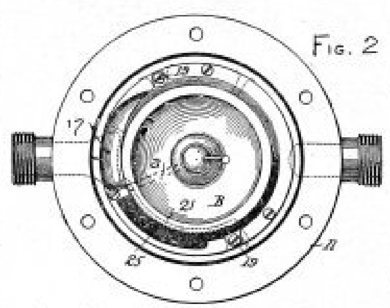


jaws to engage the jaws on the hub of the bevel pinion e^2 which is driven by e^1. The sleeve is moved into engagement with P or e^2, by the hand lever t. The wheels P and e^2 run in opposite directions, at different speeds, and one is used for feeding the cutter chain into the cut, and the other for backing out. The screw turns in a nut k, on the side of the bearing of the main sprocket wheel and spur gear E. The sliding frame or carriage B is composed of two flat bars c, united by cross bars C' and the motor frame b. The side bars C slide through suitable slots in the front cross bar a'. An additional support 3 is used to support the chain on the running in side, to prevent the cutters from jumping or gouging, and thus breaking the chain.

WATER METER.

No. 471,295. John Thomson and Frank Lambert, Brooklyn, N. Y. *Patented March 22d, 1892.* The measuring chamber of this meter is made in two sections B and C and is bored truly spherical, so that the disc 30 will fit water tight in all positions. The heads are made conical, and are shaped to form a bearing for the ball 37 to which the disc 30 is attached. The ball has a pin 36 projecting upward, which engages a small crank 35, and through it drives the gearing that moves the register in the upper part of the case. The measuring chamber is divided into two chambers by a partition a, shown by dotted lines in Fig. 2. This view shows the upper part of the case 10 removed. The disc 30 is slotted to allow the partition to pass through it, and the partition is located between the supply port 25 and the discharge port 17. The disc does not revolve as the crank 35 turns, but merely rocks or wabbles in its bearings, sufficiently to sweep through the entire space between the upper and lower heads. The disc touches each head on a line only, and as it wabbles this line of contact shifts, being exactly with the crank, on the lower head, and exactly opposite the crank on the upper head. The space in the chamber always grows larger behind the line of contact, and smaller in front of it.

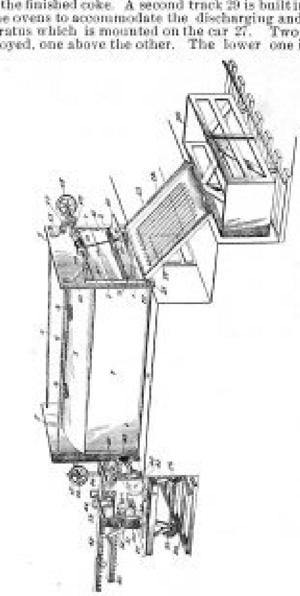




At each revolution of the crank the disc expels a volume of water equal to twice the contents of the chamber less twice the bulk of the disc and ball. The water enters at 12, passes under the chamber 15, and rises through the port 25, and enters the chamber by a wedge-shaped opening similar to the exhaust port 16. The action of the disc is continuous and the displacement is perfectly uniform.

COKE OVEN.

No. 472,115. Wm. T. Gates and George H. Sharp, Fairchance, Penna. *Patented April 5th, 1892.* The oven is made with a straight flat bottom, flat sides and ends, and an arched top having the usual vents, 4, 4. Each end of the oven is provided with three flat doors, 10, 11, and 12, and a small windlass is provided to lift them. The discharge end of the oven is provided with a screen 25, over which the coke passes to the car 26, to remove ashes, etc., from the finished coke. A second track 29 is built in the rear of the ovens to accommodate the discharging and leveling apparatus which is mounted on the car 27. Two rams are employed, one above the other. The lower one is used to



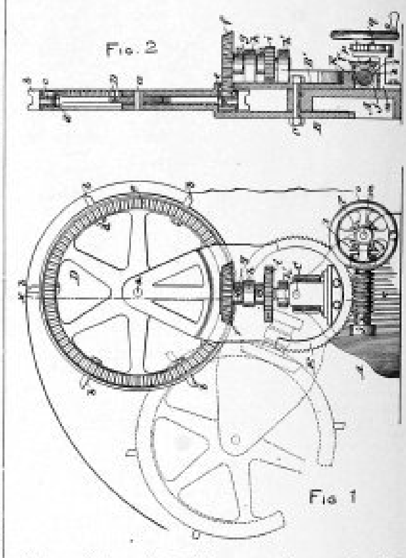
push out the finished coke from the oven to the car, and the upper one is worked back and forth to level the charge. Both rams are provided at their front ends with large T shaped heads nearly as wide as the ovens. Both bars are provided with teeth on the under side, and are propelled by pinions driven by the cranks and gearing shown. Either the upper or lower ram bar may be thrown into or out of gear with the driving pinions by the handlever 48. The doors being divided, either of the rams may be used without opening the whole end of the oven. The admission of too much air is thus prevented.

MINING MACHINE.

No. 469,608. James Taylor, Edwards, Ill. *Patented February 23d, 1892.* The stationary frame A of the machine is secured to any suitable fixed support. Two arms B B' are connected with the frame A by the pivot bolt C. The arms extend forward and between their free ends is journaled a cutting-wheel D on the pin a. The arms B B' are offset within the rim of the wheel, so that the combined thickness of the arms and the central portion of the wheel is equal to the width of the rim of the wheel, thus permitting the arms to enter into the cutting made by the wheel.

The wheel D is furnished with removable cutters b on its periphery, which are provided with shanks c, extending through the rim of the wheel, and receiving nuts d, which are turned down on the wheel-rim, clamping the cutters securely in place.

The wheel D on its upper face is furnished with a toothed rim e, which is engaged by a beveled pinion f, mounted on a shaft g, journaled in bearings h h', and secured to the arm B'. The shaft g is provided with the spur-wheel i for receiving power from an electric or other suitable motor mounted upon the arm B and moving with the said arm.



The arm B' is provided with a segmental worm-wheel E, and in journal-boxes j on the frame A is journaled a worm k, which engages the worm-wheel E. The worm-shaft is prolonged beyond one of its bearings and provided with a motor-wheel l, which is engaged by a corresponding wheel l', on the vertical shaft m, journaled in the bracket n, secured to the frame A. The shaft m is provided with the hand-wheel o, by which it may be turned, and with a ratchet-wheel p, which is engaged by the pawl q, pivoted on the bracket n.

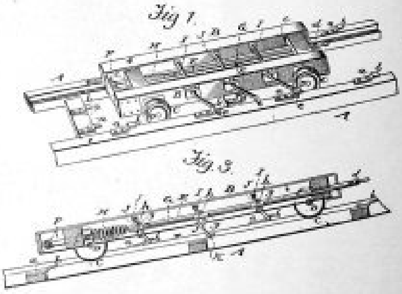
Motion being imparted to the shaft g from any suitable source of power, the wheel D is revolved, and as it is revolved the arms B B' are moved forward by turning the worm k, thus carrying the wheel D up to its work. The cutters b readily remove the coal as the wheel advances, and the wheel is constantly held up to its work by the action of the worm and by the pawl-and-ratchet mechanism above described.

The cutters b are preferably notched at the center, as shown in Fig. 2. They are readily removed for sharpening after loosening the nuts d.

Owing to the construction of the arms which carry the wheel D, the said wheels may cut a groove in the body of the coal equal in depth to nearly the diameter of the wheel. The frame A may be secured to any convenient support, or it may be fastened to the floor of the mine by means of a jack-screw.

CAR FOR INCLINED RAILWAYS.

No. 467,945. Jacob Messner, Calumet, Mich. *Patented February 2, 1892.* The draw rods E extend through both ends of the car and are cushioned by spiral springs F on their rear ends. Several rock shafts I having crank-shaped ends, extend across the body of the car, above the draw rods. Each rod or rock shaft I is provided with a slotted



arm g, which engages a pin h, on the draw rods. As long as there is any tension on the draw rods they are pulled forward and the pins h move the arms g and turn the rock shaft I sufficiently to lift the bent ends i clear of the catches k which are fastened to the stringers or cross ties as shown. As soon as the hauling rope breaks or the tension is slacked off, the spiral spring H pulls back the draw rods and drops the hooked ends of the rock shafts, which engage the catches shown and stop the car.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

VOL. XII.—NO. 12. SCRANTON, PA., JULY, 1892. WITH WHICH IS COMBINED THE MINING HERALD

AN ELEMENTARY TREATISE ON THE PRINCIPLES OF COAL MINING.

For the Use of Candidates for Mine-Foremen's Certificates, Mining-Students, Mine-Foremen, Mine-Superintendents, Mining-Engineers, Etc.

BY A. A. ATKINSON.

New Brancepeth Colliery, Durham, Eng.

The Robbing of Pillars.

The working off of pillars economically, safely, and without any great loss of coal is a subject worthy of great consideration, and when we consider how many different methods are in vogue in the collieries of Northumberland and Durham, we cannot help being struck with the idea that some of these methods are based upon wrong principles, and are neither economical for the owners, nor safe for the workmen, it is, however, of no use making such general statements as these, as although the system employed may exhibit grave defects, at the same time they are not easily removed, and we should submit that it is only by becoming practically acquainted with many different methods, and carefully observing for ourselves the various peculiarities to be seen in them, that we may hope to be able to lay down reliable rules for working off the pillars, or the "broken working," as this removal of pillars or second working is usually termed in Durham and Northumberland, and we must remember that owing to the great variety of circumstances under which coal is found, that no single rule can be given to apply to all.

In writing this the author has observed the following subdivision of the subject:

1. General remarks upon broken workings including a few observations upon creep, pressure, etc.
2. Particular descriptions of methods now in use or of those that have been employed in the working away of pillars.
3. Cost of broken workings as compared with whole workings.
4. History.
5. Appendix.

It is only in the bord and pillar (stoop and room in Scotland) system of working coal that the second or broken working occurs (except perhaps to a slight extent in the Longwall system where posts and pillars are left on each side of the gateways and which are removed after the district is finished) and as the north of England may be said to be the birthplace of this system of working coal and of removing the pillars, it is there where we find the system at the present day pursued in the most perfect manner, and that district will therefore be more particularly referred to in this paper.

In the days when coal mining was in its infancy in the North of England, very small pillars of coal were formed of minimum dimensions to support the roof and to prevent heaving or lifting of the floor of the seam during the working of the whole, and these pillars were abandoned in the mines when the boundaries were reached in the whole. This was a serious loss of coal to the owner of the minerals, to the owner of the colliery, and also to the country, but it was before the method we now know as the "broken working" was suggested, or tried and mineral owners in many cases actually stipulated for the leaving of pillars of coal of certain dimensions for the purpose of supporting the surface land, and to allow as much as possible of the royalty in the whole to be worked. The leases often provided "That the tenant shall leave good and sufficient stoops and pillars to uphold the roof," etc. It frequently happened however that the pillars were left too small for the superincumbent pressure and when they began to deteriorate and the floor to soften the mine would become practically unworkable, and the surface in many instances more damaged than if all the coal had been extracted.

Many of the pillars which were abandoned in these old pits have in recent years been worked out, and the author knows of some collieries in the county of Durham where this is being done at the present day in the Hutton Seam which contains valuable household coals.

The method of safely working off the pillars having been found to answer it soon became extensively practiced, and landowners are now very careful to have the colliery leases drawn up to provide for the working out of the pillars and secure as large a percentage of the available coal in the royalty as possible, consistent with safety, and to cautiously guard against improper modes of working the coal.

In opening out a colliery the determining of the dimensions of the pillars to be formed by the whole working is a subject demanding the most careful consideration and ought to be decided only by those thoroughly conversant with mining who are able to weigh well the various peculiarities of the coal seam, surface conditions, and various other points; for the future success of the colliery may to a large extent depend upon a judicious determination of the size of the pillars.

The first point to consider is, what is the least size of pillars consistent with sufficient strength to support the roof and prevent any heaving or lifting of the floor, and when this is determined it may be found advisable, for reasons enumerated later on, to consider, what dimensions over and above the safe or minimum dimensions the pillars are to be made. To determine the least size of the pillars consistent with safety, it is necessary to take into account the depth of the seams from the surface, because with the depth the pressure of the superincumbent strata which the pillars will have to support increases, consequently it is essential to increase the size of the pillars with an increase in depth. For instance, at a depth of 100 fathoms, pillars left 30 yds. x 14 yds. might be found to be large enough, but at a depth of 200 fathoms, pillars of the same dimensions would in all probability be found quite inadequate, and with this increase in depth it would be necessary to increase the size of the pillars to 40 or 45 yds. x 22 yds.

It is also necessary to consider the nature and strength of the stone forming the roof and particularly the floor, the reasons for this will be given when we explain the term "creep," and also the hardness or softness and thickness of the coal seam. No hard and fast rule can be laid down whereby we can calculate even approximately the dimensions of the pillars owing to the varying conditions under which coal seams occur; a rule which answered to the requirements of one district might be very misleading and inapplicable to another, therefore it will be seen that experience is alone worthy of confidence in deciding such weighty matters, and in a district where there are other collieries working the same seams under similar conditions the methods and particulars of working ought to be carefully examined and the merits and demerits weighed, so as to assist in arriving at the most suitable dimensions in each case. The table on following page has been culled from the writings some years ago of one of the Government Inspectors of Mines in the North of England.

At most of the collieries in the North of England the dimensions of the pillars are made much larger, and consequently a larger percentage of coal left than is given by the table. Take for instance the size given for pillars at the depth of 100 fathoms, viz.: 22 yds. x 9 yds. Very few if any of the collieries in Durham at or near that depth will be forming pillars of less dimensions than 30 yds. x 14 yds. and some as large as 50 yds. x 30 yds. At depths varying from 200 fathoms to 300 fathoms in the eastern district of the same county the pillars are in most of them as large as 60 yds. square.

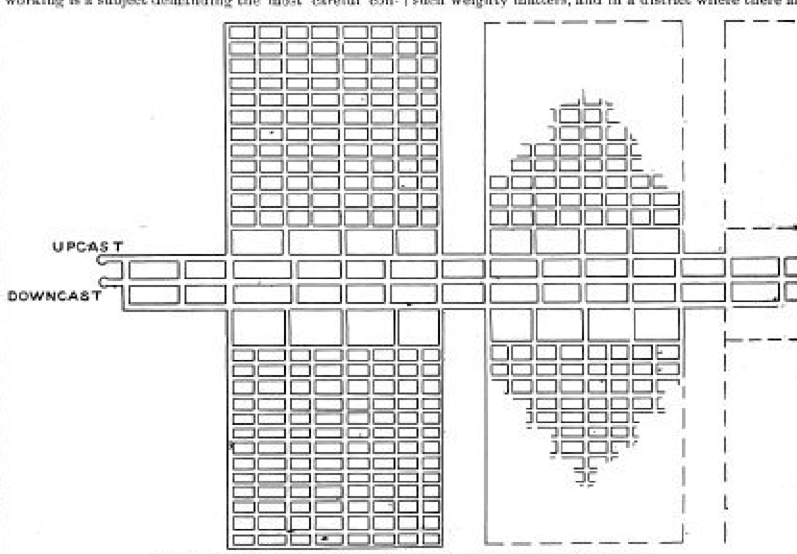


FIG 1.—ILLUSTRATING THE PANEL SYSTEM WITH BARRIER PILLARS.
(Scale, 500 ft. = 1 inch.)

Mr. G. G. Andre, in his work on "coal mining" in writing on the "Dimensions of the Pillars and Stalls" says, "the pillars are regarded, not as supports to the roof, but as masses of coal prepared for subsequent removal. Hence enormous dimensions are given to the pillars, and by this means the evils of thrust and creep are entirely avoided. As there is nothing but convenience to limit the size of the pillars when viewed as masses to be wholly worked away, in deep pits it is customary to take out by the preliminary workings that is, by the driving of the bords and headways, only from one-fifth to one-fourth of the coal, leaving pillars 30 yards long by 18 or 24 yards broad, and even 40 yards long by 30 yards broad."

We will now show in the same way the advantages and disadvantages of

LARGE PILLARS.

ADVANTAGES.	DISADVANTAGES.
(a) Fair percentage of round in the pillars.	Small proportion of whole workings.
(b) Lessened hewing or getting cost over the total area.	More broken workings to maintain.
(c) Less cost of maintaining brokens.	Greater amount of straight, narrow, or yardage work.

Such is an imperfect sketch of the considerations that must be kept in view when laying out pillars, and although some of the above may not exist at all collieries as advantages or disadvantages, yet generally speaking they will be found to be tolerably accurate. At one large and deep colliery for instance, where there is no narrow or yardage work of course this would not be an advantage for small pillars, nor a disadvantage for large ones. The inapplicability of the small or large percentage of round coal has already been cited.

Another considerable disadvantage with large pillars in seams where fire-damp is given off, is the distance that it is necessary to carry the air to the working faces by means of brattice rendering it sometimes an extremely difficult matter to keep them in a fit and proper condition for the men to work in, especially when they are about up the distance to be driven and near holing.

SCALE FOR FIRST WORKING, WITH DESIGN OF AFTERWARDS TAKING OUT THE PILLARS; THE WIDTH OF PRINCIPAL WORKINGS BEING FIVE YARDS, AND CROSS HOLINGS, TWO YARDS.

Fathoms deep.	Size of Pillars.	Proportion left in Pillars.	Fathoms deep.	Size of Pillars.	Proportion left in Pillars.
	yards.			yards.	
20	20 x 5	·41	180	26 x 14	·69
40	20 x 6	·50	200	26 x 16	·71
60	22 x 7	·52	220	28 x 18	·73
80	22 x 8	·57	240	28 x 20	·75
100	22 x 9	·59	260	30 x 21	·77
120	22 x 12	·61	280	30 x 22½	·78
140	24 x 12	·63	300	30 x 24	·79
160	24 x 14	·66	*M. Wearmth.	40 x 29	·80

*The Monkwearmouth colliery, at the depth of nearly 300 fathoms, has been worked with five yards openings, whilst the block of coal is left 40 yards x 29 yards.

It is particularly to be observed that to work cheaply in the "whole" is to a great extent opposed to an economical "broken" or second working, and for the following reasons:

First. That to get a large quantity of coal in the first working of course leaves less for the "broken," and while in the first case we get a large amount of coal for a certain length of wagon-way, engine plane, or other haulage road, in the "broken" we get a proportionally smaller quantity for the same wagon-way, etc., and consequently all charges connected with upholding the same will be very heavy upon the "broken" on account of the smaller quantity of coal to be worked.

Second. When too much coal has been taken away when working the "whole," the "broken" workings are difficult to maintain in an efficient working condition, and are very liable to "creep," that is, the floor lifts, and consequently consume a larger quantity of timber etc., than they would have done had the pillars been left larger.

Third. The coal got under the above circumstances is generally of a soft nature giving a small percentage of round, and often so crushed that large portions are left underground.

It will be seen from the preceding that if the first working is cheap the second working will in all probability be expensive, and it is therefore readily seen what a very difficult point it is for the mining engineer to decide as to the cheapest method of working his pit so that the cost of the "broken" added to the cost of the "whole" or first working, will amount to a minimum total cost over a given area of coal field.

If the excavations made during the first working are of such an extent as not to leave sufficient coal to be a support for the roof or a preventative against the bottom or floor of the seam, rising up, the second working is always very expensive, and the coal very much crushed, yet if the excavations bear such a proportion to the coal left that the weight of the superincumbent strata is not able to render the coal softer and easily worked, the customary saving in a lessened hewing or getting price may not be expected; another important consideration to be looked at demanding that the pillars should not be too large so that the coal in the "broken" should be softer than in the "whole" is that no blasting in the coal is allowed in the broken workings of many seams.

At this juncture a weighty question arises as follows: In the case of house coal would it not be cheaper to leave large pillars and so get a good percentage of round in the "broken," than getting a good percentage in the "whole" workings, but very poor in the "broken," as is the case when small pillars are left?

It is also necessary that the following question should be kept in view: Would the increased percentage of round coal in the "broken" workings more than balance the probable extra cost of getting or hewing?

In some cases we have also to look at the necessity of getting a large supply of coal at once incident upon the opening out of a new colliery or in a current going colliery upon the arrival of increased trade, in which cases it is often necessary to have many bords or rooms going at once, and in order to do this, little pillars are left.

We may put this intricate subject before our readers in this light:

SMALL PILLARS.

ADVANTAGES.	DISADVANTAGES.
(a) Large proportion of coal in the whole with a good percentage of round coal.	Low percentage of round coal in the broken owing to the pillars being crushed.
(b) The brokens being smaller or containing less coal for the same area were there larger pillars left, are soon exhausted.	Large cost of hewing or getting over the total workings.
(c) Small amount of straight or narrow work, where yard prices are paid.	Increased cost of maintaining the broken workings.
(d) More coal to be got on short notice then could be in the case of large pillars.	More to be paid for removing falls when the roof is fallen, and more liability to creep.

Besides which there are other considerations for and against the leaving of small pillars, but which it is hardly necessary to mention, at the same time it may be remarked that it depends largely upon what the coal is used for, as to the size it is advisable to leave the pillars; for instance the pillars in a gas or coking seam need not be of such a size as in a house or steam coal seam.

Mr. Buddle's plan of leaving panels separated by barriers, as shown in Fig. 1, recommends itself for these reasons, that it enables the "brokens" to stand better as regards pressure; if the creep does occur in one panel it is prevented by the barriers from extending to any others; and also as the barriers are worked off with the "broken", it gives a better percentage of round coal in the "broken".

We can, with the assistance of the preceding, and data as to costs of working over a given area, arrive pretty nearly at the cheapest method.

We will now dismiss the question as to the size of pillars, and say a few words on the ventilation of broken workings.

Anyone who is a practical miner knows well enough that "broken" workings are rarely as well ventilated as the "whole" workings of a colliery, and the reason is that in the first place the return air-ways from a "broken" are rarely maintained in such good condition as those from a district working in the "whole mine," in consequence of the workings being in an uneasy state; and secondly, because the places are more open and cannot be ventilated by means of brattice (at least the "juds" or working lifts and "loose end" places cannot) as bords and walls in the whole workings; and thirdly, more places exist at which air can escape from the working place; and fourthly, the air spreads itself to a great extent into the goaf or gob; and lastly, the removal of the pillars causes the top stone to fall, and the thill or floor to creep, so throwing open reservoirs of gas which often baffle the best ventilation. At a large colliery in South Durham, for instance, when the "broken" working was commenced in one of the seams, the roof fell and gas issued to such an extent as to render foul 38,000 cubic feet of air in the district.

The workings in a "broken" district from these causes are often badly ventilated, and the near proximity of the goaf, which may be considered in fiery seams as a large reservoir of gas and as this sometimes gives the gas off into the workings, it increases the difficulty of ventilating, and interferes with the general comfort of the workmen.

The usual method of ventilating a "broken" district is at the present time only to force the air along the goaf edge, so as to exert a sufficient amount of pressure on it to prevent the gas from escaping in such volumes as to prevent the working off of the pillars, or in other words "to keep the goaf edge clean" by a current of air sweeping along it and carrying off any gas that may exude from the goaf of greater pressure than that of the air.

In one fiery seam in Durham, we are told, however, that it was the regular custom to ventilate the goaf and have currents of air passing through it.

In Greenwell's work on "Mine Engineering" there is a plate which would appear to represent the ventilation of a goaf, yet that this system is both inapplicable and undesirable can easily be seen.

The idea has long existed that gas might be drained from the goaves near the broken workings by means of pipes open at some part of the goaf above the rest, and into which pipes the gas would flow or be exhausted by means of a fan to the surfrce. Messrs. Lyell and Faraday, in their report to the Government on Haswell explosion, proposed this method, and a paper by Mr. Fowler on the subject about twenty years ago, is a further evidence that the idea even then had not been forsaken. There can be little doubt but that these contrivances might be of some use, but when the expense is considered, it is plain that except under particular circumstances, they are practically inapplicable.

Instead, however, of adopting Mr. Fowler's process of exhausting the air from the mine, it has been proposed that it should be forced in and let the only outlet be the mouth of a tube, the other end of which is an arched chamber situated in the highest part of the goaf, by this means fresh air would be forced in at the edge of the goaf, and expel the gas through the tube and out to the surface, but to this would apply the objections of the late Mr. Dunn, H. M. Inspector, and others, that it would partially destroy the ventilation of the mine, but it need only be in operation when the pit is not working.

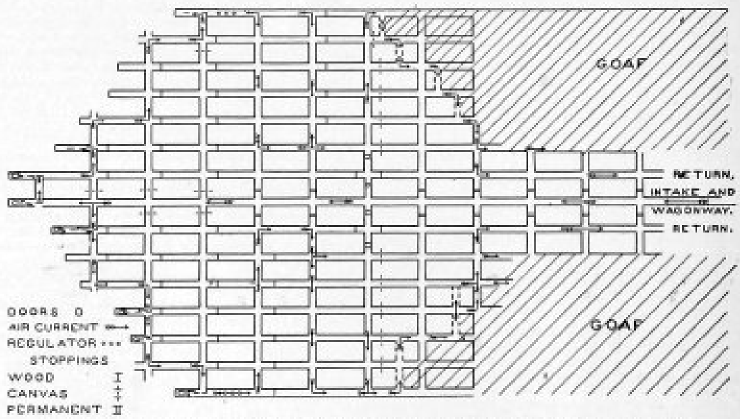

FIG. 2.—ILLUSTRATING METHOD OF FOLLOWING UP "WHOLE" WITH "BROKEN" AND THE VENTILATION OF THE GOAF-EDGE.

(Scale, 250 ft. = 1 inch.)

Mr. Buddle in his evidence on the explosion that occurred at Wallsend Colliery in June, 1835, says with reference to ventilating the goaf in pillar workings: "These wastes are not ventilated and a great quantity of foul air is necessarily engendered there, and at these situations a current of air is directed to pass the face or front of the void to carry off the gas emitted from it to the gas drift." And again before a Parliamentary Commitee in 1835 he says: "We proceed to take off the pillars of coal, always working to the windward, that is to say against the stream of air in order that whatever gas may be made, may be immediately carried off from the people working there."

It will thus be seen that the system of ventilating a "broken" is to keep the air pressing on to the goaf, but not into and through it. This is shown in Fig. 2, the ventilation of which is indicated by the arrows.

[TO BE CONCLUDED.]

We are pleased to note that the enterprise and fair dealing of the Ottumwa Iron Works, of Ottumwa, Iowa, in furnishing first-class haulage and hoisting machinery at reasonable prices has been rewarded by a strong demand for their machinery from all parts of the country. During the month of June they have shipped or have on their books the following orders:

1 Pair Geared Hoisting Engines 16" x 24" for Colorado.
1 Pair Geared Hoisting Engines 16" x 24" for Penna.
2 Pair Geared Hoisting Engines 10" x 12" for Iowa.
1 Pair Geared Hoisting Engines 12" x 16" for Kansas.
1 Pair Direct Acting Hoisting Engines 20" x 32" for Missouri.
1 Pair Tail Rope Hoisting Engines 15" x 18" for Tennessee.
1 Pair Tail Rope Hoisting Engines 12" x 16" for Ind. Ty.

Such a showing for one month is positive evidence of the favor in which their engines are held, and we advise parties contemplating the erection of hoisting or haulage engines to write them for bids, particulars of construction, etc.

REGULATORS.

BY S. M. ROBERTS.

Having noticed within the past eighteen months the difference of opinion among the readers of THE COLLIERY ENGINEER in regard to the theory of finding the area of regulators, I wish to express my opinion on the subject.

The difference of opinion among your readers has been as to which of the following formulæ is the correct one

$$\frac{k\,s\,v^2}{p} = a, \text{ or } \frac{k\,s\,v^2\,q}{n} = a.$$

Now, I don't think either of the above formulæ can be applied to find the area of a regulator. They are to find the area of an air-way "that has lateral resistance." While a regulator has no lateral resistance, all the power being expended in velocity.

Therefore we must apply some formula in which the power is expended in giving rise to velocity to find the size of a regulator, to pass a certain quantity under a given pressure.

The formula used by most authorities for the flow of fluids through a thin plate is:

$$\frac{V}{\cdot 61\ \sqrt{2\,g\,h}} = a, \quad (1)$$

where

V = quantity in cubic feet per second.

·61 = co-efficient of contraction into co-efficient of velocity.

g = gravity = 32·2.

h = head of fluid.

a = area in thin plate.

To illustrate the theory I am about to demonstrate, I will use Figs. 1, 2, 3, and 4.

Suppose we have two air-ways, Fig. 1, A B, and Fig. 2, D E; A B having a greater resistance than D E, and a quantity equal to q passing through A B (per minute) under a pressure (in air column) equal to B C. Again, suppose we have any given quantity passing through D E under a pressure (in air column) equal to F D. Then the power expended in D E will be equal to B C — F G. Then, suppose we have a hole in a thin plate equal to O under a pressure equal to F G; and capable of passing a quantity equal to that passing in the air-way D E.

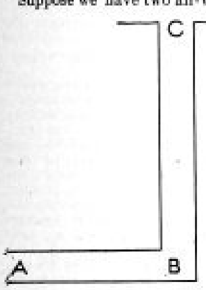

FIG. 1.

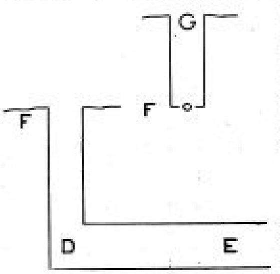

FIG. 2.

Then the same power will be expended in D E plus O as is expended in B A.

Now, suppose we take O, Fig. 2, and place it as a regulator, O, Fig. 4, then will the power expended in D E, Fig. 4, be equal to that in A B, Fig. 4, also A B, Fig. 1.

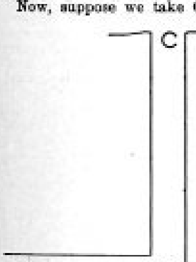

FIG. 3.

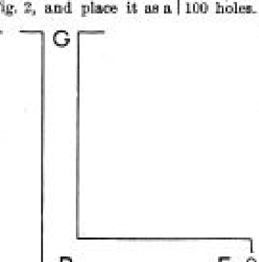

FIG. 4.

Therefore the resistance is the same (each resistance due to the column D G.)

Now we have sufficient data to base a formula:

Let H denote B C, Fig. 1.

Let h denote D F, Fig. 2.

Let h_0 denote F G, Fig. 2.

Then,

$$H - h = h_0 \quad (2)$$

Substituting the value of h_0 in (1), we have

$$\frac{V}{\cdot 61\ \sqrt{2\,g\,(H - h)}} = a \ (3) \text{ or area of regulator.}$$

To make this a little easier to understand, I will solve a problem given in a recent issue:

QUESTION.—"An air-way 6′ × 6′ × 1500′ is passing 12000 cu. ft. per minute. What size regulator should be placed in an air-way 7′ × 8′ × 600′ so as to pass the same quantity."

Let k = co-efficient of friction in air column for a velocity of one foot per minute = ·00000026881.

s = rubbing surface for air-way No. 1.

a = area in square feet for air-way No. 1.

v^2 = square of velocity for air-way No. 1.

A = area for air-way No. 2.

V_0^2 = square of velocity, air-way No. 2.

S = rubbing surface, air-way No. 2.

q = quantity = 12,000.

Then,

$$\frac{k\,s\,v^2}{a} = H = B\,C, \text{ Fig. 1.}$$

and

$$\frac{k\,S\,V_0^2}{A} = h = D\,F, \text{ Fig. 2.}$$

Substituting figures

$$\frac{\cdot 00000026881 \times 24 \times 1{,}500 \times \left(\frac{12{,}000}{36}\right)^2}{36} =$$

29·86 + = H = B C, Fig. 1, and

$$\frac{\cdot 00000026881 \times 30 \times 600 \times \left(\frac{12{,}000}{56}\right)^2}{56} =$$

3·94 + = h = D F, Fig 2.

Hence,

$$29{\cdot}86 - 3{\cdot}94 = 25{\cdot}92 = h_0 = F\,G, \text{ Fig. (3).}$$

Then substituting the value of h_0 in (1), we have

$$\frac{200}{\cdot 61\ \sqrt{64{\cdot}4 \times 25{\cdot}9}} = 8{\cdot}93 \text{ square feet of}$$

area of regulator.

(3) may be thus reduced

$$\frac{\cdot 204\ V}{\sqrt{\frac{k\,s\,v^2}{a} - \frac{k\,S\,V_0^2}{A}}} = \text{area of regulator.}$$

V_0^2 and v^2 = square of velocity in feet per minute.

V = Quantity to pass through regulator in cubic feet per second.

To give myself greater satisfaction, of the above theory, I tried an experiment on a regulator, and obtained the following result:

(1). With ·1-inch water gauge a velocity of 1,150 feet per minute.

(2). With ·26-inch water-gauge I obtained a velocity of 1,910 ft. per minute.

(3). With ·25-inch water-gauge I obtained a velocity of 1,790 ft. per minute.

(4). With a water-gauge of ·09 inches I obtained a velocity of 1,060 ft. per minute.

NOTE.—The thermometer was held in the middle of orifice while measuring the velocity.

BLASTING BY ELECTRICITY.

The use of electricity for firing blasts, either of common black blasting powder or dynamite, commends itself to all practical men having sufficient work to justify the small first outlay for the necessary apparatus: first, because it is absolutely safe, and secondly, because by firing a number of holes at *exactly* the same instant of time, the entire and combined strength of the explosive is fully secured.

The apparatus necessary for electric blasting consists of enough insulated copper wire to reach from the battery to the blast, a few feet of connecting wire, some electrical exploders or caps, and a magneto machine.

The "Pull Up" Blasting Machine is a first-class one, and is largely used in work where a large number of shots are to be fired at once. The three principal sizes are Nos. 3, 4 and 5. No. 3 has a capacity from 20 to 30 holes; No. 4, from 40 to 50 holes; and No. 5 from 75 to 100 holes.

In this Blasting Machine between the field pieces there is fitted to revolve an armature wound to a very high resistance. The rapid revolving of the armature by pulling up the operating bar, generates an electric current of high electro-motive power, which, at the moment of its maximum intensity, is sent out to the outside circuit, in which are the exploders, the explosion of which is instantly accomplished.

These machines are operated by a very easy and simple motion, which works smoothly and without any strain upon the parts. The operating bar, after being pulled up to fire, will fall back into its place of its own weight, and is ready to be used again. All parts are made strong and durable.

These machines are warranted to fire the number of holes claimed at a distance of 500 to 1,000 feet.

For blasting purposes, where the number of holes range from 5 to 8, the No. 1 "Victor" Machine is a cheap and good one. It weighs but 15 lbs. and its dimensions are 7½ in. × 7 in. × 4½ in. For tunneling and ordinary shaft sinking it meets all requirements.

The Smith Blasting Machine is a magneto-electric instrument of small size, weighing only about twenty-two pounds, occupying considerably less than one-half a cubic foot of space.

It is constructed on the Wheatstone and Siemen's principle, having a magnet of the horseshoe character, of iron, wound about with coils of insulated copper wire; between the poles of the magnet there is fitted to revolve an armature of cylindrical construction, carrying in its body other insulated wire coiled longitudinally, as to the cylinder.

The rapid revolution of the armature, by suitable means, generates and sustains in the machine an accumulative current of voltaic electricity of great power, which at the moment of its maximum intensity is, practicably, switched off to the outside circuit in which are the exploders, and in the interior of each exploder, the ignition is instantly accomplished. These machines are made in two principal sizes. No. 3, and No. 4. The first has a capacity of from 10 to 20 holes, and the second from 20 to 40 holes.

The Crescent Blasting Machine is the simplest in construction, and requires no skill on the part of the operator. It discharges a uniform current of electricity at every operation. There is no violence or rapid movement required when making the blast, and the parts are not liable to break or get out of order. It is also made in two principal sizes. The "C" machine having a capacity for 20 holes; and the "D" machine having a capacity for fifty holes.

Each machine should be supplied with enough leading wire to make two leaders of sufficient length to reach from the blast to a safe distance for the person who operates the machine, to stand. Cotton covered wire is generally used, and gutta percha covered wire is also used to a small extent. However, the most convenient leading wire is the "Improved Cable manufactured by the Aetna Powder Company, of Chicago.

A small quantity of pure copper wire for connecting the exploders in the various holes is also necessary. If the exploder wires are picked up after each blast, they can be twisted together, and used in place of connecting wire. Each outfit should also have convenient reels on which to wrap the leading wire and connecting wire when not in use.

The electrical exploders, or caps, are a very important factor. In fact without them electric blasting would be impossible. To insure success and safety *only the best quality should be used*, and exploders made by different manufacturers should never be used in the same blast, as they may be of unequal electrical resistance.

A very important and useful addition to the blasting apparatus is a roll of insulating tape. That made of okonite and sold by the Aetna Powder Co., of Chicago, is the best. It is a useful and convenient article for covering bare wire joints in blasting, either on dry ground or under water. Its composition is okonite, a superior insulating compound. It makes a waterproof joint, and can be applied instantly. The heat of the hand will cause it to stick fast to the bare wire, and it cannot be removed except by cutting it off. It is put up in half-pound packages, in widths of ½ and ¾ inches. It costs but a trifle, and should be generally used by all blasters for covering bare connections.

To use this tape the cloth, which is only placed upon it to separate the layers, and prevent the compound from sticking together, must be removed.

Wrap the joint thoroughly, taking pains to have the tape overlap, then apply a little heat from a lighted match, when it will be found impossible to remove the tape without tearing it.

The application of heat is preferable, but not absolutely necessary.

The following general rules must be observed to ensure the greatest safety and success in electric blasting:

Drill as many holes as you want to fire at one time. The distance between the holes should be about the same as the depth of the holes; thus, if the holes are 10 feet deep they should be about 10 feet apart and 10 feet back from the face of the rock. Place the electrical exploders in the center of the explosive to be used, and let the wires extend some ten or twelve inches above the mouth of the hole loaded.

Tamp the holes carefully with dry sand or fine earth.

Care should be taken when tamping not to injure or cut the insulation on the wires, as bare portions of the wire or bare joints should never be allowed to touch the ground; particularly so if the ground is wet. Many blasts have failed by allowing bare connections to come in contact with the ground and it is sometimes advisable to cover the joints with insulating tape.

When all the holes to be fired at one time are loaded and tamped, separate the ends of the two wires in each hole, and, by the use of connecting wire, join one wire of the first hole with one of the second, the remaining free wire of the second with one of the third, and so on to the last hole, making a continuous connection between the holes and leaving a free wire at each end hole.

Connecting wire should be of same size as the exploder wires. Leading wire should be at least twice as large.

All connections of wires should be by hooking and twisting together the bare and clean ends. *Great care should be taken that the connections are clean, bright, and well twisted*; more failures occur from improper connections than from any other cause.

The charges having all been connected as directed above, the free wire of the first hole should be joined to one of the leading wires, and the free wire of the last hole with the other of the two leading wires extending to the battery. The leading wires should be long enough to reach to a point at a safe distance from the blast—say two hundred and fifty feet to five hundred feet.

Everything being ready, *and not until all are at a safe distance from the blast*, clean the free ends of the two leading wires and connect one to each of the two set screws on the battery, by passing the ends through the holes in the set screws, bringing the thumb-nuts down firmly upon the wires. Then operate the battery by using the handle as directed by the rules accompanying the type of battery used.

Great care should be taken with the exploders. The Aetna exploders which are all of quintuple force, and every one of which is guaranteed, are the best. They will explode any of the high explosives, such as blasting gelatine, gelatine dynamite, ammonia powder, or ordinary dynamite. There are no second quality Aetna exploders made.

The above data has been compiled from practical experience gained in all kinds of mining, quarrying, and excavating work, and is published more in detail and with numerous illustrations in the new catalogue of the Aetna Powder Co. of 95 to 101 Randolph St., Chicago. This catalogue will be sent free on application to all readers of THE COLLIERY ENGINEER. The explosives and blasting apparatus manufactured and for sale by this company are all of first quality, and are fully warranted.

THE COAL-DUST THEORY.

Its History from 1803 to 1892—Its Production in Mines and the Various Methods of Overcoming its Dangerous Properties

BY W. WALKER, OF NOTTS COUNTY, ENGLAND.

Within the past few years the subject of coal-dust has been brought prominently and constantly before the mining world, by means of searching enquiries into the cause of explosions, and frequent reports of minute and searching examinations of mines in which explosions have occurred, lectures on coal-dust and its irritability of flame, together with numerous experiments and demonstrations illustrating its dangerous properties, and lastly, by the report just issued by the Royal Commission appointed to enquire into the effect of coal-dust on explosions in mines.

These experiments and reports have conclusively proved that finely divided dry coal-dust is capable of feeding and materially lengthening the flame and increasing the destructive properties of an explosion of marsh gas and air.

They have also proved that fine dry coal-dust is capable of raising air containing from 2 to 3 per cent. of fire-damp to an explosive point.

Also from some of these experiments it appears that certain kinds of very dry, finely divided, highly combustible and most inflammable coal-dusts, when present in large quantities and in the close vicinity of a strong blown-out shot, may cause an explosion in the absence of appreciable marsh gas, whose intensity and destructive force may be even greater than the intensity and destructive force of an explosion of marsh gas and air.

Coal-dust, therefore, becomes a most dangerous element in the art of coal-mining, and demands most careful study and care on the part of all interested in coal mining.

It has existed in coal mines from the earliest days of coal mining; it being to a greater or less extent an unavoidable daily product of coal mining.

The quantity of coal-dust produced daily in our modern coal mines is incomparably large compared with the quantity produced during the early days of coal mining; hence the dangers of coal mining have increased.

This great difference is due to the rapid extension which coal mining has undergone during the latter part of the present century, by which mines are enlarged, greater depths reached, more men employed, the use of explosives more common, greater distances along which coal has to be brought from working places to pit-bottom, and an increased velocity of transit.

These are some of the chief causes which have tended toward an increased production of coal-dust in modern coal mines.

The first mention of coal-dust as a dangerous element in connection with coal mining occurred in the year 1803, in which year an explosion occurred at the Wallsend colliery, in the North of England, by which 13 men and boys were killed, and 20 more or less seriously injured. It was decided to investigate into the cause of this explosion, and Mr. Buddle was appointed to make the necessary examination. After making all necessary examinations in the mine, he wrote his report, which stated that the mine was dry and dusty, and that the survivors who had been the furthest from the seat of the explosion were burnt by red hot sparks of coal-dust, which had been ignited by the flame of the explosion and carried along by the force of the current.

His report proved that the injury to the workmen and the destruction to the property had been increased by the ignition of these fine particles of dry coal-dust; and yet history yields no record of experiments or discussions on this new theory of mining dangers.

No more is heard of coal-dust for a period of 25 years, when its dangerous properties are again mentioned by a Mr. R. Ball; but such report seems to have had no more effect on the mining world than Mr. Buddle's report, since it does not appear to have induced any experiments or discussions on the dangers of coal-dust.

Such silence, indifference, and neglect is not to be wondered at when it is remembered that mining engineers were very scarce in those days, and colliery managers were often made out of men from other industries than mining, so that farmers, blacksmiths, joiners, &c., were often appointed indiscriminately to take complete charge of a mine; men who knew nothing of the dangers attending the art of coal mining, whose knowledge of roof and sides and their necessary support, methods of extraction, gases produced, and found in mines, their effect on animal life, and the safe removal or dilution of these gases, was *nil*.

No wonder that a knowledge of the effect of fine dry coal-dust in the presence of an explosion of marsh gas and air, or of its effects in the presence of a strong blown-out shot has been so markedly slow.

Nothing could have retarded this new theory more than the appointment of incompetent men to such responsible positions.

Meanwhile, explosions were occurring more frequently and owing to the extension of mines the number of victims were gradually increasing with nearly every explosion; thus feelings of sympathy were raised in the hearts of intelligent and feeling men, and as successive explosions occurred, accompanied by their dreaded results, taking away the stay and the support of families, rendering children fatherless, sometimes orphans, and parents sometimes childless, it was thought desirable that more minute and searching investigations should be made into the causes of these explosions; so that when the great Haswell explosion occurred, in September, 1844, by which 95 men and boys lost their lives, two eminent men (Faraday and Lyell) were appointed to investigate into the cause of this explosion.

They entered into their work earnestly, and spent much time in the mine examining minutely everything which could give them the least trace into the cause of the explosion; they also paid great attention to the evidence given at the public enquiry, and from this evidence very little gas could have been present at the time of the explosion, quite inadequate to produce such disastrous results.

During their examinations they found deposits of coked coal-dust adhering to the bars, props, and sides of the roadways along which, the flame of the explosion had passed, varying in thickness from one-half to nearly one inch.

This coked coal-dust enabled them to come to the conclusion that as the flame of the explosion had come in contact with this fine dry dust it had decomposed it, and under such conditions each particle of dust had yielded up to the flame a part, or the whole of the gas it contained, which gas fed the flame and thus increased the destructive effects of the explosion.

They presented their report to the Home Secretary in the year 1845, and after describing the possible collections of fire-damp in a mine, the different ways by which it was disturbed by atmospheric changes, the way by which it could be effected by falls of roof, consequent on the removal of timber or otherwise, thereby reducing the areas of the reservoir in which gases could collect, also the effect of certain mixtures of fire-damp and air when brought into contact with flame.

They continued their report by stating that the whole of the flame and the destructive force of the explosion, was not, in their opinion, due to an absolute mixture of fire-damp and air, but that the extent of the flame, the intensity of the heat, and the destructive force of the explosion, had been materially increased by the fine dry particles of coal-dust, as collected on the bars, props, sides, and floor of the mine.

This valuable report was given to the mining world in 1845, and in the same year Faraday lectured at the Royal Institution in London, on the effects of coal dust in conjunction with an explosion of marsh gas and air, and thus by their report, lecture, and illustrations, Faraday and Lyell tried to force home to the mining world the intensified effects of an explosion of fire-damp in the presence of fine dry coal dust.

It would seem, from the want of recorded history, to have either been forgotten or entirely ignored, or disbelieved in by the mining community, as no more appears to have been heard of the coal-dust theory for a period of ten years.

This is, perhaps, not to be wondered at, when we consider the disbelief generally introduced when any new theory or idea is introduced or propounded. Mankind is naturally very slow to accept new theories.

The knowledge contained in these reports and lecture of Faraday and Lyell's does not appear to have traveled out of England; for in 1855, ten years later, the mining world is awakened by a report from France, by M. du Souich, who had examined a mine immediately after an explosion of fire-damp, and stated in his report what he considered a new theory on explosions, viz., "The Coal-Dust Theory." He observed during his examinations the coked coal-dust adhering to the bars, props, and sides of the roadways through which the blast had passed, and came to the same conclusion as Faraday and Lyell had done in 1845.

In the year 1861 the same French mining engineer examined two mines where explosions had occurred, and in his reports of these examinations he again advanced the coal-dust theory, and tried to show how coal-dust had materially increased the destructive force of these explosions.

The continuation of these reports on coal-dust awoke the mining world from its slumber of indifference, and induced in some a desire to prove the truth of these strange statements.

From 1864-7, a Frenchman, named M. Verpilleux, had a series of experiments carried out, which proved fine dry coal-dust to be a dangerous element in an explosion of marsh gas and air. Other Frenchmen continued these experiments, but especially a M. Vital, who in 1875, made some experiments on some fine dry coal-dust obtained from a mine where an explosion had occurred in which gases were seldom detected. His experiments were carried out with a view to ascertain the effect of coal-dust in the presence of a strong flame, resembling the flame from a blown-out shot. He was satisfied that very fine, dry, and highly inflammable coal-dust would, in the presence of a strong blown-out shot, &c., suffer decomposition and feed the flame, and thereby increase the destructive force of an explosion.

Experiments were made in England, about this time, by Mr. W. Galloway, on a large scale. From these experiments he was led to believe that coal-dust would not of itself produce an explosion; but in the year 1880, he conducted a further series of experiments, and proved that certain kinds of very fine and highly inflammable coal dust would produce an explosion when present in large quantities, and in the vicinity of a highly-charged blown-out shot.

About the same time experiments were carried out by Professor Freire Marreco and Mr. W. Cochrane, at the Elswick Collieries. These experimentalists made their experiments in a model colliery, ventilated by a model Guibal fan, by which a strong current of air was maintained, and a quantity of fine dry coal-dust thickly suspended in the air current. At this stage of the experiment a pistol was fired into the air current, which was immediately followed by so violent an explosion that the model mine was damaged and the Guibal fan broken.

These experiments were continued by Messrs. Morrison, L. Wood, and G. Gray, and by the North of England and the Chesterfield Institutes of Mining Engineers.

To further illustrate the destructive effects of very fine dry coal-dust in the presence of a blown-out shot, a series of experiments were carried out by Mr. H. Hall, Her Majesty's Inspector of Mines for the Liverpool district, in conjunction with Mr. Clarke, about the year 1875. These gentlemen had placed at their service an adit level or footrill 45 yards in length, and dipping from the entrance in direction of the dip of coal; the adit was arched with bricks, and had a sectional area of about 30 feet, and it was ventilated by a vertical shaft. At distances of 15 feet sheets of a very inflammable nature were suspended across the level, and reached two-thirds of the height of the adit, and nearly touched the floor. In these sheets small holes were made, and in these holes small quantities of powder were put. Charges of gunpowder varying from 1½-2½ lbs. were fired at intervals, and under varied circumstances, from a cannon fixed at the end of the adit level.

In the first experiment the cannon was charged with 1½ lbs. of powder, and the charge rammed with underclay or clunch. When fired it was found that the flame of the blown-out shot had reached about 15 feet; no sheet or powder had been affected by this charge.

The second experiment was with 1½ lbs. of powder, but the charge was rammed with small coal and a quantity of fine dry coal-dust spread in the vicinity of the cannon, and extending eight or nine yards from the cannon. In this experiment the flame reached 30 feet, but not 45, as proved by the firing of the inflammable sheets and powder.

In the third experiment the charge of powder was 2 lbs., and rammed with small coal, and coal-dust in the vicinity of cannon, as in second experiment. In this experiment the flame reached 45 feet, but not 60, as shown by sheets and powder.

The fourth experiment only differed from the second and third in the charge of powder, it being 2½ lbs. The flame reached 60 feet, but not 75, as proved by cloth and powder.

In the fifth experiment, the adit being wet, the floor was covered by deal boards all the length of the adit, and thickly covered with fine dry dust. The charge was 2½ lbs. of powder rammed with small coal. In this experiment the flame issued in a large volume from the mouth of the adit level, and of such intensity, that had any one been standing at the mouth of the adit it would have killed them.

The temperature of the adit was 50° F.

Water was slowly dripping from the roof and the floor was wet.

No gas could be detected at the time of these experiments.

These experiments carried out as they were, under conditions very possible in a mine, proved conclusively that the length, the intensity and the destructive force of the flames from a blown-out shot was considerably increased when fine dry coal-dust was inflamed, and the length of the flame in the third and fourth experiments was increased at least 15 feet for every additional ½ lb. of powder. This was due to the additional powder increasing the force of the explosion, thereby enabling more coal-dust to be decomposed, by which more gas was thrown into the flame, increasing its length.

Mr. Hall continued his experiments, in 1890, in a vertical shaft placed at his disposal having a depth of 200 yards. He represented a blown-out shot by the firing of a cannon, pointing upwards, from the bottom of the shaft. In his first experiments he fired the cannon in the absence of dust, and merely obtained a loud report, similar to the report of a shot fired at the bottom of a sinking shaft. He then had a quantity of very fine dry dust riddled into the shaft from the surface, after which the cannon again was fired, and the flame of the shots variously increased; whilst in some of these experiments the flame issued from the mouth of the shaft, proving conclusively the danger of very fine dry coal-dust in the presence of a rapid and powerful flame such as issues when a blown-out shot occurs.

Since the majority of these preceding experiments were carried out, the Royal Commission on Accidents in Mines spent considerable time in making experiments on coal dust from different collieries, and the outcome of all these reports and experiments was that part of G. R. 12 of the 1887 A. of P. which refers to the ramming of shots and firing of shots where dry coal-dust exists.

About the same time, and also quite recently, the Prussian Fire damp Commission spent much time in making experiments, on an elaborate scale, on the effect of fine dry coal dust in conjunction with an explosion of fire-damp, and its properties in the absence of fire-damp; the outcome of their researches being the introduction of more stringent rules.

The coal-dust theory being brought so prominently and constantly before the mining world, induced Parliament to appoint, on February 9th, 1891, a Royal Commission on explosions from coal dust in mines. The first report of this Commission has just been issued, and shows how exhaustive the Commission has been in endeavoring to ascertain the opinions of some of the most influential and interested gentlemen connected directly with mining. Such gentlemen consisting of the Chief Inspectors of Mines, Mining Engineers from various coal fields, and Professors of Science.

Twenty-three witnesses were examined by the Commission, and of this number twenty-one were examined directly on the coal-dust theory, with the following result: Thirteen of these witnesses are agreed that very fine dry coal-dust is capable of causing an explosion in the presence of a blown out shot and in the absence of fire-damp; the remaining eight witnesses, whilst not admitting coal-dust as capable of causing an explosion in the absence of marsh gas, are agreed that it is dangerous element, and capable of aggravating an explosion of fire-damp; also able to render smaller quantities of fire-damp capable of producing an explosion.

In each of these commissions fine dry coal-dust is regarded as a very dangerous element in mining. Thus the coal-dust theory has gradually been gaining ground and has been the means of explaining much of the mystery surrounding several of the explosions that have occurred during the past 10 or 15 years. At the enquiries held immediately following these explosions, evidence has repeatedly been given that fire-damp has not been detected, or otherwise only to a very limited extent on the day of explosion, and therefore quite inadequate to produce an explosion, whilst the minute and searching examinations in the mines immediately after an explosion, have often revealed a state of things which, according to the coal-dust theory, were quite competent to produce an explosion.

The Seaham explosion of 1880, by which 164 men and boys lost their lives, is generally considered to have been due to the effect of a blown-out shot in a district that contained large quantities of very fine, dry, and highly inflammable coal-dust; probably with a small percentage of fire-damp in the air.

The Altoft explosion of 1886, by which 22 men and boys were killed, was proved at the enquiry to be due to a strong blown-out shot, which had been badly planted, in a district containing large quantities of very fine dry coal dust. This explosion occurred on a principal intake air-way 500 yards from the downcast shaft and along which 40,000 cubic feet of air were passing per minute. The explosion occurred in the afternoon, when all the day shift men were out of the mine, otherwise the results would have been more disastrous.

The Elemore explosion of 1886, by which 28 men and boys lost their lives, was also proved to have been due to a strong blown-out shot, which had been badly planted in a district containing large quantities of fine dry coal-dust. This explosion also occurred on a principal intake air-way, 200 yards from the downcast shaft, and along which 37,810 cubic feet of air were passing per minute.

This explosion also occurred when the day shift had been drawn to the surface, otherwise the results would have been more appalling.

Explosions of fine dry coal-dust resulting from a heavily charged and bad planted blown out shot, and in the absence of appreciable marsh gas, may generally be distinguished from an explosion of marsh gas and air, by the first results of the explosions.

In the case of an explosion of coal-dust, the seat of the explosion is, generally speaking, not much disturbed, since the first stages of an explosion of coal-dust are the feeblest; but it gathers force as it travels; being fed by the gas from the particles of coal-dust, and produces the greatest destruction where the largest quantity of dust exists.

Pure air traveling at a high velocity will favor an explosion of coal-dust, since it contains more of the element oxygen to support the combustion of the dust.

In the case of an explosion of marsh gas and air, the seat of the explosion is often most difficult to find, since its first stages are very violent.

Pure air in large quantities renders marsh gas inexplosive.

Having briefly stated the coal-dust theory, and shown how it is possible for coal-dust to either intensify an explosion of marsh gas and air, or cause air containing only a small percentage of fire damp to become explosive, or cause an explosion itself in the absence of appreciable marsh gas, but in the vicinity of a heavily charged and badly planted blown-out shot, we must next consider how coal dust is produced in mines.

The amount of coal-dust produced in a mine will depend on the following conditions:

(1) The nature of the coal.
(2) The methods of extracting the coal.
(3) The practicability of the workmen.
(4) The condition of the rolling stock.
(5) Transit from working places to pit bottom.

The nature of coals varies very considerably: some coals being soft, tender, friable or nesh, and cannot be extracted from their natural position without producing large quantities of slack and dust. Such coals cannot be conveyed over the long distances common in modern coal mines, and at high velocities, without producing small, which eventually becomes a part of the dust of mines by the passage of men, boys, and horses to and from their working places.

Other coals are hard, strong, dense, or compact, and can be extracted and rehandled without producing much slack and dust, and admit of being conveyed over great distances much safer and quicker.

This statement is proved where two coals, the one a soft coal and the other a hard coal, are extracted at the same time and in the same mine. In the soft coal roads the production and accumulation of dust is much more rapid for a given quantity extracted than in the hard coal roads. Hence the amount of dust produced will depend to some extent on the nature of the coal worked.

(2) *The method of extraction.*

There are always certain natural directions in which coals may be worked with a maximum production of large coal and a minimum production of slack and dust. A soft, friable coal will yield a maximum of large and a minimum of dust if worked on the end, a technical term employed by colliers to indicate right angles to the slines of the coals, or to nature's marks. If such coal be worked on the face, *i.e.*, parallel to the slines, it will yield a maximum of slack and dust and a minimum of large coal. If worked on any point between end and face, long or short horn, it will produce less large than when worked on end and more large than when worked on the face.

Therefore, the best way to work a soft, tender coal is on the end, other circumstances being favorable.

A hard, strong coal will yield a maximum of large and a minimim of small if worked on the face, parallel to the slines. It will in most cases make the most small and dust when worked on points between face and end, long or short horn. Therefore, the best way to work a hard, strong coal is on the face, other circumstances being favorable.

Whilst pointing out the best methods of working coal with a maximum of large and a minimum of small and dust, it must not be forgotten that local circumstances may often decide the exact point at which coals must be extracted.

No mine of any extent can at all times so arrange the whole of its working places so as to constantly advance on the best point for producing a maximum of large and a minimum of dust. The thickness of the seam of coal will affect the production of small and dust. If the seam be thin and is required to be holed and cut deep, there will be an increase of dust. If the nature of the floor or thill be so hard that the holing has to be done in the coal itself, the amount of dust produced will be materially increased. If the coal be worked with a series of cuttings, the dust produced at these points will be very abundant, due to the incessant grinding action at such points, and should the seam be thin and large quantities of air required, then the high velocity with which it travels along contracted cuttings picks up the dust and carries it in suspension, and deposits it where the velocity is decreased, due to increased area.

The amount of dust produced will depend to some extent on the readiness or otherwise of the coals to fall when liberated, without the aid of explosives, since the shattering force of an explosive materially increases the production of dust, and the blast of the explosion floats the dust in the air in clouds.

(3) *The practicability of workmen.*

Contractors, stallmen, or workmen may increase or decrease the dust unavoidably produced according to their practicability. When the workmen are sound practical men, they will always try in Longwall working, to keep their stalls straight from end to end, free from all buttocks or projections; they will have their coals holed to a good depth, if necessary, and always keep plenty of stock in advance, so as to allow the coals to soak or leave the roof, and thus be ready to fall on the removal of sprags, thereby avoiding the use of explosives as much as possible; they will by timber and packs try to avoid weights, which, when heavy, grind the coal considerably. They will constantly supervise their workmen and prevent them from unnecessarily cleaving the coal, and will see that the coal is so loaded that with ordinary tramming it will not fall down by the way from the working place to the pit bottom. Good workmen in post and pillar working are equally careful in their endeavor to extract the coal in the best and most practical way, and will be very careful to hole and cut their coals to the very best advantage. Such men usually use the least explosives, where explosives are allowed.

In their endeavor to make a day's wages, they ever keep before them the fact that it is, generally speaking, the large round coal that makes their wages, and recognize in every ton of slack and dust produced and thrown into the goaf or gob, a direct loss to themselves, their fellow workmen, their employers, and the community at large, and thus every effort is centered on a maximum of large round coal and a minimum of slack and dust.

In the case of incompetent or negligent workmen, no regular system is observed, and such workmen and their working places are always from hand to mouth, nothing is done at the proper time, therefore nothing can be found in its proper place at proper times, viz.: props, packs, sprags, cuttings, rippings. Such incompetent workmen in thin seams, working by the post and pillar system, where, generally speaking, more explosives are employed than in Longwall working, sometimes put their holes in with such bad judgment, and charge them with the same wisdom, that when the shots are fired no coals can be found at the face, the overcharged shot hole having blown the coal to slack and dust and scattered it in all directions, and to such distances as to be beyond hopes of recovery.

In mines where a round price is paid to workmen for large and slack coal, there is every encouragement to carelessness in getting the coal. In such mines the dangers are greater and more numerous than in mines where it is the large coal that makes the workmen's wages.

(4) *Condition of rolling stock.*

The condition of the rolling stock will affect the production of dust in mines.

The trams, tubs, or wagons may be considered as the most important rolling stock, and may be either box ended, or one open end, or practically both open ends. In the latter case the tram consists of a frame with two sides, with a narrow strip of sheet-iron 6 or 8 inches wide passing along one end and attached to each side.

Each of these trams are used often in the same district.

Open ended trams are not to be recommended for mines where the gradient is perceptible and variable, because of the impracticability of always keeping the open end or ends of the trams in such position as is most suitable for retaining the coal, nevertheless, they have their advantages in low seams, and enable the loading of the coal to be done quicker and easier, and can convey a great weight of coal per tram.

If the trams or tubs be not kept in good repair, they act like a sieve, and allow the smaller pieces of coal to fall through upon the roads, and a great part of such coals becomes eventually the dust of the mines. If kept in good repair, they prevent the smaller coals from falling through, and therefore assist in keeping the roads clean.

The transit of the coal from the working places to the pit bottom produces the greater part of the dust of mines, and the amount produced will depend on the following conditions:

The size of the roadways.

The condition of the roads, crooked or straight, good or bad roads.

Methods of haulage.

If the roads leading from the working places be small and partly packed up with dirt, then owing to the scrubbing of coal either on the sides of the roadways or on the roof, small and dust must be produced, and such accumulates along the roadways.

If the roads be badly laid or crooked, trams or tubs will not ride. It is a well-known fact that a good loaded tram will not ride on a bad road, and a badly loaded tram will not ride on a good road. And whenever coals are turned out of a tram, either by accident or otherwise, the whole of coal is never put into the tram again, but small pieces are left on the roads, and the workmen, horses, or trams grind it to fine dust.

If the roads be level, the removal of the coals is much facilitated and much safer, and produces less dust than when the roads are inclined. In the latter roads lockers or sprags, used in the wheels of the trams, and heavy chains running behind the trams to further assist the ponies, produce large quantities of very fine dust.

The first part of the haulage is done by men, ponies and horses, after which the haulage is generally mechanical, such as self-acting inclines, dip engine roads, tail rope haulage, and endless ropes or chains. Sometimes large quantities of dust are produced, and at the same time the air is laden with very fine dust by a runner or a breakage on dip haulage roads, due to the drawing of cap or socket of rope, breakage of rope and underchains, breakage of coupling, breakage of a brake strap, or carelessness on the part of the men and boys on the main roads.

The endless rope haulage produces the least dust of any mechanical haulage, due to the slow regular speed at which the trams run, and the necessarily large roads required for this method of haulage. The fine particles of dust always to be seen on the surfaces of the coal in trams or tubs are picked up by the air current when strong, and especially where the trams and the air current are traveling in opposite directions, which is commonly the case. These fine particles of dust are floated by the air current until they are finally deposited on the roof, bars, props, sides and floor of the roadways.

The traveling of the men, boys, and horses to and from their working places is constantly producing dust in dry mines, which remains for some time after their passage more or less suspended in the air, and finally deposited on the bars, props, and floor of the mines.

Very fine dust is sometimes carried down the downcast shaft from the screening plant, and especially if such plant be erected near the pit top, and the direction of the wind carries the dust over the mouth of the shaft.

The dust being produced in a variety of ways, the very fine particles are suspended by the action of the air current, and coming in contact with the bars, props, sides, and floor of the mine, collect particle by particle at these points until large quantities accumulate, unless systematically removed.

It will be seen from the preceding pages that coal-dust is most abundantly produced and accumulates most rapidly on the main haulage roads of a mine, because on these roads the whole of the coal must pass in traveling from the working places to the pit bottom, and as these roads are chiefly the intake air-ways for the mine, the dust will be much dryer.

Generally speaking, the dust is also dryer in deep mines than shallow mines. This is due to the higher temperature and the more or less absence of surface water.

The very fine dust produced at the working places is fresher and purer than is found at any other part of the mine.

The return air-ways do not contain dangerously dry dust, since the air, which has become more highly charged with moisture in its passage through the working places, yields up a part of this moisture in its passage through the return, and if a return has been in use for years, as a return, very little coal-dust will be exposed to sight, the whole of it being coated over with the products of combustion from the lights employed in the mine.

The dangers attending the production and accumulation of fine dry coal-dust in the working places and roadways of a mine suggest a decreased production wherever possible, and whilst there are a large number of mines in which the dust question is closely attended to in the most practical ways, there are nevertheless mines in which little, if any, attention is paid to this dangerous element.

Its production and dangers can only be decreased and avoided by a combined effort on the part of the management of the mine and the workmen employed.

On the part of the management only good and practical workmen should be employed, and these should be supplied with sufficient material to keep their working places in the best condition, and the roads under their supervision in good repair. The trams, tubs, or wagons should be constantly maintained in good condition, the roadways large, and the roads kept in good repair, the best system of haulage introduced, and the main road arrangements on the best principles.

On the part of the workmen a stricter supervision amongst themselves is necessary, so that every care is observed in working their places to the best advantage, with a view to producing a maximum of large to a minimum of small and dust. Where explosives are allowed, the greatest care and judgment in deciding the position of shot hole, the boring of the hole, the amount of explosive employed, the nature of the material employed for ramming, and the ramming of the shot, so as to avoid a blown-out shot.

In all cases of blasting on dusty main roads, which is usually done at night time, after complying with General Rule 12 and Special Rules in force at the colliery, further precautions should be taken by causing the deputy or fireman, who is generally chosen from the most practical workmen to examine the position of every shot hole before it is charged, and if not satisfactory, have another one bored under his direction, and to charge the hole with the explosive himself, or otherwise see that it is not overcharged, and be should also see that it is rammed with suitable material, damp sloom or clay, so as to reduce the possibility of a blown-out shot to a minimum of danger.

Much has been said and written during the past few years about the more or less practical ways by which the dangers of fine, dry, coal-dust might be removed or safely overcome.

In a few words, the dangers of coal-dust may be removed or safely overcome by the careful removal of a part of the dust, accompanied by a systematic sprinkling of water on the roadways, thereby keeping the roads clean and damp.

In some mines large quantities of dust are loaded up and sent to the surface, or to a gobgate, or into the working places, to be gobbed, and the most dangerous places sprinkled with water, and then swept up. In some cases water pipes have been laid on the side of the principal roadways, and at short distances small upright pipes terminated with rose ends, screwed into the main, and from these small pipes the water is directed to the dust on the roadways. This method is not largely employed.

Mechanically-arranged water tanks have been introduced, by which a spray of water is thrown upon the roads during the motion of the tram.

The most common and most practical method of watering the roads is by means of the common water-cart having one or two plug holes in the end and sides, or lengths of perforated $1\frac{1}{2}$ to 2 inch pipes attached to the ends or sides of the water barrels, the plugs are withdrawn as required, and the water flows either in a stream or in a spray.

The watering of the roof and sides of roads, and especially the roof, partakes more of theory than practice. Very fine sprays of water have been thrown into the downcast shaft, so as to saturate the air with moisture, but such an imperfect method of laying the dust in mines is not much advocated, since it cannot carry its water to the more distant roadways, but deposits it too near the pit bottom. It is also injurious to the workmen, being constantly surrounded by air fully charged with moisture.

Impure salt has been employed in North Staffordshire, and was reported a few years ago to be giving satisfaction. It was stated that 9 tons were required for every 500 yards of roadway, and such required to be done every week for the first month, and once a month afterwards. This method does not appear to meet with much favor, probably due to cost and extra work required. The removal of a portion of the dust, together with the sprinkling of water on the roads, when carried out systematically, gives general satisfaction, and induces feelings of safety.

Much has been said about the effects of water on the roadways of a mine, and it has been generally admitted that its effect on the roadways varies very much in different mines, according to the nature of the strata, and as nearly the whole of the water falls upon the floor of the roadways, it will be the floor which is most affected. It will, therefore, require more repairs to be done to the roads, which means an increased cost for repairs, but generally speaking an increased cost is not considered when the safety of the workmen and the mine is at stake.

DEFINITIONS OF TECHNICAL TERMS.

Clunch—A kind of hard earthy fireclay.
Deal Boards—Planks.
Planted—Located.
Slips—A facing or smooth parting or joint in coal, etc.
Horn Coal—Coal marked partly *end-on* and partly *face-on*.
Post and Stall—A system of working a coal seam, much the same as *Pillar-and-stall*.
Trams—Cars.
Bar—A length of timber placed horizontally for supporting the roof.
Gob-Gate—An abandoned road used for the purpose of stowing or gobbing refuse.

THE PROGRESS IN MINING.

Reviews of Important Papers Relating to Mining in the Proceedings of the Mining and Scientific Societies, and in the Mining Journals of Europe, United States, and Canada.

Chemical Means of Preserving Wood and Timbers for use in Connection with Mines.

At a recent meeting of The North Staffordshire (Eng.) Institute of Mining and Mechanical Engineers, a paper on the above subject was read by Mr. Joseph Taylor.

Mr. Taylor commenced by remarking that winter was the best time for felling timber, as it was less liable to dry-rot than if felled at any other time.

Defective ventilation is one of the chief sources of deterioration or rapid decay of timber in mines. The chief impurity in the atmosphere of mines which exercises a prejudicial influence on the timber of the mines is carbonic acid, which with a certain temperature and humidity is highly favorable to the growth of fungus. This fungus sets up a chemical change, which causes decay of the timber and vitiates the air of the mine at the same time.

Mr. Taylor described various methods in use for the purpose of preserving timber in mines and recommended creosoting as being the most efficacious. It is especially valuable as a preservative of the softer and more porous kinds of timber when placed in wet places. Any timber used in wet roadways may be rendered twice as durable by creosoting.

Trial of Coal-Cleaning Plant at a Scotch Colliery.

By invitation of Messrs. Kesson & Campbell, the makers, a large and representative gathering of coal masters, colliery managers, and others interested in the coal trade, recently assembled at Dechmont Colliery, near Newton, Scotland to inspect the dry coal-cleaning and washing machinery just fitted up by them for the Dechmont Colliery Co., Limited. The result as regards the character of the machinery was altogether satisfactory, it being admitted on all hands that Messrs. Kesson & Campbell have been successful in bringing out a set of plant which is unsurpassed by that of any other maker in Scotland, and which will compare favorably with any other coal cleaning plant.

This colliery was the creation of the Flemington Coal Company, and for a time the pits were the deepest in Scotland, the depth to the splint coal being 212 fathoms or a quarter of a mile. The company started to draw coal about the end of 1878, but as the works proved unremunerative, they were abandoned in 1882, everything being demolished except the winding engines of No. 1 pit, the pumping engines and steam winch. In the beginning of 1890, the present company entered on the lease, fitted up the pithead frames, cleared the pits of 130 fathoms of water, and commenced to draw coal about February, 1891.

At the colliery there are two pits about 140 feet apart, which are connected by a scaffold 22 feet above the ground. Under the scaffold are eight lines of railway, on which the various kinds of coal are loaded into wagons. Before the coal reaches the wagons, however, it is thoroughly cleansed and separated—the processes in use for this purpose being those known as the "dry" and "wet," the former for treating the large and the latter the small coal.

Near the middle of the scaffold are placed three revolving tippers, which are common to the two pits, so that the car loads of coal from either pit may be run into any of them as desired, and tipped onto the distributing bands. Each of these tippers is placed at the beginning of a set of machines for "dry" cleaning and separating. Each set is for the treating of a different seam of coal, and consists of a distributing band, jigger screen, coal picking band, screen shoot, and delivery plate. These being in alignment, the coal is passed from the one to the other in the order named.

The distributing band effects the uniform distribution of the coal over the jigger screen and picking band, and the jigger screen effects the separation of the coal into large and small—the large passing over the screen on to the picking band, and the small passing through the holes in a perforated plate forming bottom of screen on to a conveying band underneath. This conveying band, which is common to all the three jigger screens, conveys the small coal from them, and delivers it into the small coal receptacle. The large coal, passed over the jigger screen to the picking band, is freed from all foreign matter, which is easily seen and picked out by hand as the band carries it along. From the picking band the coal is passed over the screen shoot on to the delivery plate, and from it into the wagon. Any small that is in the coal after passing from the picking band falls out through the screen shoot so that the large coal passes into the wagon entirely free from all foreign matter and small, and ready for the market. The small falling through the screen is delivered by a conveying band into the small coal receptacle. The foreign matter picked from the large coal is treated as follows: That to which there is no coal adhering is conveyed by a haulage to the refuse heap, while that to which there is coal adhering is conveyed by a band to a crusher, where it is broken up, and then elevated and conveyed by the small coal conveyor to the small coal receptacle. This completes the "dry" cleaning process. The small coal is lifted from the receptacle by a bucket elevator to a height of fifty feet and discharged into a revolving screen. By this screen it is separated into three sizes, the first or smallest being run through a shoot into an improved washer of the conical type with revolving arms or stirrers. The coal is washed free of all foreign matter which is elevated and delivered into a car on the scaffold level from whence it is run to the refuse heap. The washed coal (or "pearls" as they are known in the trade) is carried by a flow of water into a revolving screen of fine wire meshing over which the greater percentage of the coal passes into a large hopper with a perforated inner lining, where the water is drained off and returned to the pond to be again used, the coal being delivered dry into a wagon. A small percentage of the coal passes through the meshing of the revolving screen along with the water, but this is run through pipes to a silt recovery where the coal is separated from the water and deliverd at the boiler doors for stoking purposes.

The second size of coal from the first mentioned revolving screen is passed through a shoot into a newly improved washer of the Bash type, and is there washed free of foreign matter. The washed coal in this case is taken out of the washer almost dry by means of an arrangement of inclined perforated plates and scraper blades and delivered through a shoot into a wagon. The third size of coal from the same revolving screen is washed in a Bash machine similar to that described, but adjusted to suit the larger size of coal. The coal from this machine is conveyed by a traveling band to a revolving screen, and there separated into two different sizes and delivered into wagons on separate roads. These two Bash washers are so placed as to secure a very compact and effective arrangement of the elevators for removing the refuse and recovering the small coal. The refuse is delivered into a car on the scaffold level, from whence it is run to the refuse heap. The water used for the washers is that pumped from the pits, from which it is delivered into a storage tank. From this tank it is pumped into the Bash washers by a small Worthington pump, and, after circulating through them, overflows into the range of pipes leading to the silt recoverer. The silt recoverer consists of a tank about forty feet long, by seven feet wide at top and tapering to two feet wide at bottom, and thirteen feet deep. In this tank a bucket elevator works, made so that the buckets scrape along the bottom of the tank its entire length. The buckets lift all the matter which has subsided to the bottom of the tank, and delivers it into shoots delivering at the boiler doors. The buckets being perforated, all the water is drained out and runs back into the tank. The clear water from the silt recoverer overflows through pipes into the settling pond, from which it is lifted by a Pulsometer pump and forced into the conical washer. As already described, the water overflows from this washer, carrying with it a small percentage of the washed pearls through pipes into the silt recoverer, and thus completes the circulation of the water. The motive power of the "dry" cleaning plant is derived from a 14-in. by 21-in. vertical engine, and for the "wet" from a pair of coupled engines each 14 in. by 24 in., while the silt recoverer elevator is worked by a 6 in. by 12 in. horizontal engine. As most of the machinery works automatically the whole apparatus only requires the attention of one man.

Note on the Report of the Austrian Fire-damp Commission.

Mr. W. N. Atkinson, English Government Inspector of Mines, has prepared a paper for the North Staffordshire Institute of Mining and Mechanical Engineers, entitled "Note on the Report of the Austrian Fire-damp Commission." Mr. Atkinson has reviewed some of the experiments and conclusions of the Austrian Fire-damp Commission published in the *Annales des Mines* by Mons. Chesneau, and in the *Bulletin de la Societe Minerale* by Mons. Rene Grey. With regard to the composition and properties of fire-damp and of air currents in fiery mines, he said fire-damp from a number of blowers was analyzed, and the results showed that proto-carbureted hydrogen or methane was the only hydro-carbon usually liberated by coal. The results of the analysis did not differ essentially from those obtained by the Prussian Commission, except as to those at Obernkirchen, where an extraordinary percentage of ethane was found. Hydrogen was not found in gas from blowers in any true coal, but was found in small proportion in the Trifail lignite mines, which gas also contained a considerable amount of carbonic acid and nitrogen. Gas extracted from coal by means of boreholes differed in composition according as it was taken from newly-opened workings or from the old pillars. In the former case its composition was very similar to gas from blowers, while in the latter case there was a considerable diminution in the proption of methane and a corresponding increase of carbonic acid due to the oxidizing influence of the air. It was proved that coal completely exhausted of gas by prolonged exposure would not reabsorb as much gas as it liberated. When placed in methane at atmospheric pressure the maximum quantity of methane reabsorbed did not exceed 1·61 cubic inches for 1,543 grains. Analyses of the air-currents in mines showed that owing to the oxidizing action of the air on coal the quantity of oxygen compared with that of nitrogen was always less than its proportion in pure air. Thus in the mines of Bohemia there was on the average 79·54 per cent. of nitrogen for 20·355 of oxygen, while in pure air there was only 77·04 of nitrogen for that quantity of oxygen. With respect to the pressure of gas developed in boreholes, at Rossitz a pressure of 5 atmospheres was obtained in a borehole $24\frac{1}{4}$ ft. long, and at Ostrau-Karwin 9·2 atmospheres in boreholes $21\frac{1}{4}$ ft. maximum length. Most important experiments were made as to the influence of the getting of coal and the atmospheric conditions above and below ground. The return air from the most fiery district contained an average of 1·51 per cent. of fire-damp (and 0·103 per cent. of CO), and yielded in twenty-four hours 518·91 cubic feet of fire-damp per ton extracted.

Having spoken of the quantity of fire-damp exhaled per ton of coal, he proceeded to notice the experiments made with safety-lamps, observing that in a general way it was shown that brass wire gauzes appeared more dangerous than iron wire gauzes, and that the addition of a small quantity of dust to the moving mixture increased the danger, while a large quantity, on the contrary, diminished the danger by producing an excess of combustible gas which extinguished the flame of the lamp. The Austrian Commission concluded from the experiments that the lamps used in Ostrau-Karwin—Mueseler, Wolf and Marsaut lamps—were much safer than was generally admitted, since, when shielded, they resisted the most explosive mixtures at velocities much exceeding 32·8 ft., which was practically the highest velocity encountered in fiery mines. Details were supplied as to experiments with explosives. The latter bore chiefly on the danger of shot-firing in the presence of coal-dust, and they showed that the danger of dust was greater than was usually recognized. To combat the danger of dust, watering of the working places was recommended, which, when it could be properly done, gave very good results. In dusty mines without fire-damp high explosives should be used after complete removal of the mass of dust by sweeping or watering; if practicable, safety explosives should be used, which, when stemmed with damp sand, gave great security. If there was also a small amount of fire-damp ($\frac{1}{2}$ to 1 per cent.) the shot should also be fired by means incapable of causing flame. The Commission made several recommendations as to the classification of fire damp mines, the method of opening and working mines, and ventilation. Fans were recommended in preference to furnaces for ventilation. Furnaces should not be allowed in mines producing much fire-damp, and where used in mines producing little fire-damp, or a moderate amount only, the return air should not be allowed to come in contact with the fire. Considerable attention was given to the question of lighting, and the Mueseler, Wolf, and Marsaut lamps were mentioned as good lamps, and precautions were pointed out as to the firing of shots and the working of fiery and dusty mines. Mr. Atkinson concluded by saying: "The experiments on the circumstances which influence the liberation of fire damp are interesting, and they appear generally to confirm the opinion usually held on the subject in this country and expressed in the report of the Royal Commission on Accidents in Mines. The analyses of fire-damp present no remarkable features, except that some of them show a good deal of nitrogen and carbon dioxide. The gases evolved from coal heated to 212 degs. Fahr. often contained a certain proportion of ethane, the presence of which gas has been supposed by some persons to have an effect in increasing the inflammability of the dust from the coal containing it. The pressures observed in bore-holes were not so high as some of the pressures attained in this country in the same way, a pressure exceeding 30 atmospheres having been observed on one occasion. The observations on the effect of variations of barometrical pressure accord with general experience. The statement that barometrical pressure does not effect the liberation of carbonic acid gas appears to require qualification. It may have done so in the mines experimented on, but as a general rule I believe the liberation of this gas is influenced as much as fire-damp by changes in the atmospheric conditions. It is said that the velocity of the wind on the surface, and storms, have no influence on the liberation of fire-damp in mines artificially ventilated. But such atmospheric disturbances sometimes have the effect of reducing the amount of ventilation and so increasing the proportion of fire-damp, besides which they are usually accompanied by a sudden decrease of pressure. With regard to the safety-lamp, experiments, M. Chesneau considers they were not so searching as those of the French Commission because of the limited duration of each experiment. The French experiments were made with lighting gas, and the lamps could be kept in an explosive current for an unlimited time, and the apparatus was so constructed that the lamps could be jerked about and placed at different angles with the current. He also considers the experiments made with lamps in stationary mixtures unsatisfactory because of the small capacity of the testing chamber in which the explosive mixture could not be renewed, in consequence of which the products of combustion extinguished the lamps before a proper observation could be made. The French experiments proved that in most of the lamps placed in explosive mixtures at very low velocities, so as to get rid of the products of combustion, the gas continued to burn in the lamps for an indefinite time, and in some cases to heat the gauzes to redness. He is also of opinion that 90 seconds was too short a time in which to observe satisfactorily the "caps" formed by different proportions of gas, except in the case of the Pieler lamp. It appears that in Austria the Pieler lamp is in regular use for the dection of fire-damp. The English Royal Commission condemned it as dangerous, and in the form it was first introduced no doubt it was dangerous. Subsequent modifications have made the lamp safer, but not so safe that it can be recommended for general use. In the earlier form of lamp the alcohol was apt to overflow from the wick tube and fill the gauze with flame; to prevent this the bottom of the lamp is now filled with cotton wool to absorb the alcohol. There is some uncertainty about the exact percentage of gas indicated by caps of different lengths. The cap-lengths given by the inventor of the lamp and subsequently by Dr. Brookmann for the German Fire-damp Commission exceed those given by the French and Austrian Commissions. The lamp should not be used without being completely shielded and should not be taken where gas may be present until a previous examination with an ordinary lamp fails to detect the gas. It is only useful for detecting low percentages of gas in an air-current and not for finding gas in the goaf or in holes. It should only be used by persons of discretion and experience. The experiments with explosives bore principally upon the danger from coal-dust. It was not found possible to decide the degree of danger caused by different dusts from their chemical composition and physical properties. The only conclusion drawn is that the sensitiveness of dusts increase generally with the proportion of easily inflammable hydrocarbons (especially with the amount of ethane liberated at 212 degs. Fahr.), and with the dryness of the dust. This is a question requiring further elucidation. That the dryer a dust is the more inflammable it becomes is easily understood; what we want to know is how damp it must be to be harmless. I incline to the opinion that the physical condition of coal-dust as to dryness, purity, and fineness will be found to be more important factors than its chemical composition." The soda-dynamite recommended for use by the Austrian Commission was not approved by the French Sub Commission on Explosives. The following is an extract from their report, as translated by Messrs. Brown and Bird, for the North of England Mining Institute: "The Prussian and Austrian Commissions agree in recommending the use of mixtures of dynamite and crystallized carbonate of soda. The conclusion cannot be accepted, because these mixtures have not only a very low explosive force, but, further, the easy dehydration of the salt may lead to serious inconvenience. It has been previously mentioned that if an attempt is made to thaw cartridges of frozen dynamite in warm water, the nitro-glycerine is expelled from the pores of the silica, and exudes when the water rises to 95 degs. Fahr., and the cartridges then become dangerous. The same effect may occur as has been mentioned, during summer in magazines where the cartridges are stored; and cartridges prepared some weeks back may be thus seriously damaged. It appears difficult to recommend the use of such unstable explosives, which may cause serious accidents, even in the absence of fire-damp. It is remarkable that several other salts, easily volatilized, but more stable than carbonate of soda, were not tried, as was done by the French Commission. There is no need therefore to repeat the reasons which led the French Commission to abandon mixtures of this nature, and to replace the inert salt, by a salt explosive in itself, such as nitrate of ammonia; as the desired safety may be thus obtained, without sacrificing too great a proportion of the explosive force." The classification of mines for legislative purposes according to the amount of fire-damp they produce has never been attempted in Great Britain, and it is doubtful whether such a scheme is either practicable or desirable. The recommendations of the Commission as to precautions against a fire on the surface preventing access to the mine by both shafts is worthy of consideration. No serious catastrophe from such a cause has occurred in Great Britain, but if a fire on the surface prevented access to a mine by both shafts, and the smoke went down the downcast shaft, the loss of life might be great. The opinion of the Commission that shot-firing may still be allowed, when the greatest precautions are taken, in places where there is 2½ per cent. of fire-damp, is, in Mr. Atkinson's opinion, wrong. Such a proportion can not be detected by ordinary safety-lamps, and the only safe rule to go by is not to fire shots where any gas can be detected in that way within 20 yards of the shot. It will be observed that where dust is present in addition to 2 or 2½ per cent. of gas, the Commission would prohibit shot firing altogether.

THE USE OF ASBESTOS IN MINES.

Its Superiority Over Other Materials as a Non-Conductor, and its Structural Advantages.

Asbestos is a highly refractory fibrous mineral, having about 90% of silica and magnesia in its composition. It is insoluble in water, and will not change its mechanical (that is, fibrous) structure when wet.

The application of Asbestos in operating mines, is to insulate steam connections. The problem which confronts the mining engineer is, how to secure good results with a steam boiler at the mouth of the pit, and a pump several hundred feet under ground, or a fan several hundred yards away from the boiler, necessitating the use of long lines of steam pipe which must be covered with a non-conducting material to prevent the radiation of heat.

This pipe often runs close to the tracks in slopes and along haulage roads, or is hung perpendicularly in shafts, where it meets with the roughest usage and is often subject to the constant drip of water, sometimes strongly impregnated with sulphur.

Of what form and of what materials to make an insulator that will be of service under such trying conditions is the question that must be solved. That the pipe must be covered is scarcely a matter of debate. Assuming the pipe to be 4″ internal diameter, and the run, say 1,000 feet, the exposed iron surface will be 1,250 square feet, *i. e.* the equivalent of a flat surface 125 feet long by 10 feet broad.

Assuming, further, a steam pressure of 70 lbs. we have a body of heat at 316° Fahr., 1,250 square feet in extent constantly radiating into an atmosphere about 250 degrees cooler than itself, with results which anyone familiar with the condensation of vapors can easily predict. Theoretically, it would take over 8 tons of coal per annum to remedy the waste in each 100 lineal feet of pipe, or, at $3.00 per ton, $24.00 per 100 feet, making a total waste on the line of pipe in question of $240.00 per annum, but practically the pump could not be run, as the water of condensation would clog the cylinder and valves so as to stop the motion and injure the machinery.

With the pipes properly insulated by the application of a good non-conducting covering, all this loss can be prevented, and perfectly dry steam delivered at great distances from the boiler.

The loss from radiation under such favorable circumstances is infinitesimal, and compared with the loss or waste through friction and other causes, is not worthy of note. It is hard to obtain reliable statistics owing to the difficulty of making accurate observations from apparatus covering so much ground. In a recent test, however, of a system of piping carrying hot water under pressure at 400 degrees Fahr., the total loss, in a travel of 10,000 feet, chargeable to radiation, was placed at 3%. These tests were made by competent engineers, and with the use of every means known to science. All of the pipes in question were insulated with 1½″ in thickness of Asbestos.

Having considered the possibilities of the case, we now revert to the main question. What material, if any, will answer the purpose?

Such material to fully answer the purpose must fill the following requirements:

1. It must be a non-conductor of heat.
2. It must be unaffected by heat.
3. It must be unaffected by water.
4. It must stand rough usage.

A countless list of articles have been offered by enterprising vendors, with various devices for fire proofing, water-proofing, etc., and in turn have been discarded for some fatal defect.

The fire-proof lining has been found no protection or the water-proof cover has been broken away and the water has destroyed the coverings.

It may be interesting to review a few of these to see in what way they fall short of the standard we have just set up, *i. e.*, durability under heat, water, and rough usage.

First comes Hair Felt, the oldest form of pipe covering in use, one of the best non-conductors of heat known, because so full of air cells, but hair felt is short lived under heat, and disintegrates rapidly when wet. The various fire-proof linings used under hair felt do indeed prolong its life but do not give it real durability, and for mine work it cannot be recommended. Then there is an extended list of paper pulp and wool felt materials, usually made up in sectional or cylindrical form. Some have a thin sheet of Asbestos as a lining, placed there more for appearance than use, as a close examination will show the Asbestos to be too thin to afford much protection.

The best type of this covering is made of alternate layers of wool felt and Asbestos sheathing, laid up in cylindrical form so as to leave air spaces. But this covering while efficient and durable, under ordinary circumstances, will not stand the exposure of a mine shaft; the wool felt will char, leaving the Asbestos.

We would refer right here to the well-known effect of heat and moisture on organic substances, which is to disintegrate them rapidly. Hence these, and similar coverings, containing a large percentage of hair, wool, and other organic matter will be quickly destroyed in mines, and we therefore lay down the general proposition that no covering should be adopted for use in mines that contains organic matter in its composition.

The various forms of non-conducting cements are more durable under heat but are too easily injured by rough usage to last long in a mine. We can divide them into two classes, those containing heavy clays or earths with animal or vegetable fibers as binders, and those made from Asbestos and infusorial, or fossil earths. The former are only nominal pipe coverings, as they do not retain the heat and have no real value. The latter have merit, but are not of service in the line of work we are now contemplating.

In connection with these cements or plastic coverings, we find in use several made from mixing magnesia or plaster with Asbestos. The Asbestos acts as a binder and adds to the strength of the plastic compound, which is formed into sections or slabs, but the objection urged against the use of cement in mines holds good against this form of material; it will not be found durable.

We have just referred to various forms of non-conducting coverings and point to the fact that in each case the materials used in their make-up other than Asbestos cannot be recommended for use when exposed to great heat, continued moisture, and rough usage.

We now point to another most important fact to be observed, which is that all the durability these goods possess is found in Asbestos Fibers, which they contain. The hair, wool, paper, pulp, etc., chars under heat, while the clay, magnesia, plaster, and other similar fillings wash away under exposure to moisture or crack and break when subjected to abrasion.

It was the discovery of these facts that led to the construction of the style of pipe covering manufactured by the H. W. Johns Manufacturing Company. This meets all the demands of mine work, and we will now fully describe it.

It is an established fact that the non-conducting property of a material depends not so much on the elements of which it is composed as on their mechanical arrangement. A material which is made up in solid and compact form, so that its particles be in close contact will be a poor non-conductor of heat. If, however, this same material be loosely felted together so as to form numerous air cells between its particles or fibers it will then prove an excellent non conductor of heat, and it is such substances only which admit of such treatment that are useful as non-conductors of heat. Asbestos, for instance, is popularly known as a mill board or sheathing, and in this form is only a fair heat insulator, while in the loose or fibrous form it is one of the best non conductors of heat known.

In conformity to these well proven facts the covering we are about to describe is made solely from fibrous Asbestos.

The Asbestos is taken in its crude or natural state, and by special processes it is cleaned from all foreign substances and the long silken fibers are selected and separated and divided until they are as loose and fine as a bat of cotton.

This material has been found to answer the first stipulation as laid down earlier in this article, *i. e.*, it is a good non-conductor of heat.

It also meets the second requirement and will stand the most intense radiated heat that can be brought to bear on it, for it is entirely free from all organic substances, and hence will meet the third requirement, which is to be unaffected by water.

This material is then taken and by machines, invented by the H. W. Johns Company, it is shaped into cylindrical form, of sizes to fit pipes of any diameter and of any required thickness.

These cylinders or sections of Asbestos are then cut on one side so as to open and slip over the pipe, after which they are neatly jacketted with suitable material, and provided with bands and buckles to hold them in place.

For mine work, under favorable conditions, the jacket is a light cotton duck which is afterwards coated with a water-proof paint to keep the covering dry as possible. But in very wet places, and under trying conditions, a jacket of Asbestos and wire cloth is substituted. This is a special material formed by uniting layers of Asbestos through the meshes of wire cloth after which the material is water proofed. This forms a jacket of great strength and durability, unaffected by heat and impervious to moisture.

These jacketings are to give finish to the coverings, and also to prevent any excess of moisture in them, as moisture fills the air cells and promotes conduction of heat. The covering does not depend on the jacket either for its strength, or for its protection, as the Asbestos Fibers from which it is made have in themselves great strength and will stand very rough handling. If they are wet they dry out again without in any way injuring the covering.

We have thus far treated Asbestos only in its function as a non-conducting covering, and we can justly claim to have demonstrated its unequalled merit for this purpose.

There is certainly no material known that in any way approches to it for such a purpose.

But it is not only in this way that it is useful to the miner. There are many other ways in which it is useful and doubtless many more will be devised in the near future.

It is largely used as a piston packing in cylinders of engines and pumps, and also as a flat packing to make cylinder heads, steam chests, and all kind of flange joints.

As a fire-proofing it admits of great possibilities. Its long silken fibers can be spun and woven into a fine fabric that would make an excellent brattice-cloth, and the many light flexible and durable forms into which it can be made could, when intelligently used, greatly decrease the fire risk in mines.

We venture to predict that the present known uses of Asbestos are to its soon to be discovered possibilities, as the feeble steam of the pioneer Cornish pumps are to the present million gallon Worthingtons of to-day.

We therefore commend it to the notice of every thoughtful and progressive mining engineer.

Correspondence

This department is intended for the use of those who wish to express their views, or ask, or answer, questions on any subject relating to mining. Correspondents need not hesitate to write for supposed want of ability. If the ideas are expressed, we will cheerfully make any needed correction in composition that may be required. Communications should not be too lengthy, and personal reflections should be carefully avoided.

All communications should be accompanied with the proper name and address of the writer—not necessarily for publication, but as a guarantee of good faith.

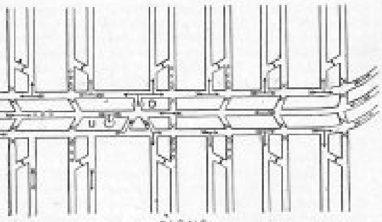
The Editor is not responsible for views expressed in this Department.

Correspondence should be in as simple language, and as free of technical signs and formulæ as possible, consistent with clear solution. Catch-questions will not be published.

Ventilation.

Editor Colliery Engineer :

SIR:—I submit the following sketch in reply to "Straggler" of Mineral Ridge, Ohio, in the May number: It is not by any means free from doors, which of course will not be in accordance with his wish, but with the plan of openings given, it is the best method of ventilation I could recommend, providing both entries have long distances to go. It will be noticed there are two intakes and one return. This could be reversed, if desired, with a very slight change at shafts bottom. By this latter method less track, etc. would be required. There are twelve doors shown but twice that number will be needed if a steady current of air must be kept up to working face, but it is not always the case that middle pillars are large enough to give space for the trips to pass through one door and the other door to be shut. Thirteen overcasts are used.



SIGNS

AIR CURRENT	OVERCAST XX
REGULATORS	UPCAST U
– DOORS	DOWNCAST D

The number and size of regulators to be used would have to be regulated according to the differences of lengths of entries from upcast and number of miners working in each split. (It would be better to regulate entries and number of miners and avoid regulators as much as possible.) If "Straggler" wishes to have his mine ventilated without doors, or nearly so, he will have to somewhat change his plan of openings.

My principal reason for replying to this question is that it may possibly induce some of your able correspondents to give their opinions as to the possibility of working mines without doors or nearly so, especially gassy mines. There is no doubt but that doors are a great source of danger and expense wherever used. I believe if the subject is taken up and discussed intelligently through the columns of THE COLLIERY ENGINEER that the time will be hastened when doors will be a rarity rather than 100 yard obstructions. Too often in the past the cost of erecting the doors only has been considered and not the expense of operating them and the dangers resulting from their use.

Yours, etc.,
JOSEPH CAIN.

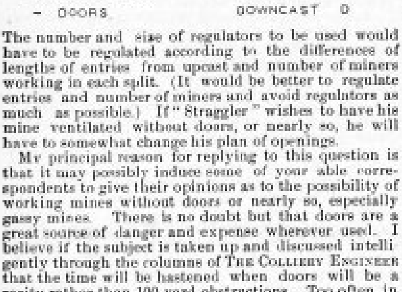
Whitwell, Marion Co., Tenn., May 30th.

P. S.—I would say that the mine could be worked entirely without doors by only having one break-through open at one time, but there does not seem to be any wisdom in that as there would not be sufficient air in the workings.

Gas Met With in Mines.

Editor Colliery Engineer :

SIR:—Please insert the following question in your next issue: A drill hole from surface to coal is 223′. A room 12′ wide is driven from No. 1 entry to drill hole, to be used as a pump room. When the fan is stopped the pump room fills with gas. Now, could this gas be



lighted at bottom of drill hole by throwing fire down, the hole being 8″ in diameter? If so, would the gas explode, and would the coal fire from the gas? When the fire was discovered how would you proceed to quench it, and when extinguished what would be the result in gases?

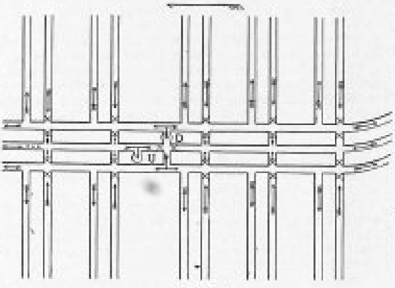
Yours, etc.,
C. H. FELLABOM.

West Newton, Pa., May 7th.

Ventilation.

Editor Colliery Engineer :

SIR:—In answer to "Straggler," of Mineral Ridge, Ohio, in the May issue, I submit the following plan:



SIGNS.

RISE OF SEAM.	REGULATOR ···
AIR CURRENT	DOWNCAST D
X AIR CROSSING	UPCAST U

In case the pitch of seam is in the opposite direction the current should be reversed in the butt headings.

Yours, etc.,
WILLIAM KELLER.

IRVONA, PA., May 23d.

Ventilation.

Editor Colliery Engineer :

SIR:—I notice that "Alberto's" question No. 4, in the March issue, has been answered by "T. K.," of Mount Olive, Ill.

I beg to submit the following in reply to "Alberto" and leave to the decision of your readers as to who is right: Taking "T. K.'s" data we have a main entry $6' \times 14' = 40'$ perimeter and two smaller entries each $6' \times 8' = 28' \times 2 = 56'$ perimeter. Now according to the first law of friction "Pressure varies directly as the rubbing surface," we have

40 : 56 :: 4 lbs. : 5·6 lbs., which would have been the pressure were it not for the second law of friction, "Pressure varies *inversely* as the sectional area." Then,

96′ : 84′ :: 5·6 lbs. : 4·9 lbs. pressure per sq. ft. sectional area of two small drifts.

Yours, etc.,
E. J.

Oglesby, Ill., June 7th.

Mathematics.

Editor Colliery Engineer :

SIR:—Please insert the following in answer to question (2) by "R. L.," of Gasford, Pa., in the May issue:

(2). A coal barge full of Bituminous coal displaces 6,625 cubic feet of water. How many tons of coal does the barge contain?

ANSWER.—In taking this question into consideration we will assume that the water in the hull of the barge is on a level with the coal; any other way of working the question would be suppositional. One cubic foot of fresh water weighs 1,000 ounces or $62\frac{1}{2}$ lbs. One cubic foot of salt water weighs 1028 ounces or 64·25 lbs.

One cubic foot of Bituminous coal varies but weighs, say, 1250 oz. or 78·12 lbs.

Now coal in its broken state as screened and sent from the mines varies in proportion likewise, say, as 62 is to 100.

Therefore in every cubic foot, 62 parts coal and 38 parts water, each would weigh:

Coal, 100 : 62 :: 1,250 oz. : 775 ounces per cu. ft.

Water, 100 : 38 :: 1,000 : 380 ounces per cu. ft.

Coal and water combined 1155 ounces per cu. ft.

Then

100 parts $\div$ 38 = $2\frac{12}{19}$ cubic feet of space to make 1 cubic foot of water.

And

$775 \times 2\frac{12}{19} = 2{,}039\frac{9}{19}$ ounces of coal space to equal 1 cubic foot of water space.

Now there are 6,625 cubic feet of water, this multiplied by $2039\frac{9}{19}$ will give ounces of coal in barge = $13{,}511{,}513\frac{3}{19}$ ounces, or

$$\frac{6{,}625 \times 2{,}039\frac{9}{19}}{2{,}240 \times 16} = 370 \text{ (nearly) tons of coal}$$

the barge contains.

Also,

$$\frac{6{,}625 \times 1{,}000}{2{,}240 \times 16} = 184\cdot84 \text{ tons of water dis-}$$

placed.

If the barge contained sea water, which is much heavier, the weight can be found in the same manner as above.

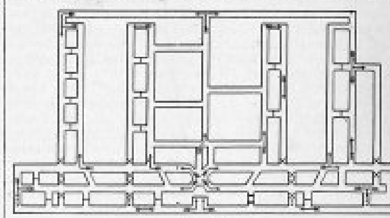
Yours, etc.,
JAMES STIRLING.

Jeanesville, Pa., June 21st.

Ventilation.

Editor Colliery Engineer :

SIR:—I herewith send plan of ventilation as requested by "C. D. R.," of Hope Church, All'y. Co., Pa., in the April number. Very little fault can be found with plan submitted by "C. D. R." Where there is one plan of ventilation as well arranged there are five inferior to it. However, I send the following in answer to Fig. 1 in hopes that it will better enable him to deal with ex-



SIGNS

AIR CURRENT	STOPPINGS =
OVERCAST X	REGULATOR ···
DOORS –	

plosive gas, if any. It will be noticed that I have seven overcasts, four more than the original plan, and two additional short break throughs. I have no doors in entries, an item of consideration, as doors are objectionable and a source of expense when used. I have placed two doors in break-throughs between main intake and main return so that if a furnace is used coal can be brought there, but if the furnace is located elsewhere they will serve as a ready means to pass in and out of air-way for inspection, etc.

"C. D. R." asks for any suggestions whereby his system of ventilation could be bettered. I would point out the following faults (Fig. 1, April issue):

(1.) Only one door separating the intake from the return whereas two should be used.

(2.) A large return air current loaded with impurities directed into main headings on north side.

(3.) An overcast used on one of the south side main headings which does not seem to be of much value as it is shown as an intake current.

(4.) No regulator where one is needed in the return from entries 1 and 2 east on north side of shaft.

(5.) No way shown to get to upcast shaft, except by going around to head of main entry.

The following are a few errors made in ventilating mine (Fig. 2, April issue):

The main intakes are nothing but doors and return air-ways. The left side main entry could be made into a true intake current by the expenditure of a few dollars in building two overcasts and the driving of a few yards of narrow work so as to make one return for each set of four entries. The value of the money spent would be soon repaid. I have no doubt but that other faults visible will be fully dealt with by others of your able correspondents.

Yours, etc.,
JOSEPH CAIN.

Whitwell, Marion Co., Tenn., April 16th.

Mechanics.

Editor Colliery Engineer :

SIR:—Please insert the following question in the Correspondence columns of your journal:

Pipe of what diameter, and boilers of what size should be used to conduct steam a distance of 400 feet, and to an elevation of 150 feet above boilers to run a fan 18 feet in diameter, 85 revolutions per minute. Size of engine 10″ cylinder by 20″ stroke.

Yours, etc.,
SUBSCRIBER.

Pocahontas, Va., June 22d.

Efficiency of Fans.

Editor Colliery Engineer :

SIR:—In looking over the back numbers of THE COLLIERY ENGINEER, I notice a question in the September issue by "M.," of Braidwood, Ill., which remains unanswered, therefore I offer the following solution:

He wants to know the efficiency of a 16′ fan making 130 revolution per minute, with a water-gauge of 3·2″. We will first find the tangential velocity of fan by multiplying the diameter

$16' \times 3\cdot1416 \times 130 = 6534\cdot5280 \div 60 = 108\cdot9$ velocity per sec.

Then,

$108\cdot9^2 \div 32 = 370\cdot6$ motive column, and

$1\cdot2 \times 12 \times 370\cdot6 \div 1{,}000 = 5\cdot33664$ theoretical water-gauge, and by dividing the registered water-gauge by the theoretical we find the efficiency, thus:

$3\cdot2 \div 5\cdot33664 = \cdot599$ per cent.

Yours, etc.,
T. K.

Mt. Olive, Ill., June 20th.

A Word of Thanks.

Editor Colliery Engineer :

SIR:—I wish to thank "J. W.," of Trotter Mine, Pa., for correcting my mistake in answering question No. 2 asked by "Alberto." I simply neglected to deduct the 2,000 feet return, otherwise, the question was solved the same.

Yours, etc.,
T. K.

Mt. Olive, Ill., June 20th.

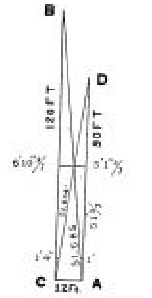
Mensuration.

Editor Colliery Engineer:

SIR:—Please insert the following answer to question (1), asked by "R. L.," of Gosford, Pa., in your May issue:

Two entries are driven parallel to each other as shown by the diagram. Now wishing to drive from A to B and from C to D what would be the distance from AC to where the lines would cross each other?

ANSWER.—From the sketch we see that gangway No. 1 is driven 120 feet and gangway No. 2 is driven 90 feet with 12 feet intervening. Now the angle ADC has a raise of 12′ in 90′, or a raise of 1′ 4″ in 10′, and the angle ABC has the same raise of 12′ in 120′, or a raise of 1′ in 10′. Therefore 1′ 4″ + 1′ = 2′ 4″, which is the distance between the two lines at 10′ distance. The foregoing



is necessary to find the length of the base of a triangle whose altitude is 12′ and having a raise of 2′ 4″ in 10′. Then, as we wish to find the distance from A and C to the point of intersection of the lines we solve thus:

$$12' \div 2' \, 4'' = 5\tfrac{1}{7}, \text{ or } 5'\,1\tfrac{5}{7} \text{ to center.}$$

$$1'\,4'' \times 5\tfrac{1}{7} = 6'\,10\tfrac{2}{7}''$$
$$1' \times 5\tfrac{1}{7} = 5\;1\tfrac{5}{7}''$$
$$\overline{\quad 12' \qquad 0'' \quad}$$

Then,

$10' \times 5\tfrac{1}{7} = 51\tfrac{3}{7}'$, and

$$\sqrt{51\tfrac{3}{7}^2 + 6'\,10\tfrac{2}{7}''^2} = 51.884'.$$

$$\sqrt{51\tfrac{3}{7}^2 + 5'\,1\tfrac{5}{7}''^2} = 51.685'.$$

Yours, etc.,
JAMES STIRLING.

Jeanesville, Pa., May 27th.

NEW MINING COMPANIES.

Names and Post-Office Addresses of the New Mining Companies Incorporated in the United States Since Our Last Issue.

The Gould Mining & Milling Co.,	Colo. Springs, Colo.
The Edwin Booth Gold Mining and Milling Co.,	Denver, Colo.
The Carmer Mining Co.,	Aspen, Colo.
The Victoria Mining and Milling Co.,	Denver, Colo.
The New York and Chance Mining Co.,	Denver, Colo.
The Amalgamating Chemical Electric Reduction and Manufacturing Co.,	Denver, Colo.
The Mettie D. Gold Mining Co.,	Cripple Creek, Colo.
The Motto Mining Co.,	Aspen, Colo.
The Carson Tunnel Co.,	Carson, Colo.
The Lincoln-Lucky & Lee Mining Co.,	Denver, Colo.
The Atlantic Mining and Milling Co.,	Fort Collins, Colo.
The Anaconda Gold Mining Co.,	Denver, Colo.
The White Star Mining Co.,	Denver, Colo.
The Atlantic Ward Gold Mining Co.,	Denver, Colo.
Southern Illinois Oil and Mining Co.,	Pulaski, Ill.
Lastle Mining and Manufacturing Co.,	Listie, Pa.
Phoenix Oil and Mining Co.,	Omaha, Neb.
Youghiogheny and Lehigh Coal Co.,	Superior, Wis.
The Soliwe Mining Co.,	Dayton, Ohio.
The Pittsburgh Land and Mining Co.,	Pittsburgh, Pa.
The New York Mining and Smelting Co.,	Pittsburgh, Kans.
Crystal Rock Salt Co.,	Chicago, Ill.
Tennessee Oil Co.,	Port Huron, Mich.
Phoenix Mill and Mining Co.,	Spokane, Wash.
The Washington and Nevada Mining Co.,	Vancouver, Wash.
The Jicarilla Iron Mining Co.,	East Las Vegas, N. M.
Troy Development Co.,	Spokane, Wash.
Rainy Mining Co.,	Seattle, Wash.
The Berniece Mining and Milling Co.,	Denver, Colo.
The Benita Mining Co.,	Cripple Creek, Colo.
The Napoleon Gold Mining Co.,	Colo. Springs, Colo.
The Elkton Mining and Milling Co.,	Colo. Springs, Colo.

The Chief Lode Mining Co.,	St. Paul, Minn.

Messrs. McClave and Brooks, manufacturers of the celebrated McClave Grate and Argand Blower have removed from No. 401 Lackawanna Ave. to more commodious quarters at Nos. 301 and 303 Seventh St., this city. In the future they will be in better shape to meet the rapidly increasing demand for their grate and blower. We advise all steam users who have not seen these arrangements in use to write to them for one of their illustrated catalogues. There are hundreds of these grates and blowers in use, all of which are earning the highest commendations from users. The New York Steam Co., which has the largest steam heating plant in America, experimented with various grates and blowers for several years, and now use none but those manufactured by Messrs. McClave & Brooks. Hon. Eckley B. Coxe, of Drifton, Pa., who has probably done more experimenting in mechanics connected with mining than any other man in the country, has also adopted the McClave Grates and Argand Blowers at the steam plants connected with all of Coxe Bros. & Co.'s collieries.

On a recent order for Selden Patent Packing received by the manufacturer, Mr. Randolph Brandt, of 38 Cortlandt St., New York, the following foot note appeared:

"We consider the 'Selden' Packing far superior to any other packing we have ever used. It has so proven to us for both water and steam." Signed

MARTIN CAHILL,
Manager Mutual Mining Co., of Cannelburg, Ind.
J. N. CASSIDY,
Engineer Mutual Mining Co.

These gentlemen have been using the Selden Packing on large plunger pumps for over a year.

Messrs. Thomas Carlin's Sons, of Allegheny, Pa., write us as follows: "At present we are having quite a run on plans for grinding fire and red brick clays, and our hoisting engine department is also fairly busy."

HEAT AND FLAME.

Delivered in the Guildhall, Derby, February 27, 1892.

BY GEO. FLETCHER, ESQ., F.G.S., A. INST. E.E.

Of the Derby Municipal Technical College.

Mr. Fletcher said: The subject to which I ask your attention this afternoon is one of great importance to those engaged in mining and engineering work. It includes a large number of questions of great practical value. In the first place, I shall attempt to make clear certain great principles which will enable you to connect together many of the facts which I shall this afternoon illustrate by experiment. In the younger days of science, when what passed for philosophy concerned itself with speculations rather than experiments, heat was regarded as a material substance, and while philosophers like Bacon, Boyle, and others, imagined that heat was a kind of motion among the particles of a heated body, it remained for such investigators as Rumford and Davy to show that heat was not a material substance, but might be created by friction. Time would fail me to do more than mention the labors of these men. It is now an accepted fact that heat is simply a state due to the molecular condition of the heated body. We must regard it as a form of energy. As such we can convert it into other forms of energy and convert these in their turn into heat. It is one of the familiar facts of every-day life that friction gives rise to heat. Everyone knows that the tendency of friction is to destroy motion. We endeavor in our machinery to reduce friction to a minimum. Why? Because we know it is wasteful of the energy of mechanical motion, and also because we have heat produced where the friction takes place, in some cases to such an extent as to cause trouble with the bearings of machinery, and the greater the amount of friction the greater the quantity of heat developed. We see then that while mechanical motion may be destroyed, the energy which that motion represents cannot be destroyed; it is only converted into some other forms. Let us consider in what different ways heat may be produced. We may produce it by the friction of substances, by the striking together of two bodies, or simply by compression. Here is a brass cylinder into which fits a piston, to one end of which is attached a small piece of German tinder. If I suddenly push the piston into the cylinder so as to compress the air, sufficient heat is generated to set fire to the tinder. (Experiment.) In all these cases you will see that the heat is generated at the expense of motion, at least of visible motion, for as I shall presently hope to make clear, the destruction of the visible motion is accompanied by the quickening of the motion of the molecules which constitute the heated body. Thanks to the labors of such investigators as Mayer and Joule, the precise numerical equivalence between heat energy and mechanical energy has been determined. The latter, by a series of the most careful experiments, showed that if the work done by a body one pound in weight in falling through a distance of 772 feet were wholly expended in producing heat, that heat would be sufficient to raise the one pound of water through 1 deg. F. Or, conversely, if the amount of heat liberated by one pound of water falling, say from 60 deg. F. to 59 deg. F., be wholly expended in lifting a weight of one pound, it will be sufficient to lift it through a distance of 772 feet. Thus *the mechanical equivalent of heat* is 772 foot-pounds. The practical and theoretical importance of this determination cannot be overestimated.

There are yet other ways in which heat may be produced, but in every case the heat is generated at the expense of some other form of energy. You are already familiar with the conversion of electrical energy into heat and light. We may also produce it from what may be termed the energy of chemical separation. In order to dissociate the elements of a chemical compound, we have to apply energy. Thus we may separate the elements of water—oxygen and hydrogen—by means of the electrical current. The separation of these two gases represents the energy expended in dissociating them, and we can, by mixing them together and applying a light, cause them to reunite, with the production of heat. In all cases of combustion, in the burning of a fire or a gas, we have the energy of chemical separation converted into the energy of light and heat. (Experiments.)

The physical effects of change of temperature on bodies is of immense practical importance. As a general rule, solids, liquids, and gases expand with an increase of temperature. Their constituent molecules are caused to move more rapidly, and a change of volume results. Here is a rod of iron, which, as you see, fits accurately in a gauge bar. On heating it, however, it becomes too large to go in the gauge, but on cooling again it resumes its original dimensions. The force of the expansion and contraction, due to heating and cooling, is considerable. The contraction of this bar of wrought iron in cooling is sufficient to break this small rod of cast-iron. (Experiment.) Liquids expand more than solids for an equal rise of temperature. You will perceive that only a slight amount of heat is necessary in order to expand the water contained in this flask, and when the water is heated over a flame, the rise of the liquid within the tube indicates the rapid expansion. It must not be forgotten that the flask itself is expanding, but the liquid is expanding at a far greater rate. Here is another flask containing air. Through the cork runs a tube open at both ends. When the flask is heated the air expands considerably, and you observe that when I hold it with the open end of the tube below the surface of water, a continuous stream of bubbles passes through the water. The contained air is not very hot, and when I withdraw the flame it begins to cool. This is accompanied by contraction, as is manifested by the fact that the water is now being forced up the tube. Now it has reached the top of the tube and is running into the flask, and you notice that as soon as this takes place the air within is rapidly cooled by the water, which is projected against the end of the flask with some violence, forming a beautiful miniature fountain. You will see by the quantity of water in the flask that the expansion must have been considerable. Air, and, indeed, all gases, expand 1-273d part of their volume for every degree centigrade. This is known as the co-efficient of expansion for gases. There is one important exception to the general law of the expansion of bodies by heat to which I must refer. I refer to water. If we take water at 32 deg. F. (freezing point) and heat it, contraction will take place until a temperature of 39 deg. is reached, above which the liquid expands. This temperature is known as that of the maximum density of water.

In the case of a solid, increased temperature leads to an increase in volume, which means that the molecules which constitute it are driven further apart. This may take place to such an extent that the force of cohesion, which becomes feebler and feebler as the molecules are pushed further apart, is at last insufficient to prevent the particles from moving freely one over the other; and we have the change from a solid to a liquid state. With a still further increase of temperature, the molecules are driven further apart, until at last they are entirely freed from the influence of cohesion, and the gaseous state is reached. As you are perfectly aware, the temperature at which different substances change their state differs considerably. Some substances are gaseous at very low temperatures, while others cannot be rendered gaseous by the most intense heat which we can artificially produce.

Accompanying these changes of state are thermal phenomena of great importance. This may be well illustrated in the case of water. If we take ice and apply heat, we find that it does not melt suddenly, but that in order to melt it we must supply a considerable amount of heat. This heat is absorbed without raising the temperature, and hence is called latent heat. It is really employed to bring about that separation of the molecules which I have previously referred to. As soon as the last particle of ice has disappeared, the temperature begins to rise, and continues to do so until the boiling point is reached, and then the temperature is once more constant until all the water is turned to steam, the heat being employed to overcome the molecular cohesion.

The manner in which the heat is transmitted from one place to another is a subject of considerable importance. It may either pass *through* matter—conduction, *with* matter—convection, or independently of matter as ordinarily understood—radiation. In this case the medium of transmission is the ether. Different substances differ from each other very markedly in their ability for conducting heat. You will see that the heat from this flame, when applied to the junction between a compound bar of copper and iron is transmitted more rapidly through the copper than through the iron. (Experiment.) Liquids and gases become heated by means of convection. Water, as you will see, is a very bad conductor of heat, for when I heat the water in the upper part of this tube to the boiling point, that in the lower portion remains quite cold. If, however, I heat the water at the bottom of the tube, the heated water rises and cold currents descend to take its place. Here the water is heated by convection. You have an excellent example of the manner in which heat is transmitted through space independently of matter—namely, by radiation—in this little instrument (exhibiting Crooke's radiometer, which he explained).

It has already been explained that heat is produced by combustion. Now the burning of gas or a candle, or the coal on the fire, are examples of combustion—of chemical combination. The constituents of these substances are uniting with the oxygen of the air; the products of burning are given off, and light and heat are evolved. In each case the flame is produced by the chemical union of gases, which, in the act of combining, develop so much heat that their products are rendered incandescent. It is seen that it is necessary to initiate this chemical action by applying a light in the first place, but that as soon as started the action continues, for in the act of union, great heat is evolved, and this is communicated to other neighboring parts of the burning substance. The temperature required to initiate the action is different in many cases. Thus, certain gases combine spontaneously with oxygen at ordinary temperatures, while others, such as coal gas, require a high temperature to start the action. Unless the gases be raised to the temperature necessary they will not combine, or if gases in the act of combination—a flame—be cooled below that temperature, the action will cease. Thus, if a coil of copper wire be placed around a candle flame, the copper conducts the heat away so rapidly that the temperature of the flame is reduced and goes out. This does not take place if the coil of wire is previously heated. This is a fact of immense practical value. Upon it depends the action of our safety-lamps. Sir Humphrey Davy found, in his early experiments on explosive mixtures of fire-damp and air, that a high temperature was necessary to bring about an explosion and that, therefore, it was not difficult to cool down the flame below the temperature essential in order that combination should take place. He found that metallic tubes, a fifth of an inch in diameter and 1½ inch long, stopped an explosion, and that the flame would not pass through wire gauze, owing to the cooling action it exerts upon the flame.

The heat liberated by the burning of a particular gas will, of course, depend upon the rate at which the action of combination takes place. If we increase the supply of air to a burning gas, we increase the rate, as in the case of a blowpipe flame. Here I have a blowpipe, in which, instead of air, I supply pure oxygen, and we get intense heat produced—so intense that, as you see, wrought iron is rapidly melted, and iron filings are instantly raised to a white heat and oxidized. Here the rate of combination is very rapid.

Where we have the two gases between which union takes place *mixed* with each other, the combination takes place with great rapidity, and an *explosion* results. It must not, however, be imagined that this is really instantaneous. A number of experiments have been made with a view to determine the rate at which flame travels through various explosive mixtures. In the case of a mixture of oxygen and hydrogen of maximum explosive power, it was found that flame travels at the rate of about 37 yards per second, and in many other mixtures at a much slower rate.

It will be interesting now to consider upon what the luminosity of flames depends. Here is a burner in which air is allowed to *mix* with coal gas before burning. It is known as a Bunsen burner, and you will observe that the flame produced is non-luminous. If I close the holes which are at the bottom of the tube, and so prevent the air mixing with the gas, the flame becomes luminous, as with the use of an ordinary burner. There is another important difference between the flames: that of the Bunsen burner is smokeless and will not blacken anything placed over or in it. The luminous flame is smoky, and covers with soot a glass rod or other body placed within it. Is there any relation between the two phenomena? Davy's idea was that the luminosity was due to soot in the flame; but it has been argued that there are certain luminous flames (such as the flame of phosphorous burning with oxygen) which cannot contain solid particles. Professor Frankland proposed a theory which explains the luminosity as due to the presence of dense gases. He had observed that a candle burning on Mont Blanc gave less light than under ordinary circumstances, although the rate of burning was unchanged. Experimenting in the laboratory, he found that the luminosity of any flame was diminished by a diminution of pressure, and *vice versa*, while a non-luminous hydrogen flame becomes as luminous as a coal-gas flame of the same size under a pressure of 20 atmospheres. He discovered that soot from a flame contained a quantity of hydrogen which could not be separated, and it was found that under pressure a hydrogen flame yields a spectrum in which the hydrogen lines widen out until the spectrum becomes continuous. He thought that the soot from a flame was purely a condensation product, and urged that, if a flame contained solid particles, it would not be transparent. The German chemist, Heumann, however, showed that soot was not a condensation product—that if you heat a porcelain rod and held it in the flame you will get as much soot deposited upon it as if it were cold, and also that you would get a larger amount deposited upon the under than upon the upper side. He further showed that a flame casts a shadow, due to the solid particles it contains, and that if you mix with luminous coal gas carbonic acid gas, or even hydrogen, its luminosity is diminished, or even destroyed. Indeed, if by any means you can prevent the carbon from being separated out as soot you reduce the luminosity. Now a certain temperature is necessary to separate the carbon from the carbon-holding molecules, and if you added an indifferent gas, such as nitrogen or carbonic acid gas, the carbon-holding molecules are separated one from the other; the carbon is not separated, and the flame is non-luminous. Gas used for illuminating purposes should, then, be as free as possible from these indifferent gases, which diminish the luminosity.

It is found that heat aids the separation of the carbon as soot. Here I have a Bunsen burner with a platinum tube. You notice that we now have an ordinary non-luminous Bunsen flame. I will now direct upon the platinum tube a blowpipe flame, and you notice that as it gets hot the flame becomes more and more luminous. I now extinguish the blowpipe flame and direct a current of cool air across the tube. The flame again becomes non-luminous. We see the advantage then of warming the gas before it is burnt, and the gas may be carried over its own flame, as is now commonly done in street lamps. You will further see that if I allow two ordinary gas flames to play one upon the other, we get a greatly increased luminosity without increased consumption. It is also advantageous to use burners with nozzles of low conducting power, such as steatite.

In conclusion, Mr. Fletcher dealt at some length with the influence of suspended combustible dust, such as coal-dust, in enhancing the effects of explosions in coal mines, illustrating his remarks with experiments.

TESTING FOR GAS IN COAL MINES.

A Lecture Delivered in the University College, Nottingham, (Eng.), February 6th 1892.

BY PROFESSOR CLOWES.

Professor Clowes said: The term "gas testing" should refer only to the best ways of detecting the presence of low percentages of fire-damp in air, and of measuring their amount. This involves the careful use of an appropriate safety-lamp or other apparatus. Any form of safety-lamp in unskilled hands will indicate proportions of fire-damp exceeding about 6 or 7 per cent. Such mixtures make the flame increase in size, and then flare and flicker, or they totally extinguish it if the proportion of gas is high. These signs of the presence of gas cannot be mistaken, and they are supplemented in some of the less perfect forms of lamp by the burning of the gas itself inside the lamp (experiments shown).

The Garforth detector, which serves to introduce the gas, taken from any suspected part, into the lamp, and make it light the flame, serves well to find gas, if it is not mixed with much air (gas was shown by this detector).

When the proportion of gas to be detected falls below 2 per cent., however, only the careful use of a suitable lamp or apparatus will serve to detect it and measure its amount.

It may be urged that very low percentages of gas need not be detected, as they give rise to no risk of explosion. This statement, however, certainly requires qualification in the light of what is now known with regard to the influence of the presence of fine coal-dust. Air containing less than 2 per cent. of gas becomes explosive if it is mingled with coal-dust, and accordingly, in dusty mines, percentages of gas less than those which can be found by an ordinary lamp must undoubtedly be looked for.

Then, again, in order to test the sufficiency of the ventilation, and more especially to ascertain that the air reaching the mine by the "downcast" is properly divided up into the "splits," so that each split gets its due share, it is absolutely necessary to ascertain periodically the percentage of gas in the "returns." The percentages of gas to be determined in the returns will usually be below the lowest quantity detectable by an ordinary safety-lamp.

If there should exist amongst managers any unwillingness to use the most perfect means of gas-testing, simply because they do not wish to know the worst concerning the state of the ventilation of their mines, either as regards its amount, or its proper distribution, this feeling must surely give way in the present age of scientific progress, and in view of the preventable danger which is incurred by such recklessness.

The only satisfactory and trustworthy methods of gas-testing at present known depend upon the fact that even the smallest percentages of gas in air, which cannot be kindled by a flame, will yet burn completely if they are kept in contact with a sufficiently hot surface (experiment shown). Thus, air containing a mere trace of gas shows a pale mantle of flame, or "flame-cap," around an ordinary flame which is burning in it (experiment shown). Also a wire maintained at a red heat by the passage of an electric current, when introduced into such air, becomes visibly brighter; this is due to the gas present in the air burning around the wire, and imparting the heat of its combustion to the wire. It is on these facts that the most important methods of gas-testing rest.

The most satisfactory gas-indicator as yet produced is that of Liveing. It consists of a small box, enclosing apparatus for producing an electric current. This current is passed through two spirals of fine platinum wire, and heats them to redness; both of them being maintained at the same heat. One of the spirals is enclosed in air free from gas, the other is exposed, with suitable precautions, to the air of the mine. If gas is present in the air of the mine, the spiral which is immersed in the mine-air glows more brightly than the other. This increase of brightness is proportioned to the amount of gas present; and by a simple arrangement for measuring the difference of the brilliancy of the spirals, the percentage of gas present in the air can be at once read off upon a scale. The delicacy of this instrument is shown by the fact that, with 2 per cent. of gas in the air, the spiral becomes no less than five times as bright as the other; and the difference of its brightness is easily perceptible when only 0·25 per cent. of gas is present (this apparatus was explained, and its uses illustrated by means of a large dissected model, by diagrams and projected photographs, and by the exhibition of the indicator itself). The only objections which seem to be raised to the use of this apparatus in the mine is that it is costly, that it necessitates the carrying of a special apparatus, and that some trouble has arisen from the spirals being rendered useless by fusion of the metal, caused by overheating them. If no simpler and less costly and troublesome apparatus is available, these objections surely are not of very great weight; they seem insufficient to account for the neglect with which this apparatus has been treated since its invention in 1880.

Another apparatus depending upon the use of an electrically-heated wire is that devised by Maurice, a man practically connected with coal mining. In this apparatus a sample of the air to be tested is enclosed, and a wire is kept glowing in it by means of electricity for a few minutes. Any gas present in the air is thus burnt. The percentage of gas in the air is then measured by the decrease of pressure which occurs, and which is measured upon a water-gauge. The gas in burning causes three times its own volume of air to disappear: hence arises the decrease of pressure, which will be proportioned to the amount of gas present. This apparatus is sound in principle. It seems doubtful whether it is as simple in practice as that of Liveing (Maurice's apparatus was explained by diagrams, by a working model, and the apparatus was shown).

In endeavoring to devise a satisfactory and delicate gas-indicator, attempts have been made to improve the method originally employed, that of detecting the gas by the "cap" appearing over the flame of the safety-lamp. The ordinary forms of safety lamp, even in the hand of those experienced in gas-testing, will not with certainty indicate less than 2 per cent. of gas. The delicacy of the "flame-cap" test has, however, recently been vastly increased. The examination of lamps specially designed for gas-testing has been undertaken in Prussia, and has resulted in the recommendation of an extremely sensitive lamp devised by Pieler. The examination of the sensitiveness of certain modified lamps for gas-testing has also more recently been reported upon by a Royal Commission on Accidents in Mines. The lecturer has devised a special apparatus for the purpose, and his experiments have thus far had the result of proving that the Hepplewhite-Gray lamp, as modified by James Ashworth, is capable of detecting and measuring extremely low percentages of gas.

The Pieler lamp burns methylated spirits; the flame is large and is shielded from the eye; the "cap" seen over this flame with very low percentages of gas is large and well-defined; there is no difficulty in detecting and measuring it. The cap is over an inch in height when only a quarter of 1 per cent. of gas is present (the Pieler lamp was shown in action). Objections have been taken to this lamp on the score of its being useless for lighting purposes, since its flame is pale; this necessitates the carrying of a safety-lamp with it. It is also said to be dangerous; in one sense at least there is danger incurred when the lamp is in careless hands, since the spirits, if spilt upon the flame, will blaze, and its vapor is explosive when mixed with air and fired (proved by experiments). These sources of danger, however, vanish with care (the Pieler lamp was shown burning in air containing gas).

The modified lamp introduced by Ashworth, when it is burning benzoline is open to the same objection when it is placed in careless hands. Benzoline is an inflammable spirit, and its vapor when mixed with air is explosive. But it presents no other danger, and it has the decided advantage of furnishing either a brilliant illuminating flame or a pale gas-testing flame as may be desired. The preparation of the part of the glass cylinder immediately behind the flame also adds immensely to the sensitiveness of the lamp for gas-testing. The "flame-cap" is so pale that in order to render a small cap visible, the lamp-flame must itself be almost non-luminous; and, further all reflections of the flame from the glass must be abolished. By a low-pitch screw, the wick of the lamp can be gradually drawn down until the flame is small and pale blue in color. This flame is then examined against a lamp-glass ground at the back, so as to give no reflections. A still better surface is obtained by smoking the back of lamp-glass inside with the flame of a wax taper. Ashworth's modified lamp used in this way readily detects half a per cent. of gas by a cap about 7 millimeters, or a quarter of an inch, in height: with one per cent. the cap is 10 millimeters, with 2 per cent. 14, with 3 per cent. 20, with 4 per cent. 25, and with 5 per cent. 30 millimeters in height. Here we have a lamp which is at once a good lighting and a good testing-lamp. Mr. Ashworth has arranged for burning safe oils, which are free from the dangers of benzoline, in his lamp. With these oils the lighting power of the lamp is admirable, but the lowered flame is not absolutely pale, and is not, therefore, as sensitive for gas testing as the benzoline flame (the lamp and its special glasses were shown, and the lamp was shown with full lighting power, and with a cap in gas).

It will be seen that much has been done towards producing a safety-lamp which is very sensitive for gas-testing, and is at the same time a good illuminator. But, probably, more may yet be done; and an arrangement for gas-testing may be applied to a safety-lamp which will free the lamp from the reputed danger of burning benzoline or inflammable spirit of any kind, and yet give good flame-caps.

What is to be desired is a flame which shall not only be pale, but hot, and also sufficiently large. The flame produced by drawing down the wick of a safety-lamp burning oil is not sufficiently pale; it is also so small that it lacks the heat necessary to produce a large and well-defined cap; while the very smallness of the flame makes it liable to go out, and to cause the gas-tester to lose his flame in a place where he cannot relight it.

As far as my experiments have gone at present, they indicate that the flame of burning hydrogen fulfills all the conditions required for very delicate gas testing. I shall probably have more to say about this in a future lecture.

The apparatus which I have constructed for testing the sensitiveness of lamps for gas testing consists of a large air-tight wooden box of about 100 litres capacity. It is mounted on legs of a convenient height. In the front is a window for examining the lamp in the interior; the lamp being introduced through an opening in the bottom of the chamber, which is closed by a small tray of water. The interior of the testing chamber is painted dead-black. And a large thin board, almost equal in size to the section of the chamber, is suspended from an axis in one of the upper corners, so that it can be swung up and down in the chamber to mix the gas and air. The gas is introduced in measured quantity from a gasholder into the top of the chamber, the air which it displaces being allowed to escape below. After the gas and air in the chamber have been mixed, the lamp is introduced, and the size and appearance of the flame-cap caused by the known percentage of gas is observed. The experiments are made in a dark room, and the eye should have been in darkness for some time before examining the flame. The gas used in the experiments was marsh-gas chemically prepared. The apparatus furnishes a ready means of testing the sensitiveness of safety-lamps as gas-indicators; and I am at present applying it to other matters of interest in connection with gas-testing (the testing-chamber was exhibited, and explained by diagrams and photographs; it was then charged, and a lamp was introduced).

WESTERN PENNSYLVANIA CENTRAL MINING INSTITUTE.

An Interesting and Well Attended Meeting Held at Pittsburgh.

The Western Pennsylvania Central Mining Institute met in the Court-House at Pittsburgh June 28th. In absence of the President, Inspector J. T. Evans was made President *pro tem.*

The first paper was read by Inspector William Duncan on "The Advantages of a Slope over a Shaft." Mr. Duncan took the ground that under certain circumstances the advantages in economy of construction and working were as 5 to 3 in favor of the slope.

This view was combated quite briskly by several, and ex-Inspector F. C. Keighley asked, and was granted leave to prepare a paper for the next meeting showing "The Advantages of a Shaft over a Slope."

The next question for debate was "Does The Present Bituminous Mine Law Need Revising?"

The general expression was that it did and that the law proposed at the last session of the Legislature was in general a very good one and with a few changes would be acceptable to both miners and operators. After a discussion of the weak points of the present law the Chair was authorized to appoint a committee consisting of the eight Inspectors, three operators and three miners, to serve without pay, who should consider the matter and report to the next meeting of the Institute what changes should be made in the law as proposed to the last Legislature.

The general feeling shown during the debate was that several points of the law were impossible of enforcement and impractical, and that if these could be modified there would be little opposition to it.

The next question was: "Should a Miner Have a Theoretical Knowledge of Mine Gases?"

There was considerable discussion on the question, but it was very one-sided, and the meeting decided the question unanimously in the affirmative.

The next question was: "What are the Relative Advantages and Disadvantages of the Exhaust over the Blowing Fan for Ventilating Purposes?"

Inspector Jenkins said he thought the blowing fans best as the exhaust fan rarifies or lightens the air and allows the gas to come forth in undue quantities upon small changes in the barometer, while a blowing fan compresses and to a large degree overcomes this tendency. Also if there is black-damp the extra pressure from the blowing fan serves to keep it back in the falls and unused places. Also, an exhaust fan on account of handling the expanded air will require more power than the blower, as the blower puts it into the mine under pressure and in smaller bulk and it expands in the mine. In case of falls stopping the current, the exhaust fan rarefies the air, and the mine is quickly filled with gas.

Mr. Stinner said: The exhaust fan will produce more air than the blower, for while the blower fan makes the air heavier it thereby increases the friction.

Mr. King said he knew of no particular advantage for either. Fans should be so put up that they can be used either as force or exhaust. In the Broad Top region it is necessary that they shall be able to work in either direction at different times of the year, as the great difference in elevation between the intake and outlet causes a powerful natural current which changes its direction with the changes of outside temperature.

Mr. Keighley favored the blowing fan, and gave some figures in regard to a change which he had made from exhaust to force fan. He said, however, that certain natural conditions had much to do with the apparently favorable results of the force fan, so that the test was hardly a fair one.

Mr. Evans said: The advantages of an exhaust fan are: *1st.* The fouled return air does not pass through the haulage road. *2d.* In case of an explosion the jar to the fan is less. *3d.* It has advantages in protecting the shaft timber. Its disadvantages are: *1st.* The air meeting loaded mine cars causing greater friction; *2d.* Winter causes ice in the shaft; *3d.* Pressure is less and more gases are liberated.

Mr. Hartley considered force fans dangerous in gaseous mines, as on account of compression the gases are held in the waste places and crevices, and a sudden diminution of the ventilating pressure will allow them to come out and expand, thus filling the mine quickly.

Mr. Blick preferred exhaust fans. It was better to take all the pressure possible off and let the gas come out and be carried away than to pin it up with a blowing fan and have it let loose by some unexpected accident.

The meeting was about equally divided on the merits of the two fans. The meeting then adjourned till the next morning.

When the meeting was called to order on the morning of the 29th the report of the committee on oil and gas wells was read. This committee was appointed at a former meeting of the Institute to consider how coal mines should be protected from oil and gas wells. The report was debated by the Institute article by article, and as finally adopted is as follows:

REPORT OF COMMITTEE ON GAS AND OIL WELLS.

Owing to the imminent danger and constant menace to the lives to the miners working in the Bituminous mines of this State, and the great liability of many of the valuable coal properties thereof being rendered useless from the blind policy that is being pursued by the oil operators in boring oil and gas wells through the workings of the said coal mines without proper regulation, and regardless of what might become of the lives of the workmen or property rights of others, therefore we, your committee appointed at the last meeting of this Institute, beg leave to make the following suggestions which we deem necessary to afford a reasonable degree of protection to all engaged in operating mines in the oil and gas regions of this state:

First. That we petition the Legislature at its next session to enact a law for the protection of workingmen employed in the Bituminous mines and to guard against the probable destruction of valuable mining properties from the escape of explosive gas and oil into the coal mines from bore-holes bored into the gas and oil bearing strata which underlie the coal measures in so many counties of the State.

Second. That an expert Mining Engineer be appointed to enforce the statue regulating the boring of oil and gas wells through the coal measures and the sealing of the same after abandonment.

Third. That all bore-holes which are to be bored for natural gas or oil shall be properly located by the State Mining Engineer on a county map immediately after boring operations begin, said maps to become the property of the State and a copy of all such to be kept at some of the State departments for public inspection and a copy also to be filed as a public document with the prothonotary of the county in which said wells or bore holes are situated.

Fourth. That before any individual, firm, or corporation owning or operating a gas or oil well shall abandon the same, he or they or their lawful agent shall notify the said State Mining Engineer of their intention of abandoning it, who shall immediately visit the said well and shall see that it is properly sealed from bottom to top by an approved cement.

Fifth. That after the sealing of the well has been approved by the said State Mining Engineer, he shall issue a certificate as evidence of the fact that said well has been hermetically sealed, after which the oil or gas company shall be released from further liability.

Sixth. That if any coal operator, firm, or corporation shall have opened a coal mine, thereby giving them the prior right of working their mineral property, no individual, firm, or corporation thereafter desiring to bore oil or gas wells shall be allowed to locate said wells at such places as to interfere in any way with the main passages or projected passages, main or cross-headings and air courses of the mine.

Seventh. That when any gas or oil well has been bored through solid coal, the coal company, provided the well is not abandoned and hermetically sealed, shall be required to leave a solid block of coal around the producing well, of such dimensions as the State Mining Engineer shall approve; but for each ton of coal left for such purposes the oil operator or company shall be required to pay to the owner or operator of said coal a reasonable compensation for the amount of coal left, provided said coal cannot be profitably recovered by the mining company after the well is abandoned.

Eighth. That when gas or oil wells are bored through an abandoned part of a producing coal mine, and the roof strata above the coal seam have not subsided, stone or brick walls shall be built by the parties boring such wells and said walls shall be of such size as the State Mining Engineer shall approve and should the roof strata have thoroughly subsided in said abandoned parts, the said oil operator shall be required to put in the well, for a depth of at least ten feet below the floor of the excavated coal seam, a strong outer metal casing, leaving between it and the main casing of the well, a space of at least one inch at all parts.

Ninth. That all pipe lines for conveying gas over coal properties which are being mined or over abandoned parts of any mine that is in operation, shall be layed on trestle work on the surface and the method of laying the pipe line shall be approved by the State Mining Engineer.

Tenth. That the State Mining Engineer shall be empowered to locate, at the expense of the State or county, all abandoned holes, such holes to be filled up as herein set forth.

Eleventh. That each deed of property shall describe the number of holes that are being or have been drilled on the estate that the deed represents.

Twelfth. That all individuals, companies, or corporations, before drilling a hole shall cause to be deposited in the hands of the State or County Treasurer a sum equivalent to the cost of locating and filling up such hole or holes.

Thirteenth. That all oil or gas companies shall be placed under bonds to faithfully carry out the provisions of the act.

The consideration of this question consumed all the morning and it was found necessary to omit part of the program for the afternoon.

At the afternoon session, the first paper was by W. S. Gresley, of Erie, Pa., entitled "The General System of Longwall." Mr. Gresley was not present, and the paper was read by Inspector Evans. At the close a vote of thanks was given Mr. Gresley for his paper. The next was a paper by Inspector Blick, entitled "The Longwall that would be Applicable to the Pittsburgh Seam." This was a very able paper and excited much interest and some criticism. Mr. Blick explained several points that were criticised. After this the meeting adjourned to meet again next December.

The Mineral Wealth of Newfoundland.

In a report to the Colonial Office on the condition of Newfoundland, it is stated that ores of antimony, zinc, molybdenite, manganese, chromite, nickel, hæmatite, rutile, gold, silver, etc., are all known to exist; while of the earthy minerals and non-metallic substances there are a great variety, and in many cases an abundance of material. During the year 1890 valuable seams of coal were discovered in the vicinity of St. George's Bay. Previous to this the St. George's Bay carboniferous area was generally thought to be destitute of workable coal seams, and as being occupied almost entirely by the lower measures, namely, the carboniferous limestone and millstone grit series. It is gratifying to be able to state that, upon reference of the fossil plants and samples obtained during the year to Sir William Dawson, Principal of M'Gill University in Montreal, one of the most eminent authorities upon fossil botany in North America, he has given it as his opinion that "the specimens sent indicate a development of the coal measures not unlike that of Eastern Cape Breton, with which the beds may be connected under the gulf;" and he adds that the government of this colony would do well "to inform the English Government of the value of the coals on the west coast and their prospective importance to Britain and Newfoundland as well as to the other colonies. You have," he adds, "the nearest coal to England on this side the Atlantic." The investigation in the section of country referred to has brought to light 27 ft. of coal, which is but 10 ft. less than that of the North Sydney Section. The analysis of this coal gives a percentage of carbon not inferior to that of Cape Breton coal.

Messrs. Abendroth & Root Manufacturing Company, 28 Cliff St., New York City, recently furnished two 266 H. P. Root water-tube safety steam boilers to the great Shattuck & Babcock Co. Mill, De Pere, Wis., one of the finest pipe-making establishments in the Fox River Valley paper district.

This mill is also using a large quantity of the celebrated Root spiral riveted water-pipe, which is also manufactured exclusively by Messrs. Abendroth & Root Manufacturing Company, and becoming very popular with paper-makers.

The Colliery Engineer.

AN ILLUSTRATED JOURNAL OF

Coal and Metal Mining and Kindred Interests.

ESTABLISHED 1881. INCORPORATED 1889.

PUBLISHED MONTHLY AT SCRANTON, PA.

WITH WHICH IS COMBINED THE MINING HERALD.

Entered at the post-office at Scranton, Pa., as second-class matter.

THOS. J. FOSTER, RUFUS J. FOSTER, MINING ENGINEER, } EDITORS.
ALEX. DICK, MINING ENGINEER, ASSISTANT EDITOR.
THE COLLIERY ENGINEER COMPANY, PUBLISHERS.

TERMS.

Subscription, (*Postage in the U.S., Canada, or Mexico, prepaid.*) **$2.00 a Year**

TO FOREIGN COUNTRIES IN THE UNIVERSAL POSTAL UNION $2.50.

Remit by P. O. Order, Express Money Order, Bank Check or Draft or Registered Letter.

P. O. Orders.—You can buy a Money Order at your Post-Office, payable at the Scranton Post-Office.

Express Money Orders can be obtained at any office of the American Express Company, the United States Express Company, and the Wells, Fargo & Co.'s Express Company.

Registered Letters.—If a Money-Order Post-Office or an Express Office is not within your reach, your Postmaster will register the letter you wish to send us on payment of ten cents.

We Cannot Be Responsible for money sent in letters in any other way than by one of the four ways mentioned above.

EXPIRATION OF SUBSCRIPTION.

The date after your name on the wrapper of THE COLLIERY ENGINEER shows to what time your subscription has been paid.

RENEWALS, ETC.

If you do not want THE COLLIERY ENGINEER continued for another year after your subscription has run out, you should notify us by postal card to discontinue it. The courts have decided that subscribers to newspapers who do not order their paper discontinued at the expiration of the time for which it has been paid, are held liable for the payment of their subscriptions up to the date when they order the paper discontinued.

NOTICE OF DISCONTINUANCE.

THE COLLIERY ENGINEER is sent to subscribers until an explicit order for its discontinuance is received by us, and all payment of arrearages is made, as required by law. *Papers returned are not notice of discontinuance, as we cannot tell where they are from.*

CHANGE OF ADDRESS.

A Subscriber wishing to have his address changed should be careful to give his *former* as well as his present address; otherwise we cannot find his name on our mailing list.

All communications should be addressed

THE COLLIERY ENGINEER COMPANY,
Coal Exchange,
Scranton, Pa.

Cable Address—"Retsof, Scranton."

Vol. XII. July, 1892. No. 12.

THE SALARIES OF THE BITUMINOUS MINE INSPECTORS OF PENNSYLVANIA.

ONE of the peculiar differences existing between the Anthracite and Bituminous Mine Laws of Pennsylvania, and a very unjust one, is the inequality of the salaries of the Inspectors of Mines. The Inspectors of the Anthracite mines are each paid $3,000 per year, while the Bituminous Inspectors are paid but $2,000. That the salaries paid the Anthracite Inspectors are not too high, is proven by the fact that a number of them, in the past, have resigned to accept more remunerative and less laborious and less hazardous positions with large firms or corporations engaged in the coal business. They were offered these positions on account of superior mining ability, such as is absolutely necessary in a competent Inspector, and which also made them desirable to their new employers. If superior mining ability is worth more than $3,000 per year to private firms and corporations, it must certainly be worth $3,000 to the State.

The Bituminous Inspectors, to comply with the spirit and letter of the Bituminous Mine Law, must be men equal in ability to the Anthracite Inspectors. Their duties are equally as laborious and hazardous, but they only receive a salary of $2,000 per year each. This is unjust and tends to keep many men of superior ability from competing for the position, because they can do better with private corporations.

No class of men connected with the mining industry of Pennsylvania are exposed to as many dangers as the Inspectors, and nobody could cope with these dangers more fearlessly and with more disregard for self than they do. The ordinary superintendent or mine foreman must only meet the dangers incident to the mine or mines with which he is directly connected. The Inspector must be on hand and direct the work of rescue after every serious accident at any of the many mines in his district, and he is frequently called to assist in similar work in neighboring districts. He must lead the rescuing party into the very jaws of death, and on his judgment and coolness the lives of scores of men often depend. In the discharge of his duty, even when no accident has occurred, he must visit dangerous localities and direct how the dangers are to be removed. He must, besides his mining ability and good judgment, be sufficiently politic to secure the enforcement of the law without causing friction between employer and employe, and between the State as represented by himself and all parties coming under the provisions of the law. Taken all in all, he must be just such a man as is desired by every large mine owner as a manager, and should therefore receive from the State a salary large enough to make it an object for him to remain in the employ of the Commonwealth.

The Bituminous inspection districts, as a rule, cover much more territory than the Anthracite districts, and as railroad facilities are generally not quite as good, the Bituminous Inspector is compelled to spend more time away from his home than the Anthracite Inspector. To fill his office satisfactorily, he must be the peer of the Anthracite Inspector in knowledge, judgment, and courage. He is called on to perform exactly the same duties, and is exposed to exactly the same dangers. His services are in demand from Bituminous colliery owners who offer him less laborious and less hazardous positions with greater salary.

Recently the H. C. Frick Coke Company wanted a well-qualified superintendent for one of its extensive collieries and General Manager Lynch offered the position with a fair salary to Inspector Austin King, of the Eighth Bituminous District, and secured his services. Mr. King resigned an office with most onerous duties, to accept a more profitable position, with less work and fewer dangers, and the State lost the services of a most competent man. It is true, the State secured a good man in his place, but it has no guarantee that his successor will not follow Mr. King's example at the first opportunity, and he cannot be blamed if he does. Another similar instance occurred when Mr. F. C. Keighley resigned as Inspector of the Fifth Bituminous District. If the salaries paid Messrs. King and Keighley had been $3,000 per year instead of $2,000, they would probably not have resigned.

If the salaries of the Bituminous Inspectors are placed at $3,000 per year, the State will simply be doing justice to deserving and hard-worked officials. With such a salary attached to the office many men of superior ability, who will not now accept the position, will appear before the examining boards and naturally the efficiency of the inspection service will be increased.

Great Britain pays her Chief Inspectors £800 or $4,000 per year, and her first-class Assistant Inspectors £400 or $2,000 per year, and the inspection districts are not nearly as large as those of Pennsylvania. Besides the term of office is for life or good behavior. The result is that the inspection service of Great Britain has reached a high standard of efficiency. To attain such a result in Pennsylvania, the State must pay sufficient salary to not only obtain, but to retain first-class talent. An increase of the salaries of the Bituminous Inspectors to $3,000 per year will be a move in the right direction and it will be productive of good. All colliery officials and miners should employ every means in their power to influence the next Legislature to pass an amendment to the Mine Law of 1885, fixing the salaries of the Bituminous Inspectors at $3,000 per year instead of $2,000 as they now are.

FALLS OF ROOF AND SIDES.

OVER 40 per cent. of all the fatal accidents which occurred in the mines of Pennsylvania during the year 1890 were due to falls of roof and sides. This percentage is about the average of similar accidents in the other States in the Union and in Great Britain.

Two papers which have been recently read before the Manchester Geological Society (Eng.) afford a few statistics and practical suggestions on this subject.

In England during the past 40 years the deaths from all kinds of accidents have decreased from 1 in 219 to 1 in 530 persons employed. During the same period the deaths from falls of roof and sides have only decreased from 1 in 661 to 1 in 1,135 persons employed. In other words, the number of deaths from this kind of accident has only been reduced to $\frac{3}{5}$ of what they previously were, while deaths from *all* kinds of accidents have decreased to $\frac{2}{5}$, so that the fatalities from falls have not decreased in as great a ratio as the whole.

Mr. Henry Hall, English Government Inspector of Mines, states that during the 17 years ending 1889 the total deaths in England from falls of roof and sides was 7,790, or 45 per cent. of the total number of deaths from accidents.

In Northumberland the ratio of deaths from falls was less than in Lancashire. It was generally supposed that the good roof in the former district was the cause of its comparative freedom from such accidents. As the percentage in Northumberland is, however, gradually decreasing, while that in Lancashire remains steady, this reason does not seem to be good.

Mr. Hall says that Northumberland men work 1½ to 2 hours less per man per day than the Lancashire men and are therefore exposed a shorter time to danger. This may be a reason for the lower percentage but the real reason is that in Northumberland the timbering is done by skilled officials, and not left to the workmen. In Lancashire the timbering at the working face is done by the miners themselves.

In every branch of mining it is noticeable that where the work is done by the owners the security of life is greater, but where it is left to the men working on contract no appreciable advance has been made. As circumstances vary in every mine, Mr. Hall suggests that each manager should have a rule, and be compelled to enforce it, specifying how far the props should be placed apart suited to the special conditions of the mine. This distance would depend on the nature of the roof and floor and on other conditions, and while it is not feasible to alter the present custom of the miners setting their own timber, more official control might be secured in this way.

ELECTRICAL TERMS.

A GREAT number of mining students are desirous of obtaining some practical knowledge of electricity, but find at the outset difficulty in understanding the terms used. When an Englishman first comes to reside in America he is best able to appreciate the value of his purchase at the stores by converting the dollars and cents into pounds, shillings, and pence. It is just the same with the young electrical student. He knows by reading a text-book on electricity that the "volt" is the unit of electric pressure but he has no means of estimating what relation there is between volts or amperes, and pounds or gallons.

Practically there is no thorough definition of electricity. No one has as yet found out really what the subtle force is.

Probably the best way is to compare it with some force, with which we are familiar and the best for that purpose seems to be hydraulics, or water power.

In some large cities there are pipes laid underground called high pressure hydraulic mains. These mains pass water at a high pressure for the purpose of supplying water power for working hydraulic hoists, etc., in the city. The water is passed through these mains under pressure supplied by the engines at the main pumping station. In electrical practice the power is supplied by what is called the dynamo at the generating electric station. This power is passed through wires either under or above ground to the electric motor.

A tabulated statement will help to make the comparison clear.

WATER POWER.		ELECTRIC POWER.
Pumping Station	=	Generating Electric Station.
High Pressure Main Pipes	=	Conducting Wires.
Water Motor	=	Electric Motor.

There are other conditions in hydraulics which have their equivalents in electricity. For instance, the water in passing through the pipes underground meets with a certain amount of frictional resistance in rubbing against the sides of the pipes and the extent of the resistance is in proportion to the diameter and length of the pipes. A certain percentage of the total pressure or power exerted at the pumping station is thus absorbed and only the remainder is available at the water motor. In the same way a certain percentage of the total power exerted at the generating electric station is absorbed in passing through the conducting wires and this percentage depends in the length, size, and quality of the wire used.

The effective pressure of the electric motor is expressed as so many "volts" in the same way as the pressure of the water motor is expressed in "pounds per square inch." The quantity of electricity is measured in "amperes" as the quantity of water is measured in "gallons." The resistance of the wires is expressed in "ohms" as the frictional resistance of the pipes is expressed in "pounds" pressure required to overcome it.

The "volt" is the unit of electric pressure as the "pound" is the unit of water pressure. The voltage or number of volts is sometimes called the electro-motive force, or for ›hort the E. M. F.

The value of a "volt" is the amount of pressure required to cause a current of one "ampere" to flow through a wire with a resistance of one "ohm." It is the measure of the energy of any electric battery or cell. An ordinary Daniell's cell newly made up has an E. M. F. of 1·072 volts, a Leclanche cell as used for electric bells or household use has an E. M. F. of $1\frac{1}{2}$ volts and a bichromate cell, well known from its bottle shape, has an E. M. F. of nearly 2 volts.

The "ohm" is the unit of resistance and is that offered by a column of mercury one square millimeter or ·00155 inch in section, and 106 centimeters or 41·733 inches in length. A copper wire 1000 feet in length and $\frac{1}{100}$ of an inch in diameter will, if the metal is pure, offer a resistance of 1·0068 ohms at a temperature of 60° Fahr. A German silver wire only 36 inches long and $\frac{1}{250}$ of an inch in diameter will offer a resistance of 1·12 ohms.

The "ampere" is the unit of current and is the amount which a pressure of one volt can force through one ohm. The volt is represented by the letter E, the ohm by R, and the ampere by C, the number of amperes can be obtained by dividing the volts by the ohms, thus:

$$\frac{\text{Volts}}{\text{Ohms}} = \text{Amperes},$$

Or, using symbols:

$$\frac{E}{R} = C.$$

In mechanics, hydraulics, etc., we do not speak of pounds pressure but of horse-power, and we know that a horse-power is the power required to raise one pound 33,000 feet in one minute or 33,000 pounds one foot in one minute. A horse-power is therefore called the unit of power and in the same way the unit of power in electricity is called a "Watt." This horse-power is most usefully employed when the greatest percentage is used in doing work and is least usefully employed when a large percentage is needed to overcome friction before it gets to the point where the work is to be done. In the same way a "Watt" is doing its best work when it is giving the best results either in electric light or as mechanical power, and it is least effective when it is wasting its power in heating the wires, the dynamo, or the motor.

The horse-power is the pressure multiplied by the quantity, the Watt is the volts multiplied by the amperes, and as volts is equivalent to pressure and amperes to quantity then a Watt is equivalent in character to a horse-power. We say they are equivalent in character but they are not, however, equal in power as a Watt is only $\frac{1}{746}$ of a horse-power, to find out therefore what horse-power is being exerted by an electrical installation, we must multiply the volts by the amperes and divide by 746, thus:

$$\frac{E \times C}{746} \text{ or } \frac{\text{Watts}}{746} = \text{H. P.}$$

In the same way if we have a certain horse-power and want to know to how many Watts it is equivalent we use the following formula:

$$\text{H. P.} \times 746 = \text{Watts},$$

and

$$\frac{\text{Watts}}{\text{Amperes}} = \text{Volts},$$

or,

$$\frac{\text{Watts}}{\text{Volts}} = \text{Amperes}.$$

EDITORIAL NOTES.

A NEW explosive. Messrs. Von Dahmen & Co., of Castrop, Westphalia, Germany, have introduced a new explosive called Dahmenit. Experiments have been made with it at several coal mines and stone quarries throughout the Westphalian and Saarbrucken mining districts. The results have proved everywhere very satisfactory. It is claimed that Dahmenit is quite harmless, and can be handled with safety. It explodes only by the action of a powerful detonator. The flame of the explosion is not communicative, and there is no danger of the ignition of coal-dust or gases. This has been tested and satisfactorily reported upon by several German mining experts. As a proof that the compound is quite harmless, it may also be mentioned that the German State Railway authorities have given the company permission to dispatch it by rail, as ordinary goods, a privilege which no other explosive can boast of. Herr Hans Ritter von Dahmen is the inventor of this explosive, and patents have been taken out in all countries. A number of Westphalian mine-owners are interested in the undertaking.

THE great Przibram mine fire. A disastrous mine fire broke out on May 31st in the Maria shaft of the Birkenberg silver mine, near Przibram, which is the richest and most extensive in Austria-Hungary. There were 807 men in the mine at the time and only 475 escaped. The 332 who lost their lives leave 292 widows and 692 orphans below 14 years of age.

The Austrian Socialist Congress has passed a resolution declaring charges of culpable negligence against the management.

The cause of the outbreak is said to be the ignition by some lighted tapers of a small wooden altar erected by devout miners in honor of John Nepomak, the patron saint of Bohemia.

The mines which belong to the State yield an annual revenue of $300,000. The principal production is silver, but lead and ochre are also mined in smaller quantities.

This is probably the worst metalliferous mining accident on record.

THE following is a summary of the present condition of the Anthracite blast furnaces in the Schuylkill valley, including Swedeland, Port Kennedy, Norristown, Phœnixville, Pottstown, Bechtelsville, Birdsboro, Reading, Temple, Leesport, Potteville, Topton, Macungie, Robesonia, Sheridan, and Alburtis. At all of these places there is a total of 31 furnaces, and of these 17 are in operation, 13 out of blast and one is banked.

The 17 in active operation include four in Reading, two each at Swedeland, Pottstown, and Alburtis, and one each at Port Kennedy, Birdsboro, Pottsville, Topton, Macungie, Robesonia, and Sheridan. There are two idle each in Reading and Birdsboro, and the remainder are scattered along the main line of the Phila. and Reading Railroad and near-by points. Iron men say that this condition of affairs presents a very hopeful aspect, and that among the furnaces in operation are some of the largest in this valley. There are furnaces at Ringgold, Lyons, and Kutztown, which have been idle for many years, and may never be put again into operation, while several others have been dismantled during the past few years.

THE COAL TRADE

The Anthracite Trade.

The Anthracite coal trade continues quiet and there is not much new business being done, but large quantities of coal are being moved from the mines to various points of distribution. The stock of coal at Port Richmond is lower now than it has been at any time since the strike in the latter part of 1887 and early part of 1888. The sales-agents of the coal companies met in New York on the 29th ult, and advanced the price of coal to Eastern points as follows: Broken coal, 15 cents a ton; stove, 30 cents; egg, 35 cents; chestnut, 35 cents. A general increase of 25 cents per ton for coal for Western points was also decided upon.

The agents also fixed the production for July at 3,500,000 tons.

The Bituminous Trade.

The Bituminous trade is fairly good for this season of the year, though prices rule low. The New York Central contract for 1,500,000 tons has been awarded. It includes the supply of coal needed for the Rome, Watertown and Ogdensburg and West Shore roads. The contract has been divided between The Fairmount Coal and Coke Co., and The Bell, Lewis & Yates Mining Co., of Buffalo; Morgan, Moore and Baine, and Osborne, Sager & Co., of Cleveland, have secured the larger part of the contract, but how much each party interested received is kept quiet by those interested.

The Coke Trade.

There has been no improvement in the coke trade since our last report. The same dullness, prices, and conditions exist, and the iron trade remains the same, with the prospects of a general lockout strong. This of course has a very depressive effect on the coke trade.

PERSONALS

MR. JABEZ WOOLEY, one of the pioneer miners of the Schuylkill region, and now located at Evansville, Ind., spent a portion of the past month visiting old scenes and old friends in the Mahanoy valley. Mr. Wooley is full of interesting reminiscences of early mining in that valley. Before any railroads entered the valley, the Boston Run mine and the old Pott Run tunnel, down the valley, were opened under his direction. He also opened the Lee and Wren mines, now known as Elmwood Colliery, P. & R. C. & I. Co., and for some time operated the old Trenton colliery. He was surprised to learn that old Boston Run, the first house of which was occupied by himself, was no longer in existence as a village, the houses, on account of the caving in of the surface, having been removed to the other side of the valley. He was equally surprised to learn that the name of Pott Run mine has faded out of the memory of most people. He was also a pioneer in the Ashland district. He prospected there, and was the first to open up and develop the Mammoth vein with a water-level tunnel. This work was done before the Gordon Planes and old Mine Hill Road were constructed. Some twelve years ago, Mr. Wooley was prospecting in the then wilderness of West Virginia, far from any settlements or railroads, and he secured some coal interests there that, owing to the development and opening up of the country by opening railroad extensions, have become valuable. Before returning to his home he intends visiting his West Virginia properties and make arrangements to either develop them or sell them.

MR. JAMES F. BEATTIE has been appointed mining engineer for the Guyandot Coal Land Association, a corporation owning large tracts of coal and timber land on the line of the Norfolk & Western R. R., and whose headquarters are in Philadelphia. Mr. Beattie's headquarters are at Dunlow, Wayne County, West Virginia.

MR. HUGH ROSS, formerly inside foreman at the Mullin Mine of the McClure Coke Company, near Mt. Pleasant, Pa., is now filling the same position for the J. A. Strickler Coal and Coke Company at Southwest, Westmoreland County, Pa. The mine he is in charge of is a slope opening with a tipple fitted for raw coal. There are no coke ovens as yet erected, the raw coal being of excellent quality meets with ready sale.

MR. S. W. GILMAN, of Chicago, for the past three years president of the Brazil Block Coal Company, has resigned on account of ill health. Mr. Charles H. Niblock, for some years past engaged in mining in the State of Washington, and at present president of the Snoqualmie Coal and Coke Company and general manager of the Acme Coal Company, both of Tacoma, Wash., has been elected president in Mr. Gilman's stead.

MR. JOHN MCGONIGAL, inside foreman for R. B. Wigton & Sons at Troy mine, has been appointed assistant to Mr. Charles E. Sharpless, engineer and superintendent for the same firm. Mr. McGonigal's title will be assistant superintendent.

JONATHAN WEIR fire-boss at the Lehigh & Wilkes Barre Coal Company's South Wilkes-Barre shaft, has been appointed inside foreman for the West End Coal Company at Mocanaqua, Pa., vice John Protheroe, deceased.

MR. GEORGE MAUE has disposed of his Hazleton *Sentinel* to a stock company, with Mr. C. F. Paul as business manager. John McCarthy, for some time past associated with Mr. Maue in the editorial work, becomes the editor, and Mr. Maue takes charge of the job printing department. The new management has secured the Associated Press service and will undoubtedly publish an interesting and readable journal. It has one great advantage over most of its contemporaries in have as editor a young man with a remarkably vivid imagination, who, in case the Associated Press service becomes impaired, can improvise one.

THE death of Mr. Harry M. Luther, assistant engineer in charge of the Mahanoy District, P. & R. C. & I. Co., has caused a redistricting of the company's collieries in the Mahanoy and Shenandoah valleys. Mr. Luther's old district has been divided. One half of it has been added to the Shenandoah district, under charge of Mr. John H. Pollard, assistant engineer, and the other half has been added to the Ashland district, under charge of Assistant Engineer F. P. Weiser. The force of transitmen and chainmen formerly under charge of Mr. Luther, have also been assigned to work in the offices of Messrs. Pollard and Weiser.

WILLIAM SCAIFE, of Coal City, Illinois, has been appointed inside foreman for the Pacific Star Coal Company, at Mystic, Iowa.

MR. WM. GRAEBER, Coal Inspector for the Philadelphia & Reading Coal & Iron Company, died at his home in Shenandoah, Pa., on the evening of the 5th ult. Mr. Graeber was well-known in mining circles in the Schuylkill region, and was for some years superintendent of the Philadelphia & Reading Coal & Iron Company's North Franklin collieries at Treverton, Pa. He resigned this position on account of failing health, and was given the position he held at the time of his death, because its duties were not confining and not beyond his failing strength. He was a man of most kindly disposition, and his jovial voice, always marked with a strong German dialect, was an index of his sunny and kindly disposition.

MR. E. G. TUTTLE, of Hondo, Coahuila, Mexico, general superintendent of the Coahuila Coal Company, was a visitor to the Anthracite regions during the past month. The object of his business was to purchase a lot of mining machinery, consisting of hoisting engines, screens, etc. After inspecting the machinery in use at several of the larger collieries in the Wyoming valley, he placed his order with the Vulcan Iron Works, of Wilkes-Barre, Pa., and started for home via New York City.

ANTHRACITE COAL STATISTICS.

Statement of shipments of Anthracite coal for month of May, 1892, compared with the corresponding period last year. Compiled from the returns furnished by the Mine Operators.

	May, 1892.	May, 1891.	Difference.		For Year 1892.	For Year 1891.	Difference.	
From Wyoming Region,	2,040,436·02	1,807,931·04	Inc.	232,504·18	8,506,273·03	7,480,189·11	Inc.	1,026,083·12
From Lehigh Region,	518,243·03	557,314·05	Dec.	39,071·02	2,269,870·11	2,319,621·10	Dec.	49,750·19
From Schuylkill Region,	972,442·10	974,289·08	Dec.	1,846·18	4,799,171·00	4,385,040·07	Inc.	414,130·13
Total	3,531,121·15	3,339,534·17	Inc.	191,586·18	15,575,314·14	14,184,851·08	Inc.	1,390,463·06

The stock of coal on hand at tide-water shipping points, May 31, 1892, was 684,662 tons; on April 30, 1892, 714,842 tons, decrease 30,180 tons.

EXPLOSIONS IN COAL MINES.

BY J. B. ATKINSON.

[From the Transactions of The Mining Institute of Scotland.]

No industry has been subject to disasters involving so large a loss of life as coal mining, and these disasters have been principally due to explosions.

The magnitude of colliery explosions has strongly directed public attention to the dangers of mining, and has led to the passing of Mines' Regulation Acts, each more stringent in its provisions than its predecessor.

It is now held by many persons that the extension of nearly all the larger explosions has been caused by coal-dust, and even that some explosions have been wholly due to the combustion of that agent.

The words "coal-dust" do not occur in any Mines' Regulation Act except that of 1887. It is evident, therefore, that an important factor in colliery explosions has been overlooked, and it is probable that many explosions have occurred simply from a want of knowledge in which all connected with mining have shared.

The influence of fire-damp in explosions has been two-fold, it is itself the cause of explosions, and it has diverted attention from another factor—coal-dust.

We may even go further, and say that one of the precautions, large currents of air, adopted to lessen the danger of fire-damp, has directly assisted in increasing the danger of coal-dust by rendering the mines dryer, and promoting the formation of the most dangerous class of dust deposits, those due to the fine upper or wind-borne dust and common on many main intake and haulage roads.

If these considerations be true it is clear that our knowledge of the causes of colliery explosions, and of means for their prevention, will require to be recast, and in this paper attention will be especially directed of coal dust as the cause of explosions that is least understood.

Explosion may be defined as the sudden large increase in volume of matter.

In practice accidental explosions are of the following kinds:

(*a*) The expansion of gunpowder and allied explosives on combustion.

(*b*) The expansion of dynamite and allied explosives on disassociation.

(*c*) The expansion of mixtures of inflammable gases or vapors with air on combustion.

(*d*) The expansion of mixtures of inflammable dusts with air on combustion.

(*e*) The expansion of gases or vapors under pressure on the rupture of retaining walls.

a,b,c, and *d* may be called chemical explosions, and are accompanied by flame; *e* may be called a mechanical explosion, and is not accompanied by flame.

Explosions under the above heads occur in mines. This paper will, however, be confined to the consideration of the explosion of mixtures of fire-damp and air, and of mixtures of coal-dust and air, and also of gunpowder and other explosives, so far as they initiate the two former classes of explosions.

A true explosive is a body containing within itself the power of explosion. Thus gunpowder on the application of heat, or nitro-glycerine compounds on detonation or shock, explode without the assistance of any other body. These are true explosives. Fire-damp and coal-dust are not explosives. Mixtures of fire-damp and air or of coal-dust and air are explosive, but the oxygen of the air is as essential to the explosion as the fire-damp or coal dust. It is scientifically incorrect to speak of the explosion of fire-damp or coal-dust. Gunpowder is an example of a solid explosive, nitro glycerine of a liquid explosive, and there are explosive gases, but they are never met with out of the laboratory. Thus one of the oxides of chlorine (hypochlorous acid) is an explosive gas. When slightly heated it decomposes with explosion.

Fire-damp is usually a mixture of marsh gas, with nitrogen, oxygen, and carbonic acid gases. The marsh gas, or light carbureted hydrogen, is the combustible constituent. Fire-damp is pent up in the strata at high pressures, and issues into the workings of a mine, usually as a steady flow, but sometimes as a sudden outburst. In elevated unventilated parts of mines it collects, and often issues from such places in large volume on a fall of the barometer.

When flame is applied to fire-damp issuing as a jet into the atmosphere, it burns at the point of issue like ordinary lighting gas. There is combustion but no explosion. If mixed with air in certain proportion, flame passes rapidly through the mixture, and explosion results, the explosion being wholly due to the expansion of the resultant gases, caused by the heat of combustion. There is no absolute increase in volume of the mass, such as takes place when gunpowder is fired when the resultant products, apart from the expansion due to the heat of combustion, occupy many times the volume of the original gunpowder.

The temperature of ignition of an inflammable mixture of fire-damp and air, the speed of the passage of flame, the temperature of combustion, the increase in volume of the resultant gases if free to expand, the increase of pressure if confined, and the composition of the resultant gases, are all points for consideration to which it is not proposed to direct attention. Recent researches, however, have shown that, as regards the speed of flame, the pressure developed, and the composition of the resultant gases of an explosion of fire-damp and air, the older text-books are not altogether correct.

Coal-dust is more or less prevalent in all dry coal mines. When the heat of a mine raises the temperature of the air entering the mine its capacity for absorbing moisture, or its drying power, is increased; and if the quantity of moisture in the strata mined, and that due to the respiration of men and horses, and to the combustion of lights is not sufficient to saturate the air, the mine becomes dry. The temperature of the strata increases with the depth, while the quantity of moisture usually decreases. Deep mines, are, therefore, dryer than shallow mines.

Some coal seams produce more dust than others—the more friable the coal the more dust. Coal seams are traversed by joints or cleavage planes running at right angles to the plane of stratification, and by partings parallel to the stratification. The latter planes of division are very generally coated with a dull, black, friable substance, known as mother of coal, dant, or mineral charcoal, which probably is largely present in fine coal-dust.

The hewing, filling, and leading of the coal are the principal causes of coal-dust deposits in mines. Two other causes (1) the falling of coal from the sides of the passages, and its subsequent trituration by the feet of men and horses, and (2) the carrying down of coal-dust from the screens on the surface by the air current descending the downcast shaft.

If a pound of ordinary coal is placed upon a fire it burns and is eventually consumed; first the combustible gases that are driven off combine with the oxygen of the air, producing flame and heat; next the solid carbon is consumed until nothing but ash remains. It can be shown by calculation that if the combustion of the pound of coal took place suddenly the heat given off would so expand the resultant gases that explosion would result, exactly as in the case of the combustion of fire-damp. If the pound of coal was in the form of fine dust and suspended in air, under some conditions such rapid combustion will take place, and this is a coal-dust explosion.

The explosions of fire-damp and air of coal-dust and air are therefore in some respects similar phenomena; in each case the explosion depends on the heat of the combustion expanding the resultant gases, and each explosion is accompanied by flame and a vitiation of the atmosphere.

A mixture of fire-damp and air readily takes place—the motion of the air in a mine, the mobility of the fire-damp, and the property of diffusion which gases possess, even when stationary, all favor the mixture. The fire-damp is readily ignited, and does not require to be broken up before combustion takes place.

With coal-dust and air the conditions are different, and opposed both to the ready formation of an explosive mixture and its subsequent ignition.

Coal-dust is a solid body: it is not present in the air of a mine under ordinary conditions in any considerable quantity, but requires to be raised from the floor or dislodged from the sides and roof before a cloud is formed; it requires to be broken up, or the gases it contains driven off, before combustion takes place. The combined effect of these conditions makes it difficult to initiate an explosion of coal-dust and air. The fact that it requires special conditions to obtain an inflammation of a cloud of coal-dust in an air free from fire-damp does not, however, prove that the extension of an explosion in such a mixture is equally difficult to obtain, because the conditions are then different. After an explosion is started in a mine the coal-dust is no longer quiescent, but is blown into the air by the explosion, and forms a dense cloud; behind the cloud is heat, flame, and pressure.

The behavior of coal on an ordinary fire resembles somewhat that of coal-dust in an explosion. The first step to start a coal fire is to ignite paper. The paper ignites wood, which in turn ignites the coal; once a coal fire is thoroughly kindled it is self supporting, but the coal cannot in the first instance be readily ignited without the assistance of heat from other material.

The heat and consequent force developed by the inflammation of a mixture of fire-damp and air in such proportion as to secure complete combustion is greater than the heat and force developed by a similar mixture of coal-dust and air.

Mixtures of fire-damp and air are, however, only capable of transmitting flame within certain limits. There must be from 5 to 20% by volume of fire-damp in the mixture. The case, with respect to coal-dust and air does not appear to be parallel. 1 lb of coal dust and 160 cubic feet of air are required for complete combustion. Assuming an air way to be 8 ft. by 5 ft. sectional area, and taking coal-dust to weigh 26 lbs. per cubic foot, then for each 160 cubic feet of air in such a road to be supplied with 1 lb. of coal-dust, the surfaces of the road would require to be coated with a film of dust [illegible] inch thick. Such a quantity is far below what in practice is present on ordinary dusty roads, along many of which it has been observed that an explosion has passed with great force. These roads would, at the time of the explosion, have suspended in the air a quantity of dust in excess of 1 lb. to 160 cubic feet of air, and in no case where the dust was pure has the writer seen any evidence that the passage of an explosion has been checked by an excess of dust. It seems that in a coal-dust explosion a minimum quanity of dust must be present, which is probably much greater than the quantity named as being required for perfect combustion, but practically no maximum. If this be true, it has an important bearing on the question. The minimum quantity of coal dust occurs constantly over long lengths of roads in mines, and consequently the conditions are present for the propagation of a coal-dust explosion. That is to say, many roads in mines, in their normal condition, contain the necessary agents for an explosion of coal-dust and air; while a similar state of things, due to the presence of fire-damp and air, is an abnormal condition.

With regard to the force developed by an explosion of coal dust and air, as compared with the force developed by the explosion of fire-damp and air, the following is worth consideration:

In an explosion confined to coal-dust and air, traversing a road in a mine containing a large excess of fine coal-dust, there will probably be only coal gas distilled from the dust consumed; the combustion of coal gas results in more heat than the combustion of an equal volume of fire-damp, the coal gas containing free hydrogen; if this excess of heat is equal to the heat absorbed in distilling the coal gas from the dust, then the heat available to expand the resultant gases will be as great in the one case as in the other. Experience in actual explosions shows that, where there is a large excess of fine coal-dust, the force developed is greatest.

In an explosion of either fire-damp and air or coal-dust and air, a limiting factor is the quantity of air the road contains; fire-damp, if present in volume so as to form the most explosive mixture, occupies one-tenth of the air space; coal-dust may be present in excess, and yet practically leave the road full of air.

Sir F. A. Abel, when experimenting on coal-dusts, observed that one of the samples of dust, consisting largely of stone dust, had the property of determining the ignition of a mixture of fire-damp and air not inflammable *per se*. This led him to experiment under similar conditions with non-inflammable dust, such as calcined magnesia, and he obtained similar results—that is to say, a mixture of fire-damp and air not inflammable *per se*, became so on the addition of a non-inflammable dust. This shows that coal-dust may act in two ways in explosions: 1st, it may supply combustible matter; and 2d, it may cause mixtures of fire-damp and air not inflammable *per se*, to become capable of transmitting flame.

Having satisfied ourselves that fire-damp and coal-dust are the only bodies that, in conjunction with air, cause explosions in mines, we can investigate the subject (1) by the study of actual explosions, and (2) by experiment.

Explosions may be studied by observation made in the mine after their occurrence, or by the perusal of published accounts.

The writer has visited the scene of a large number of explosions in mines, most of which were caused by the ignition of small quantities of fire-damp, and were not generally followed by any death, or caused much damage to the mine. Some of these ignitions resulted in one or two deaths—the persons injured usually living for a few days after the accident. In a few cases of undoubted fire damp explosions, lives were lost in the mine, but this was exceptional.

The most considerable explosion of fire-damp which the writer has personally investigated occurred at Whitehaven Colliery on the 25th April, 1885.*

In a few cases of minor explosions, investigated by the writer, coal-dust has had some influence more as extending the flame of a gunpowder shot.

The writer has had opportunity of becoming acquainted with the circumstances attending the large explosions described in Table I., soon after their occurrence, and he at the same time made more or less complete examinations of the mines; he believes that in these explosions coal-dust played a leading part.

TABLE 1.

No.	Colliery.	Date.	Lives Lost.	Flame causing explosion.	Agent first inflamed.	Agent causing extension of explosion.	Point of origin of explosion.
1	Seaham.	25th October, 1871	26	Gunpowder shot.	Coal-dust.	Coal-dust.	Intake air-way.
2	"	8th September, 1880	164	" "	" "	" "	" "

10	St. Helens.	19th April, 1888	30	Fire in the mine.	Fire-damp.	Fire-damp, coal gas and coal-dust.	" "

The explosions in the table are, it must be noted, not selected, but comprise all the large explosions the writer has personally investigated.

The reasons that lead to the conclusion that coal-dust was the principal factor in these explosions will be stated shortly.

First, there are reasons of a negative character depending on the apparent impossibility of ascribing the explosions to the combustion of fire-damp, the only body other than coal-dust likely to cause them.

In Nos. 1, 2, 4, and 7, the explosions were entirely confined to the intake air-ways; in Nos. 3, 6, and 8, the principal effects of the explosions were observed on the intake air-ways, although some of the working faces were traversed, and the return air-ways affected to a very limited extent. In No. 5 the intake air-ways, the working faces, and the return air-ways were all traversed. In No. 9, a small explosion, the working face and return air way of one district were affected. In No. 10 the working face of one district and intake air-

*This explosion, as well as Nos. 2, 3, 4, 5, and 6, in table I., are described in detail in a book entitled "Explosions in Coal Mines," prepared by Mr. W. N. Atkinson and the writer.

way were traversed, but owing to operations that were being carried out to isolate a fire at the working face, the direction of the air current had been changed shortly before the explosion, and a part of the intake air-way was return air-way at the time.

On the whole the explosions had traversed longer distances of intake air ways than other parts of the mines, in some cases being entirely confined to such roads. That is to say the roads least likely to contain fire-damp were most affected.

Experience in mines would justify the expectation that an immensely greater proportion of explosions of fire-damp would extend along the return air-ways than along the intake air-ways, whereas the reverse was the case in these explosions.

In the North of England, where this feature had long ago been observed, it has been customary to say with what has been termed "the unlearned wisdom of experience" that explosions of fire-damp always faced the fresh air, or that the gas sought the purest air.

In some of these explosions it was observed that the blast, on arriving at points on the intake air-ways where the air current split, had afterwards traversed one of the splits only. If the air current, before dividing, and in one of the splits, was in an explosive condition through the presence of fire-damp, how did the other split escape being in a similar state? In one case it was observed that the split which escaped was a continuation of the straight line which was the course of the explosion up to that point, the split traversed by the explosion deflecting to one side.

In Nos. 1, 2, 3, 4, 5, 6, 7, 8, and 9, so far as a judgment could be formed, no person in the mine was in a state of alarm at the moment of the explosion.

In No. 10 the mine was on fire, and all the ordinary workmen had left the pit. The persons who were in the mine at the time of the explosion, engaged in isolating the fire, were, however, under no apprehension of a large explosion taking place likely to injure them; they were 600 yards from the fire.

It does not seem possible in the first nine cases, that fire-damp could have entered the air currents in such volume as to have made the explosions possible without the officials or workmen observing it.

In Nos. 1, 2, 4, 5, 6, 7, 8, and 9, a shot was fired, and was the point of origin of the explosions; had fire-damp been present in the air current in sufficient quantities to make the explosions possible through its agency alone, it is highly improbable that any shot would have been fired.

In the collieries where the ten explosions given in the table occurred, safety-lamps only were used at the working face, and in some of them also on the intake air-ways, therefore we must go to other explosions for a condition which supplies a negative reason why fire-damp is not the principal factor in some large explosions.

In many mines worked entirely, or nearly so, with naked lights, a great explosion has swept over the whole pit. Scotland affords an example of this in the explosion at Blantyre in the splint coal. It does not seem possible that any great area of a seam in which naked lights are scattered here and there could be so charged with fire-damp as to render an extensive explosion possible. A sudden fouling of the air current from any cause would lead to an explosion at the first open light encountered, and so would limit its extent. Yet at Blantyre, Clifton Hall in Lancashire, Llanerch in Monmouthshire, and in many other cases, the mines were working with open lights, and all at once an explosion traversed the whole seam, causing in the cases just mentioned the death of 207, 178, and 176 persons respectively.

On exploring the mines after the occurrence of the explosions given in the table, there was no evidence of any outburst of gas or failure of the ventilation to account for the presence of fire-damp in sufficient quantity to cause the explosions. In No. 9 a single issue of fire-damp could have explained the explosion. In the other cases the course taken by the blast could not be explained by supposing that fire-damp had entered the air current at any particular point; on such an assumption roads that should have been traversed were missed out, and roads were traversed that should have escaped. By no reasoning could the explosions be ascribed with any degree of probability to fire damp only.

The positive reasons that support the view that coal-dust was the principal factor in these explosions are as follows:

The intake air-ways were in all the cases, except No. 9, also used as haulage roads. In Nos. 1, 2, 3, 4, 6, 7, 8, and 10 mechanical haulage was in use on these roads, the main and tail-rope system in all except No. 7, where the endless chain was in use. In No. 5 horses were employed. These roads were dry, they were traversed by large currents of air, and coal-dust was blown off the trains of laden hutches passing, often at high speeds, in the opposite direction to the air current. The result was that fine coal-dust accumulated on the roof and sides, as well as coarser dust on the floor. Near the downcast shafts coal-dust, carried down with the air from the screens, assisted materially in forming these deposits. The writer has not seen a road in a colliery in Scotland containing so much of the upper or wind-borne dust as occurs on similar roads in the dry mines of the north of England. These dust-laden, intake air roads were the roads principally affected by the explosions, and, as already stated, in Nos. 1, 2, 4, and 7 the explosions were entirely confined to them. In Nos. 1, 2, 4, 6, 7, and 8 the explosions originated on them.

The inner portions of the haulage roads, where the laden hutches, drawn by horses and ponies moved at slower speeds against feebler currents of air, contained little of the upper dust, and often the coal-dust on the floor was much mixed with stone-dust. The explosions were often checked on reaching such points.

In some cases, however, where these roads and the working face contained a considerable quantity of coal-dust they were traversed by the explosions.

The explosions were in many cases stopped by damp ground. This was specially noticeable with regard to the explosions which extended to the downcast shafts, which was the case in Nos. 2, 3, 4, 5, 6, 7, 8, and 10. When the downcast shafts were wet the explosion were arrested, and did not cross them. In No. 2 the shaft was dry, and the explosion crossed it. In No. 3 the downcast shaft was very dry, and the explosion entered it and extended upwards to the surface, and downwards to four levels below. A dampness in the floor, it was observed, was not sufficient to arrest an explosion if upper dust existed.

In Nos. 3, 5, and 9 short lengths of the return air ways were affected principally next the working face where coal-dust was present in quantity greater than is usual in such roads. The return air-ways on the whole could be said to be free from coal-dust, and were not so dry as the intake air-ways. At Altofts the return air-ways were used as traveling roads for the colliers, and were full of stone-dust ground up from the floor of the seam.

If the explosions were caused by the combustion of coal-dust, the absence of alarm on the part of the workmen can readily be understood. The mines were in their normal state up to the moment of the explosion, and there was no new condition present calculated to cause alarm.

Naked lights could be in use all over a dusty mine and be a source of no immediate danger, although the necessary elements for propagating an explosion in the shape of coal-dust resting on the floor, roof, and sides, and pure air were everywhere present.

The fact that some of the explosions were originated by the firing of a shot, is strong evidence that the air current was not in an explosive condition from the presence of fire-damp alone where the shots were fired, and affords some presumption that coal dust, either alone or in conjunction with such a proportion of fire-damp as not to be considered dangerous by the person igniting the shot, was the agent first inflamed, as the danger of coal-dust is not understood.

The personal experience of the writer points strongly to the preponderating influence of coal-dust in large colliery explosions. How far this may be true for other large explosions, it is in many cases now almost impossible to say. Until a few years ago coal dust was not recognized as a factor in these disasters and in published accounts of earlier explosions, it is only mentioned incidentally. The explosions were always referred to fire-damp, and theories to account for its presence in sufficient quantity by a sudden outburst, the leaving open of ventilating doors, or some other cause, were put forward with more or less confidence.

There are, however, so many points of resemblance between the explosions briefly described and most other large explosions that the writer does not hesitate to express the opinion that in almost all widespread explosions the influence of coal-dust has been predominant.

It is not, however, probable that so large a proportion of other large explosions have been caused by coal-dust in air practically free from fire-damp, being the agent first inflamed, as in the cases tabulated. Fire-damp ignited by the flame of a naked light or safety-lamp or a mixture of coal-dust and air containing a small percentage of fire-damp ignited by the flame of a shot, have probably been the origin of most large explosions.

The experimental investigation of the influence of coal-dust in colliery explosions has been undertaken by individuals, Committees, and Government Commissioners, both at home and abroad.

Mr. H. Hall, H. M. Inspector of Mines for the West Lancashire District, and Mr. Clark, mining engineer, described in a paper read before the North of England Institute of Mining Engineers, in June, 1876, some experiments they made with coal dust in a mine from the surface. The mine was 45 yards long, and 30 feet sectional area. They scattered coal-dust on the floor and fired a cannon at the face to represent a blown-out shot. The most decisive result obtained by them may be given in their own words:

"Coal-dust having been scattered on deals the whole length of the slant (the thill being very wet), fired 2¼ lbs. powder; in this case flame issued strongly at the mouth of the slant, having traveled 45 yards. The blast was very fierce, and would certainly have proved fatal to any one struck by it in its course."

In 1890 Mr. Hall experimented by firing a small cannon at the bottom of shafts after coal-dust had been emptied into them, and caused explosions extending to the surface or in one instance 180 yards.

These are the only experiments on a large scale in Great Britain.

Mr. Wm. Galloway, who was probably the first to recognize the great influence of coal-dust in large explosions, has conducted and published the results of many experiments on a small scale in which he demonstrated the inflammability of coal-dust. The Chesterfield and Derbyshire Institute of Engineers conducted experiments on a small scale, but obtained no very definite result, and appear to have been led by the negative results obtained to underestimate the importance of the question.

Sir F. A. Abel carried out experiments with coal-dust on a small scale, at the request of the Home Secretary, in connection with the enquiry into the Seaham Colliery explosion (No. 2 in list). He obtained no decisive result as regards the inflammability of coal-dust and air alone, but he discovered, as already mentioned, the effect of dust, as dust and apart from its inflammability in promoting the inflammation of mixtures of fire-damp and air.

He also conducted some experiments in larger galleries with coal-dust and blown-out shots, which showed that coal-dust "will feed the flame projected by a blown-out shot so as to carry it on to a comparatively considerable distance."

The most important experimental work in connection with this question is that of the Prussian Fire-Damp Commission, a translation of whose report will be found in Vol. 34, of the Transactions of the North of England Institute of Mining and Mechanical Engineers.

The experiments were made in an elliptical gallery, 167.3 ft. long, and having a sectional area of 17⅙ sq. ft. A side gallery 32.8 ft. long was added to the main gallery at a later period. Shots were fired at one end of the gallery from cannons to represent blown-out shots. The Commission sum up the result of their labors at considerable length. They state:

(1.) "The *presence of coal-dust* in more or less abundance in the immediate vicinity of the working face, *gives rise to more or less considerable elongation of the flame* projected by a blown-out shot, *whether small quantities of fire-damp be present in the surrounding air or not.*

(2.) *a.* "*In the complete absence of fire-damp, the elongation or propagation of flame is generally of limited extent*, however far the deposits of dust may extend in the mine ways.

b. "*There are, however, certain descriptions of coal-dust which*, if ignited by a blown out shot, will not only *continue to carry on the flame, even to distances extending considerably beyond the confines of the dust deposits*, but will also *give rise to explosive phenomena or results, in the complete absence of any trace of fire-damp*, which, in character and effects are similar to those produced with some other dusts in air containing 7 per cent. of fire-damp.

(3.) *a.* "All *the phenomena produced by the burning of, and propagation of flame by coal-dust are intensified by the presence in the air of small proportions of fire damp.*

b. "*Certain dusts* which, under favorable conditions, appear to have the power of propagating flame to an indefinite extent in a dust-laden area, the air being free from fire damp, *will, if only sparsely suspended in air containing fire-damp in some proportion below 3 per cent., render such a gas-mixture susceptible of explosion by a blown out shot.*

(4.) "Special experiments, in which the branch gallery, described as opening into the main gallery near its extremity, was charged with a fire-damp mixture (retained by brattice cloth), demonstrated that *a coal-dust ignition or explosion, developed in the complete absence of fire-damp, can communicate ignition to an explosive gas-mixture existing at a very considerable distance from the point of first ignition.*"

The Royal Commission on Explosions from Coal-Dust in Mines now sitting will probably experiment on a large scale. From the volume of evidence issued by the Commission, it appears probable that an artificial gallery, 200 yards in length, will be erected. This length will not be sufficient to test all the questions that arise. The writer's suggestion to the Commission was that some experiments should be made in a gallery not less than half a mile long.

From actual observation in mines, it appears that a coal-dust explosion proceeds from 50 to 100 yards from the point of origin before developing its maximum force. It is doubtful if this can be illustrated in a gallery 200 yards long. The arresting of a coal-dust explosion, traveling with maximum force and velocity, by a space free from dust could not be tested in such a gallery.

REMEDIAL MEASURES.

The first step in this direction is to obtain a proper conception of the causes of explosions in mines. The danger arising from fire-damp is well known, and also the precautions necessary to prevent its accumulation and ignition, such as sufficient ventilation and the absence of naked flame. The danger of coal-dust is not so generally understood or admitted, but it is hoped that this will be secured by the labors of the Royal Commission now sitting.

The danger arising from coal-dust in mines may be met (1) by precautions to prevent its ignition, and (2) by the adoption of means to prevent its accumulation or to render it innocuous.

The formation of a cloud of coal-dust in mines and its subsequent ignition is practically caused by the disturbance and flame attending the explosion of shots or of mixtures of fire-damp and air; both of these will, it is believed, under some conditions raise and inflame a cloud of coal-dust in air, and initiate a coal-dust explosion which becomes self supporting.

Most shots are fired at the working face, and in mines deep enough to be dry and dusty some fire-damp is nearly always present in the air in such situations, and fire-damp may be liberated by the shot: the coal-dust, however, is confined to the floor, and is not so fine as the wind-borne dust on main haulage roads. At the working face a blown-out shot fired near the floor, or pointing to the floor, is most dangerous, and the dust must be present in considerable quantity before a coal-dust explosion is possible, and then the effect of the probable volume of fire-damp present in the air is to be considered.

On main haulage roads where, after their completion, it must be noted comparatively few shots are fired, and where fire-damp is practically absent, coal-dust of the finest character is often found on the roof and sides, as well as coarser deposits on the floor, and strong currents of air are usually present to sustain any cloud formed.

The effect of a shot in disturbing dust on such roads is twofold. The powder gases rushing from the shot agitate the air in its vicinity, and shock or tremor is communicated to the solid sides of the passage. At the working face, the first cause only operates. Any tremor given to the floor on which the dust there rests would have no effect in raising a cloud; but where dust is on the roof and sides as well as on the floor both causes assist in forming a cloud.

The combined effect of these conditions appear to make it much more dangerous to fire a shot on an old haulage road, where there is much dust, than at the working face. Nos. 1, 2, 4, 6, 7, and 8 explosions were, it is believed, caused by shots, which were not blown out fired in stone on old intake and haulage roads, where the air was practically free from fire-damp.

Nos. 5 and 9 explosions were caused by shots fired in stone at the working face. In these cases there was an unusual quantity of coarse dust on the floor near the shots, and there would probably be from 1 to 2 % of fire-damp in the air. In No. 5 the position of the shot hole could not be determined; in No. 9 the shot was partially blown out, and pointed to the floor.

The raising of a cloud of coal-dust by shots may be prevented by removing or damping the dust in their immediate neighborhood, as is required by the present Mines Act, without resorting to any general system of removal or damping.

The use of a flaming explosive in conjunction with some material to kill the flame, or the use of a flameless explosive (if such exist) are remedies adopted.

The danger arising directly from explosions of fire-damp and air is a sufficient reason for adopting every reasonable precaution to prevent their occurrence. In dusty mines, where such explosions may be indefinitely extended by coal-dust, even greater precautions are necessary.

No. 3 explosion was probably originated by a local explosion of fire-damp at an open light; No. 10 was caused by fire-damp ignited by the flame of a fire. The fire-damp had collected in passages near the working face from which the air current had been cut off by the erection of a stopping in the intake in order to isolate the fire, the initial explosion so caused being extended to the downcast shaft by coal dust.

Means to prevent the formation of dust deposits, or life occasioned thereby, as registered in the reports of the Inspectors of Mines, from the year 1851 to 1891, both inclusive. There are 2104 separate explosions, causing the loss of 9172 lives, the average death rate per explosion being 4.36.

It has occurred to the writer that some argument in support of or against the coal-dust theory may be founded on these figures.

It will be observed that the number of explosions causing the loss of one life is 1430, of two lives 303, and so on to the final explosion causing the loss of 334 lives. The number of lives lost by an explosion is, roughly speaking, in proportion to the area of the field of the explosion.

Three assumptions may be made with respect to these figures:

1st.—That the explosions are all due to fire-damp.

2d.—That the explosions are all due to coal-dust.

3d.—That the explosions are due to both agents.

The first assumption, that the explosions are all due to fire damp, has been held until recently, and is still held by some persons, modified by the admission that coal-dust has aggravated or intensified some explosions. On this assumption there appears to be some difficulty in explaining the figures. Why should there be such an extremely rapid decrease up to a certain point of the number of the explosions as their fatality increases? If fire-damp is the cause of the large number of small explosions causing 1, 2, and 3 deaths and also of the monster explosions might not a considerable greater number of intermediate explosions have been anticipated? A reason that might be suggested is that the use of safety-lamps renders a large explosion possible in some mines by enabling a great length of air current to become explosive before it is ignited, while the use of naked lights in other mines causes the large number of small explosions. The explosions causing the loss

to render them innocuous, will be briefly glanced at.

Main roads are watered on the floor, and in some cases mechanical sprayers are used, so as to damp the roof and sides as well. Water pipes are laid along the main roads, the water issuing under pressure as a fine jet at intervals. Compressed air is used in connection with the water so as to secure a fine spray, and both damp the roads and saturate the air current with moisture.

In some cases the water pipes are simply provided with cocks at intervals, to which a hose pipe is attached when watering is necessary.

At some collieries the laden hutches are watered at the engine landings. More attention is paid to the construction of the hutches, so as to prevent coal and coal-dust being shaken out of them.

By the use of steam the temperature of the air descending the downcast shaft has been raised to the temperature of the mine and at the same time saturated with moisture; the air current passing round the mine then ceases to have any drying power.

Hygroscopic or water-absorbing salts have been sprinkled on the roads to secure dampness.

Coal-dust from the screens on the surface should be prevented as far as possible from descending the downcast shaft with the air current.

The above table shows the number of fatal explosions due to fire-damp and coal-dust, and loss of of one life are undoubtedly nearly all due to fire-damp; this the writer can state from investigation of a large number of them. Had mines been free from coal-dust, probably the number of big explosions would have been less. As the rate of fatality increases, so it is believed does the influence of coal-dust.

The second assumption is clearly untenable. Many explosions occur in mines free from coal-dust such as damp coal mines, oil shale, ironstone, and occasionally in lead mines; it may be noticed, however, that in such mines large explosions do not occur. If coal mines had been free from fire-damp, the dust remaining the same, probably the number of small explosions would have been less.

On the third assumption the figures may be explained bearing in mind the following facts: Fire-damp is readily ignited and as many mines yielding it in small quantity are worked with naked lights, local explosions due to it are not unfrequent. On the other hand the danger of fire damp is well known, and if present in large quantity suitable precautions are taken. Coal dust is not readily ignited, and in the past no precautions have been thought necessary with regard to it, but if it is once inflamed it is likely to cause a large explosion, because it is present in dry mines continuously over wide areas, and in many large explosions the loss of life has been practically that of all the miners underground.

Book Review.

REPORT OF THE DEPARTMENT OF MINES, NOVA SCOTIA, FOR THE YEAR 1891.—This report which is issued six months ahead of our Pennsylvania reports for the same year gives full particulars of the production and sales of all the various minerals and metals. It also gives an account of the technical schools of instruction now in existence in the Province.

ANNUAL REPORT OF THE BOARD OF REGENTS OF THE SMITHSONIAN INSTITUTION FOR THE YEARS 1889 AND 1890.—These two volumes which have just reached us contain complete reports of the operations, expenditures, and condition of the Institution. They also contain a number of papers on Mathematics, History, Travel, and Scientific Research, and are generously illustrated throughout.

NINTH ANNUAL REPORT OF THE BUREAU OF LABOR AND INDUSTRIAL STATISTICS OF THE STATE OF MICHIGAN, FEB. 1, 1892. — We are indebted to Mr. Henry A. Robinson, Commissioner, for a copy of the above report. It is full of interesting statistics as to wages, hours of labor, yearly expenditures and savings, etc., etc. The volume contains several illustrations of the principal industries of the State.

Additional Fast Express to the Southwest via Pennsylvania Railroad.

In order to better accommodate the increasing traffic to the Southwest, the Pennsylvania Railroad Company have placed in service a new fast train to Cincinnati and St. Louis. This train is known as the Southwestern Express, and leaves New York at 8.30 P. M. daily; Newark, to take on passengers for the West, 8.50, Trenton at 10.03, Philadelphia at 11.10 P. M., Washington 9.40, Baltimore 10.40 P. M., Harrisburg 2.05 A. M., Altoona, 5.40, Johnstown 6.53, arriving at Pittsburgh 9.15 A. M., Cincinnati 6.15 P. M., and St. Louis 7.00 A. M. the second morning after leaving New York. It is completely equipped with Pullman sleeping cars to Pittsburgh, St. Louis, and Memphis, via Cincinnati, and coaches to Pittsburgh. A dining car is attached at Altoona, from which all necessary meals are served. The Southwestern Express is the fastest and best equipped train to the Southwestern territory, and is a great convenience to travelers to the Mississippi River and beyond.

The Western Pennsylvania Mining Institute.

The Fifth Anniversary of the Western Penna. Mining Institute will be celebrated by a meeting in Monongahela City, Pa., on the 9th inst., commencing at 9 A.M. The following interesting and instructive papers will be read and discussed:

1. Health, Light, and How to Lessen the Force of an Explosion in Coal Mines. By John Foley, Courtney, Pa.
2. Mining: Its Past and Present and What it Might Be. By R. C. Campbell, California, Pa.

The above two papers will occupy the morning session. The programme for the afternoon session is as follows:

1. The Present Ventilation of Coal Mines on the Monongahela River, Compared With the Past. By O. Crede.
2. Analysis of Fire-Damp Taken From Fayette City Mine.
3. A Tramp Through the Minute Book. By Wm. Seddon, Secretary of the Institute.

On a recent visit to Western Pennsylvania we were being shown through the pump-room of a large furnace plant by the General Manager. Among the various pumps at work were several of the famous "Yough" pumps manufactured by Boyts, Porter & Co., of Connellsville, Pa. Laying his hand on one of them, the Manager said, 'Here is a first class all-around pump. It works equally well with clean or gritty water, and I have seen good sized pieces of coal pass through one at our coal mines, without doing any damage to the pump. For general mine work it beats anything I have yet tried for efficiency and durability. It is especially constructed for rough usage, and Captain Boyts made no mistake when he placed it on the market as an ideal mine pump."

The receipt of Messrs. Boyts, Porter & Co.'s new illustrated catalogue reminded us of this remark. We advise our readers to send for a copy of this catalogue and learn more of the merits of the "Yough" pump than we have space to give here. Besides being a fine piece of typographical work it contains a considerable data and a number of valuable tables concerning the flow of water through pipes, pumping, and general hydraulics.

The largest single order ever received for Reducing Valves was placed on June 21st, by the Consolidated Car-Heating Co., with the Mason Regulator Co., of Boston, Mass. It was for 500 locomotive reducing valves. There is an old adage that "the proof of the pudding is in the eating." It can in this case be paraphrased to "the proof of superiority is evidenced by the demand." The Mason Regulator Co.'s Reducing Valves are most successful and the Consolidated Car-Heating Co. naturally wanted them.

Mr. Geo. D. Whitcomb, proprieter of the well-known and most successful Harrison Mining Machine, has removed his general offices from 175 Dearborn St., Chicago, to No. 1224 Manhattan Building, 307 to 321 Dearborn St., same city, where he will be pleased to receive calls from all coal men interested in machine mining.

EASY LESSONS FOR BEGINNERS

IN THE STUDY OF THE

ART OF MINING

AND THE

SCIENCES RELATED TO IT.

This department is intended for miners and others, who in their youth have not been able to attend school and who are now desirous to inform themselves in the theory of mining and to learn how to answer the questions in ventilation, mine surveying, and mechanics which are asked at the examinations for mine manager's and mine foreman's certificates, and which it is important for them to understand as foremen and officers of mines. All the questions asked at the different examinations for mine manager's and mine foreman's certificates and for mine inspectors in this country are printed and answered in this department. The principles involved are explained in detail so as to be easily understood and the calculations are worked out at length for the benefit of those who are not familiar with figures.

GEOLOGY

In Its Relation to Coal, Iron, Oil, Gas, and Ores.

100. What is the difference between a spouting well and a dry well?

When boring for any of the three substances one may finally drill down into a stratum that contains them. If they are under pressure they will spout up to the surface, otherwise not. For example, the well W, Fig. 14, is drawing water from the stratum B; if the accumulation is deep and extends up above the level of W, as at C, for instance, then the well will spout. But if the surface is more like that at D and W is higher, the water will only rise to some point like F. Now the first example is one of a spouting well, the second, of one that is a pumping well, it requires power to raise the water. A dry well would be one that either did not reach B or else went through A and let the water out.

101. Is that the same with petroleum and gas?

Somewhat, though it is not like water in that there is *no perennial supply*. The rain is continually feeding the stratum B with water, but there is nothing to keep up the supply of oil or gas. The accumulations of ages may be exhausted in a few months. The spouting oil wells are the lucky strikes into the reservoirs of nature that have been long collecting.

102. How is it accumulated underground?

In Figs. 15 and 16 you will see what I want now to explain. Rocks are quite porous, and some have caves caused by the action of underground currents of water. Sandstone is very porous, and so is shale, therefore oil and gas can circulate freely in them. Besides this limestone has caves in it something like Fig. 15. Water is very solvent as you have already seen in the description of iron ore formation. If it flows long, it eats away the cave like at M and as it trickles from the roof of the cave it forms icicles of lime called stalactites. The Mammoth Cave, of Kentucky, and Ouray Caverns are good examples. Some caverns may not have stalactites. In the rocks are such caverns which somehow accumulated the oil and gas like in Fig. 16. Oil is lighter than water and so will float on top of it. So also gas will gather above the oil as in the figure. Now one man may sink a well at B and get gas only; another hole drilled at A will get oil and later gas; the hole sunk in C will strike salt water. As these have accumulated from the decomposition of coal or organic matter with great heat, the gas is under heavy pressure, just like steam in a boiler. It forces itself out through B, or else A or C, driving out the other materials first. It may be a long time before the oil is all forced out at A but in time the gas will escape. This has been the history of several neighbors in the oil country.

Fig. 15.

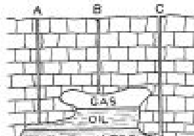

Fig. 16

103. Where should one bore for gas or oil?

If one can strike the rocks of the oil-bearing series, one should try to reach a spot on the top of the folds of the strata. Experience does not prove this to be always true, but it naturally tends to accumulate in the gently crumpled strata.

104. Why does the explosion of a cartridge at the bottom of a dry hole bring oil or gas?

In the oil country, you expect to find oil in certain rocks. If, however, you fail to get a pumping or a spouting well you simply have not bored into one of the caves or reservoirs. But you may be near one. So by putting 50 or 100 pounds of nitro-glycerine in the bottom of a hole and dropping a drill rod on it you may, possibly, break into a neighboring reservoir and so get oil, but it is not certain. This method is never advisable in shelly ground unless the hole is lined with tubing, for the blast will cause a caving that will be forever troublesome and has often resulted in the abandonment of the hole.

105. Are there any surface indications?

Yes, what is called oil show is one. On the surface of pools or springs a scum floats and gives good sign; while again there are what be called burning springs—rising gases which may be set fire to.

106. Where does the petroleum come from?

Russia and America are the chief oil-producing countries of the world. But other countries have large supplies. Geologically speaking it occurs with natural gas.

107. How much oil is produced in America?

Last year it was 1,160,000,000 gallons. And since 1870 it has been steadily growing from 1000 wells giving 201,471,000 gallons until there has now been produced altogether 18,400,000,000 gallons. Russia, during 1886 alone turned out 260,000,000 gallons; Scotland has slates that are mined and hoisted to the surface where the oil is sweated out of them. The Kimmeridge clay of England, is able to furnish a one-half barrel of oil from every cubic yard.

108. Is the supply without limit?

Geologists estimate an area of over 200,000 square miles as having more or less oil. The amount can not be estimated but is still very large, and the number of spouting wells, while uncertain, has not been decreasing. The Census reports show that the United States produced \$223,066,388 worth of petroleum during the past ten years and \$76,863,674 worth of natural gas. Some of this came from Colorado and California but far the largest amount is produced in States bordering on the Ohio River. The natural gas supply will be much more quickly exhausted than the oil and that of Ohio and Indiana will not last as long as the Pennsylvania gas fields. The average pressure of the gas in the wells owned by the City of Toledo, Ohio, is now only about 115 pounds to the square inch. In 1889, it was 250 pounds, and in 1890 it fell to 175 pounds. Many of the gas wells originally had a pressure of 400 pounds.

109. Why is the origin of oil associated with coal?

Do you remember how in Q. 8 we showed the coal to be a marsh product? You are aware of the miasma and gas that comes from a marsh—we call it marsh gas. Now, coal, when burned in the stove, or a coke oven or in a gas works, or in the analysis (See April number) gives off some gaseous material, coal gas; some volatile liquid, as naptha; some liquid as coal oil; some tar and a little pitch. We find in nature a similar series—gas called natural gas, or fire-damp if it occurs in a mine; that which comes out at springs or from bore-holes some light oils as rock-naptha; liquid petroleum; tarry substances like bitumen; and some solid material like asphalt. From these similarities we believe that petroleum had an organic origin. (See page 145, February, 1892, number of The Colliery Engineer.)

110 Has natural gas the same composition as marsh gas?

Natural gas is composed of	Marsh gas	95·50 %
	Hydrogen	2·00
	Oxygen	1·50
	Carbonic acid	1·00

Marsh gas is a compound of 1 part of carbon with 3 parts of Hydrogen. Fire-damp is nearly pure marsh gas. (See Q. 65 of Ventilation of Mines, and also p. 66, October, 1891, number of The Colliery Engineer.) You see the gases are about the same in composition, but fire-damp stayed in the seams and pores of the coal while natural gas succeeded in escaping. In the Anthracite region the rocks were nearly all broken up, thus giving escape to most of the gas which remained in the Bituminous districts.

111. Is natural gas as dangerous as fire-damp?

Exactly as bad. The blowers, as you call them, that let in fire-damp at the faces of the coal is practically natural gas. That is why there is so much complaint about the leaky main pipes that carry natural gas. At the points of leakage the gas works into the ground and affects the air of shallow mines near by.

POWER IN MINING.

The Elementary Principles of Mechanics—Steam—Boilers—Engines—The Machinery Employed in Mines.

75. Does the power of water depend upon the height of the fall and the weight of water?

Yes, Niagara falls is 160 feet high and over twenty million cubic feet of water tumbles over it every minute. Each cubic foot weighs 62·5 pounds. So the work that might be obtained from the Niagara would be over $160 \times 20{,}000{,}000 \times 62{\cdot}5 = 200{,}000{,}000{,}000$ foot lbs. per minute or over 6,000,000 horse-power

76. Can all the work be utilized?

Not all of it. The moment that a piece of machinery is introduced, some work is lost in friction. No water wheel can give more than 85% of the work it receives—and that is only obtained from the best wheel. Common overshot wheels will give 60%, while undershot water wheels give only about 40%.

77. What is this called?

The ratio between the work a machine actually does and what it should do is called the efficiency, or modulus. The better the machine, the higher is its efficiency. For example, the efficiences of the wheels quoted in Q. 76 are 0·85, 0·60 and 0·40 respectively. The modulus of a steam engine is about 0·80; of a very good one, 0·90, and an ordinary one, 0·70.

78. What becomes of the remainder of the power?

It is lost in friction and imperfect machinery. The steam that enters an engine cylinder loses some of its power by condensing or leakage and some power by not escaping freely from the cylinder. Then the friction due to tight packing and the wearing of rubbing parts consumes some power. These causes take from 10 to 30% of the steam power, leaving 90 to 70% with which the engine may perform work. (See p. 153, February, 1892, number of The Colliery Engineer).

79. What causes the loss of so much power in a water wheel as you say in Q. 76?

The losses of power in a water wheel are due to friction on the bearing; the loss from the water which splashes out of the buckets and also that due to the fact that the wheel will not turn as fast as the water naturally would fall.

80. What is the principle of the water wheel?

The overshot receives water in the buckets and in its fall the wheel is turned. The weight of the water in the buckets falling a distance equal to the height of the wheel gives the work of the water. As said, however, the wheel can not turn as rapidly as the free falling water would. So the efficiency of the wheel is not over 60%.

81. If a water wheel is 50 feet diameter, and a flume delivers 6 cubic feet per second to it. What power does the wheel give?

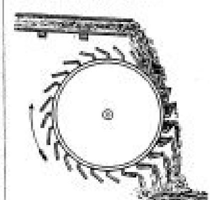

Fig. 15, overshot wheel.

Six cubic feet weigh 375 lbs. and each minute the wheel receives 22,500 lbs. of water, which fall 50 feet. This would give 1,125,000 ft. lbs; but the efficiency of the wheel is 60%, which gives 675,000 ft. lbs., or 20·4 horse-power.

82 If an undershot wheel is 20 feet high and receives 760 cubic feet of water per minute. What would be its power?

The height of an undershot wheel is of no consequence except for the disposition of the buckets on it But we must know the fall of the water or its velocity. If the velocity of the water is 60 feet per second, the practical fall of the water is 56·3 feet, as we shall learn later.

So, $760 \times 62{\cdot}5 \times 56{\cdot}3 \times 0{\cdot}40 = 1{,}069{,}700$ ft. lbs.

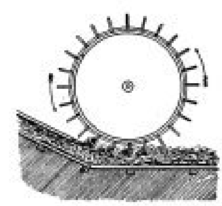

Fig. 16, undershot wheel.

83. How is it with a turbine wheel?

The principle is much the same. A timbered shaft or penstock, is built so that its top is on the level with the ditch or creek supplying the water and its bottom encloses a wheel, as in Fig. 17. The water column presses upon the wheel; its weight and velocity of discharge determine the work of the turbine.

84. A turbine 20 inches in diameter under 10 feet of water gives what power?

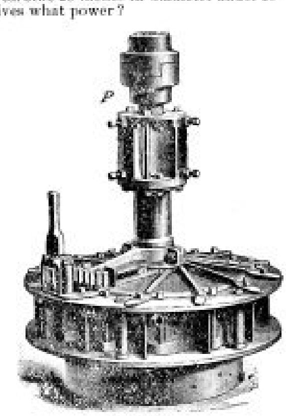

Fig. 17.

If the wheel can turn so fast as to consume 476 cubic feet of water (which weigh 29,750 pounds) per minute and these falling 10 feet give 297,500 ft. lbs., and if the wheel has an efficiency of 87%, then the wheel gives nearly 8 horse power. $476 \times 62\frac{1}{2} \times 10 \times 0{\cdot}70 \div 33{,}000 = 6{\cdot}3$ horse power.

85. Then you simply multiply the weight of the water consumed by the height through which the water falls?

Yes. Each cubic foot of water weighs 62·5 pounds and multiplying the number of cubic feet by 62·5 gives the weight of water. If you have gallons instead of cubic feet, multiply by 8·35 instead of 62·5, for each gallon weighs 8·35 pounds. Then the height of the penstock, in which the water is held above the wheel (as in Q. 83, the height of the overshot wheel) is multiplied by the weight of the water to get the theoretical work; or, to get the amount actually performed, multiply by 70%, or thereabouts.

86. Why do you multiply by the height of the water?

We call that height the "head" and when the water falls through a certain height, no matter if it takes a year to do it, or if the fall is affected in a minute, the work it is capable of doing, is the same that would be required to lift it the given height. The "head" is always the equivalent height of water to that which produces the work. And whether the water is all vertically above the turbine or not, the difference in level between the surface of the water and the point of discharge measures the "head." (See Fig. 18 where T is the turbine, and O T the theoretical head.) Though there may be more water in the pipe N T than in O T, there

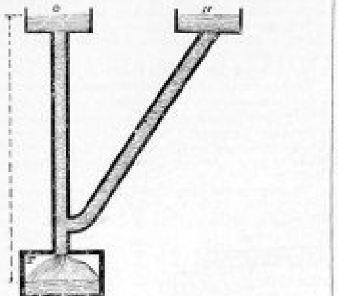

FIG. 18.

will be no more water discharged from one than from the other at T, so that the work is the same in either case Perhaps the student may not appreciate the statement that the inclination has nothing to do with the volume of water discharged (excluding the effect of friction) but let him try the case of a pipe almost horizontal. He would find how slowly the water would flow out of it, whereas, if the pipe were held more nearly vertical the amount would be very great, as the water would pour out very fast; while if the pipes were of different lengths and so placed that their ends were on the same level, the same amount of water would be collected from the pipes—indeed, owing to friction, the longer pipe would discharge less water than the short pipe.

87. What effect has friction upon the flow of water through the pipe?

It reduces the head so that the effective amount of water flowing is less than there would be if there were no friction.

Will you explain?

88. I can not now, but will later show how both the diameter and the length of the pipe affect the flow of the water. An air current flowing through the galleries of a mine behaves in very much the same manner and both these will be discussed together.

[TO BE CONTINUED.]

VENTILATION IN MINES.

Including a Description of the Gases Met With in Mines and the Atmospherical Conditions Necessary to be Known to Understand the Laws of Ventilation.

75. Then you think that the only security is in having a good air current?

Yes, that is all.

76. How will an air current act?

Just as you can mix vinegar and water and whisky together by shaking, so you can sweep a current of air and it will mix the carbonic acid and fire-damp together and carry them out of the mine.

77. How can you reach all the places where these gases are?

By a proper splitting of the air. I would drive it through every place. I would send plenty of air along the gob and goaf and would carry it straight along every face of coal that is exposed; each gang of men or each entry should have its own air, directly from the intake and after having passed along every nook, I would send it out to the return air-way or upcast, where it would meet the returns from all the other entries or panels.

78. How much air is required?

The amount should be enough to dilute the various mine gases to such a degree as not to be dangerous. The laws require from 100 to 200 cubic feet per man per minute. But the allowance should be made not only for the number of miners but also for the extent of the mine. A mine with a large goaf and a long working face should have more air than a small mine which has less chance of being filled with gases. So 200 cubic feet per hour is added for every acre of goaf.

79. What means are there for distributing the air to the working faces?

In some specially difficult mines to ventilate the faces receive air, through a pipe of iron or of wood and from a blowing fan that takes its supply from the main gangway. Other faces are ventilated by a brattice so placed in an entry as to give an ingoing and outgoing current and which is always carried along as fast as the work advances. Check curtains are the quickest means for turning the air to working places.

80. What precautions should we take in using brattice?

The brattice is only good if it is air tight and well nailed, to cut the gangway into two separate air-ways. A working face can only be well aired by continuing the curtains along behind you as fast as you advance. The rooms must have air carried up, into and through them to be safe. That is one reason why Longwall may be better ventilated than bord and pillar.

81. What is the test for bad air?

A test for bad air is not easy to give. Generally speaking bad air is that which has much carbonic acid (see Q. 60) or fire-damp or is hot. If a room receives an amount of fresh air equal to 100 cubic feet per minute per man working therein, it has pretty good ventilation.

82. How can we know whether there is that much entering a room?

Go to a place in the entry feeding the rooms or to a through. Measure off 100 feet or so of its length and also measure its size. If you fire off a little gunpowder at one end and see how long it takes for the smoke to travel the distance you measured off. Then the quantity of air moving in cubic feet per minute is found by dividing the distance measured by the number of seconds it takes to travel that distance, then multiply this result by the area of the road and by 60.

83. Is there not some other method?

Yes. Instead of watching how long it takes smoke to travel, you could hold up an anemometer at arm's length from you and that will tell you how fast the air is moving. Let the wheels turn for exactly one minute. Then multiply the reading by the area of the airway. See Fig. 4.

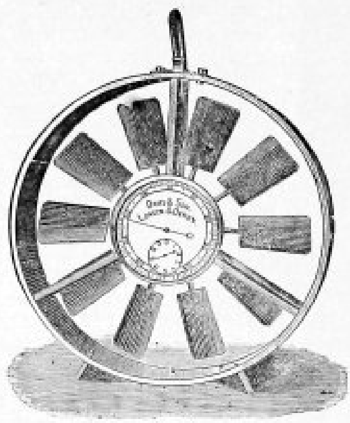

FIG. 4.

84. What is the anemometer?

See p. 163, February number of THE COLLIERY ENGINEER. The anemometer is like a weather vane and when held up in the air-current will revolve nearly as fast as the air-current. Its pointers show how fast it does turn.

85. Could I not measure the air current by the candle?

Yes. Hold the candle out from you, its flame will be bent by the wind, but if you walk as fast as the wind the flame will remain upright. So the speed with which you must travel to keep the flame erect gives you the speed of air-current.

86. Does the ventilation improve as the velocity is greater?

Not necessarily If a large air-way has air moving rapidly through it there may be a very large amount of air and plenty. But the velocity of the air-current may be great while the air-passage is very small. Then the amount of air may be too small for good ventilation.

87. But is not the air better as the current is faster?

To a certain extent, yes. But the air must not be too strong in the entries. It is chilling and uncomfortable It is unsafe in fiery mines and it increases the friction. too fast to be economical.

88. What should be the speed of the air-current?

It may be anything up to, say, 600 feet in the airways while the velocity is often as much as 1000 ft. per minute in the shaft, slopes, or entries connecting mine with surface. Greater than 600 feet per minute would drive the flame against the gauze of the lamp (see p. 285, July, 1891, number of THE COLLIERY ENGINEER), and induce explosion.

89. How does the friction affect the velocity?

You will remember how in Q. 37 we spoke of the drag of the mine as influencing the height of the water-gauge? The greater the friction of the air in passing through a mine, the higher will the water-gauge stand and the greater must be the value for the pressure p (Q. 34) which is necessary to force the air through the mine. As p increases, so must the power u, required of the fan or the furnace in the proportion $u = p\,q$.

See also THE COLLIERY ENGINEER for discussion of this formula under "Power in Mines."

Now the friction increases with the square of the velocity while the power necessary to drive a given volume of air q is proportional to the cube of the velocity. From this, it will been seen that it is cheaper to have the velocity as low as possible provided you get the requisite amount of air.

90. But in reducing the velocity the amount of air is reduced, is it not?

That is so when a certain air-way is considered. But as a given mine requires a stated amount of air, it becomes necessary to so enlarge the air passages that the air will flow readily at a safe velocity.

91. What fixes the amount of air to be delivered to a mine?

The ordinary legal requirement of 100 cubic feet of air every minute for every man employed underground.

92. Does a man breathe as much air as that?

Oh, no. The average miner inhales into his lungs 1,500 cubic inches of air every minute, and he expels from them 52·5 cubic inches of carbonic acid, or about 3½ % of the amount inhaled every minute. This must be diluted with pure air and washed away at once, because it has a poisonous effect upon those breathing it. (See Q. 95).

Then, again, a mine employs one mule for every 10 miners and air must be furnished for the animal which should have 4,000 cubic feet every hour. The explosion of gunpowder produces gases which must be cleared away. And, finally, as the fresh coal face is continually throwing off gas from its pores, an extra allowance of air must be made in proportion to the area of the working and worked-out faces. For each square foot of face, exposed, one-third of a cubic foot per hour is added. Counting up all these allowances it will be found that for each man employed, there will be required at least 100 cubic feet of air per minute. Some States insist upon 300 cubic feet a minute per man.

93. What is the theory of the ventilating current?

To create a current of air large enough in volume to dilute the vairous gases produced in the mine to a very harmless proportion; and sufficiently rapid to remove the gases at once.

94. Is that the only means of giving pure air?

Yes and it is the only preventative of accident by explosion of fire-damp.

[TO BE CONTINUED].

ANALYSES OF COAL, ORES, ETC.

Instructions in Sampling and in Making Analyses to Ascertain the Quality and Value of Coal, Ores, &c., &c.

Assay for Lead is performed in a crucible. When the sample is received it is pulverized and thoroughly mixed. From various parts of the heap ten grammes (one gramme = 15·432 grains) are taken. Pour into a crucible and add material which will help to fuse the ore and reduce the lead. [The simplest flux is a mixture of 1 part of flour and 10 of bicarbonate of soda. This should be made in quantity and kept in stock, as "black flux substitute."] With the ore thoroughly mix 25 grammes of the "b. f. s." Now insert 3 nails, points down, and cover all with salt. Place this in the muffle by means of the scorifier tongs. Then as many more crucibles, usually not more than 9, never more than 12, are charged as there are ores to be assayed, *but never until the muffle has become white hot*. It usually takes about one and a half hours to get up heat enough for fusion. A zinc plate or a fire-clay stopper is put at the mouth of the muffle and the furnace is kept up at high heat for one-half or three-fourths hour, until the bubbling has ceased, and all is quiet in the crucibles.

The mould, Fig. 14, is now placed on the shelf at D and the crucibles removed from the furnace by the right hand, while with the left the cupel tongs are employed to gently pull out the nails. The crucible is then tapped a little and its contents poured out into the mould. The crucibles in turn are taken out, their nails removed, tapped, and poured.

In a short while the contents of the mould will be found to have cooled sufficiently for handling. They will be found to consist of a lead metallic button in the bottom, covered by a slag composed of all the other material in the ore. This button is handled with a pair of pincers, while it is pounded by a hammer into a small cube. The clean button is then weighed and represents the amount of lead in ten grammes of the ore. By simple proportion the percentage is found. If the button weighs 4·1 grammes, then the ore contains 41 per cent. of lead, because

$$10 : 4{\cdot}1 :: 100\,\% : x$$

The precautions are:

Keep up a very hot fire.

Never use moist or wet substances in the furnace.

Be expeditious in removing the crucible as soon as the boiling ceases.

Use the scorifier tongs for the crucibles, and the cupel tongs *only* for nails and for cupels.

Be careful that none of the broken slag enters a fresh wound or cut in the hand.

Unless very great accuracy is desired, one crucible charge is sufficient, otherwise duplicates are put through. To avoid errors in the tests the assayer is advised to systematize his work by numbering each test 1, 2, 3, etc.

In the note-book the tests are described opposite their respective numbers. The weighing of the tests follows the same numerical order. They must be placed in the muffle in the same way, observing always the order shown in Fig. 15. This plan saves confusion and prevents mistakes. When the crucibles are emptied into the mould, the order is again observed, No. 9 being first emptied, but into its corresponding cup with 6 poured in front of it and 8 emptied into the cavity alongside.

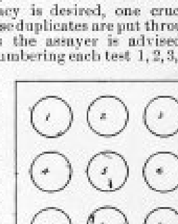

FIG. 15.

Assaying for Silver and Gold. The process described above is the industrial method of recovering lead from its ores on a large scale and includes the mode of saving the silver and the gold, but for many reasons the assayer has not carried out the latter part of the smelters' method in his more delicate, yet not more efficient process. The lead button which is weighed contains most of the precious metals, but not all, so another method called the Scorification or roasting process is employed. Before describing the method it is necessary now to explain a few details of measurements.

A ton of silver or gold contains 29,166⅔ Troy ounces, and all ores are valued by the number of ounces of gold or silver contained in a ton of ore. An ore of eighty ounces silver per ton is very rich. One of 200 ounces is exceptional. It becomes necessary therefore to have some simple weight by which to compare the assay results with the actual weights. Now, an ore of eighty ounces per ton avoirdupois is one which has eighty ounces of silver out of 29,166⅔ ounces of ore; so an ore of 200 ounces has 200 parts out of 29,166⅔ parts of ore.

Suppose we take 29,166⅔ milligrammes (29·166⅔ grammes) of the ore, then it should have 80, or 200, milligrammes of silver in it, according to which ore we are assaying. Then if we make a brass mass, weighing 29·166⅔ grammes we might call it an *assay ton*, [A. T.], letting each milligramme of it represent an ounce of the actual ton of ore, and we might weigh up an A. T. of the ore and find how many milligrammes of silver the fire assay will produce out of it. Then there are as many ounces of silver in the actual ton of ore as there were milligrammes of silver button reduced from an assay ton of the sample.

In general the assay of gold and silver ores are embodied in the following steps:

1—Preparation of the sample.

2—Reduction of the ore and the collection of the precious metals in the lead button.

3—The cupellation of the lead.

4—Weighing the metallic globules after 3.

5—Separation of the silver and gold.

6—Weighing the gold.

The first has already been explained.

The second, in crucibles, has been indicated, but instead of relying solely upon the lead in the ore for the collection of the precious metals, lead is added in conjunction with other chemicals.

The amount of the ore taken depends upon the probable richness of the ore. For gold ores from 1 to 4 A. T. are taken. For silver ores, from ½ to 1 A. T. Whatever the amount, it is placed in the crucible with sufficient litharge to furnish a lead button weighing about 20 grammes. An ore containing much lead may require little litharge for producing a button of the most convenient size. An ore without lead should have litharge charged with it, perhaps as much as 50 grammes. The object of seeking to obtain a final button weighing about 20 grammes is to facilitate cupellation, as will be seen later.

To reduce the ore and melt lead out of the litharge, which is only an oxide, 1 gramme of argol or ¼ gramme of charcoal must be added to the charge for ½ assay ton of the average ore requiring 50 grammes of litharge. Again, to obtain a clean fusion of the earthy matter of the ore, another agent must be introduced. If the earthy matter is silicious, add some borax (fused and pulverized); if it is basic and contains much zinc or spar, instead of quartz, add silica, finely ground. With care and a little observation on the part of the assayer, the required amounts of the various ingredients may soon become known.

To recapitulate, the assayer will weigh out from ½ to 4 A. T. of ore and add about 50 grammes of litharge, a gramme of argol, or ¼ gramme of charcoal, and silica or borax; after mixing thoroughly on a clean sheet of paper, it is poured into a crucible, covered with a layer of salt, and inserted into the muffle. When ebullition has ceased, the contents are poured into its proper cavity of the mould and allowed to cool, after which the lead button is cleaned and hammered into a cube, as before explained, and returned to its proper place in the mould for cupellation. Should the button happen to be of an excessive size, say over ½ inch on the side, there has been too much reduction. The assayer may repeat the test, using less litharge, or less of the reducer, or adding some niter for oxydizing the ore, otherwise, he may place the lead button in a scorifier with a little borax and conduct the operation as will be explained below.

The process of scorification is the more common one for silver and gold ores because it is simpler. The majority of the ores of silver require roasting or oxidation of the sulphur. To accomplish this in a crucible requires niter which has the unhappy faculty of boiling over, destroying not only the analysis, but also injuring the floor of the muffle. The broad exposure of surface of the scorifier permits of oxidation without any such risk, and hence is invariably employed.

The ordinary-sized scorifier will receive a charge of $\frac{1}{10}$ A. T. of ore which having been carefully weighed is mixed with about a thimble full of pure granulated lead. The whole charge is then covered with another thimble full of granulated lead and topped with three or four lumps of *fused* borax about the size of a pea. If great accuracy is required or a large quantity of ore desired for assay, two, or even three scorifiers are used, each charged as above. As mentioned above, should the ore contain much spar, some powdered silica is added. If zinc blende or grey copper be present in the ore, the charge of granulated lead should be increased.

Having prepared as many tests as are to be "put through" in the given "run," the scorifiers are placed in order as previously observed. The muffle should be white hot, in which state it may receive nine charges without seriously reducing the temperature. The muffle is then closed by means of the stopper, S, while the fire is being stirred up. In five or ten minutes it is removed to allow a free, liberal access of air. The contents of the scorifiers, which should now be in fusion, the ore floating on the bath of molten lead. Fumes will be seen to arise, and as long as they continue, the oxidation should be permitted, but the draught should not be excessive. This may be judged by the slow movement of the fumes. When the ore disappears, the fire should be raised somewhat and white lead fumes will begin to escape, a ring of slag will form and gradually encroach upon the lead bath, the exposure of which grows rapidly smaller. If the slag does not appear to be very fluid, a little borax or silica is added by means of the small shovel. If borax has been previously charged, perhaps silica may assist the fusion of the pasty mass, otherwise add a little more borax. In about thirty minutes the lead will have oxidized sufficiently to be completely covered by the enlarging ring of slag, when the operation is complete. As soon as all of the scorifiers are thus "closed," the doors are closed a moment to ensure a perfectly fluid slag. The contents are then poured out in proper places in the mould, Fig. 14, and allowed to cool. In time, the lead buttons are freed from their adhering slag, hammered into a cube and replaced for cupellation. Should any of the lead buttons appear to be covered too quickly, a little granulated lead wrapped in paper is dropped into it by means of the cupel tongs.

The lead button resulting from any of the processes mentioned should be malleable. A little granular button indicates the presence of sulphur, arsenic or antimony. A button larger than twenty grammes must be re-scorified with borax; brittle buttons, also, should be re-treated with lead before attempting to cupel them; those containing copper cannot be cupelled and must needs be again scorified.

SURFACE APPLIANCES.

The Preparation of Coal and Ores for Market

83. Are they of same make?

The machines are not identical with those used for coal because they are intended only for small quantities

First, there comes the separators based upon the second principle mentioned in Q. 21, called hydraulic separators. These are to separate the particles into two classes; First, those which have a given resistance to falling in a body of quiet water, or which fall with equal facility in still water; and second, those which have a greater resistance than the first class. These are fed directly from the fine crushers.

Second, the numerous forms of tables upon which the fine mineral is treated in a thin current of water.

Fig. 8 is the view of a concentrating mill, at which C is the crusher, R the rolls, E the elevator, S, S², etc., the screens feeding to the jigs J¹, J², etc. The tailings from the jigs after crushing go to H¹, H², H³, etc. which in turn feed to certain machines at B¹, B², B³, etc.

84. Describe the separators.

These may be of two classes, according as to whether they are intended for the second or third method Q. 21. Those operating upon the third method are very simple.

Imagine a long trough inclined at a convenient angle. At the head a stream of water and fine ore is received and washes down the plane with a velocity sufficient to carry everything before it. At about 6 feet down the plane, the trough suddenly widens out to twice the width of the first 6 feet. The stream being spread over a greater surface has its carrying capacity reduced. Six feet further on there is another sudden widening of the trough that still further reduces the ability of the water to wash away its suspended contents. If this constituted the entire machine, nothing would be accomplished. But at the end of each 6 feet length there is a pointed V box having its mouth open and the apex at the bottom closed by a valve.

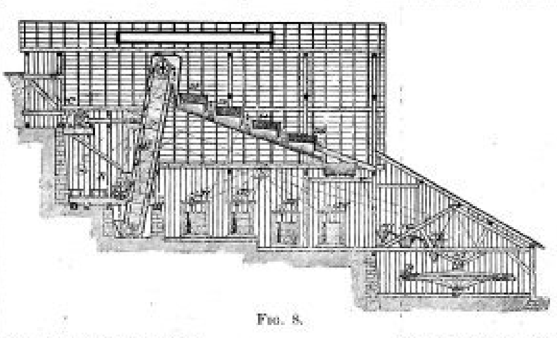

FIG. 8.

The first box is at the point where the second part of the trough suddenly widens. Therefore it is at the point where the carrying capacity of the current is diminished and hence where some of the sandy mineral will be released. So in this first V box is received the material which the current is the least capable of moving—the heaviest mineral is therefore the first collected.

Meanwhile the current of water at a lower velocity continues until it encounters another V box, larger than the first, at another point of change. Here again the stream parts with the next heavier material. After which the finest slime is deposited in the third V box in similar manner.

In each box, the contents differ in weight and size, while the material that fails to settle in the third box is allowed to escape into the creek. Each box is being filled automatically, and no labor or attention is required beyond occasionally watching its progress. Each box is emptied into its bin whence the contents are delivered to the proper machines for concentration. For although the contents are classified according to their weight (that is the particles of heavy and light mineral are of such sizes as to weigh the same) we have merely an agglomeration of small heavy and large light particles.

85. Are not the products of these several classifiers at once salable?

No. Each V box has collected quite a range of particles, as mentioned, extending from the comparatively coarse quartz to the very fine galena, and unless they be further separated we have not accomplished a concentration. Hence the classifier is merely a preparatory stage in the treatment of fine mineral.

86. How large is the material you are now referring to?

What I have called "coarse" is perhaps of the size of a small mustard seed or a grain of sand. The fine particles are those which are about $\frac{1}{150}$ of an inch in size and are called "slimes." The contents of the last V box are even finer than the material mentioned. Some of it will remain in still water, without settling, for several minutes; it is so very light.

87. If each box produces such a variety of unsized material, why could not their contents be delivered to screens and thus be separated in sizes?

That plan might be adopted, for by screening the material from each box separately, that which goes through the finest mesh screen is the heaviest, and is therefore the mineral; that through the next finest screen is still quite rich in heavy mineral; while that which fails to go through the coarsest screen is composed of large particles of quartz and spar. This method, however, is too expensive for practical work on a large scale. So the V box savings are treated on other machines.

88. Are there any means of producing at once a salable concentrate out of the fine material?

We have several forms of machines and more every day being patented. You will readily appreciate the necessity for some efficient machines, when you recall that at least 40 % of the valuable mineral of the ore is present in the tailings of the jigs. In many mills even more than this amount is lost, especially if there is any free silver minerals. For though they are much heavier than water and should sink, they are so flaky in character as to be borne away on the current. It is to save this material that the majority of machines are constructed.

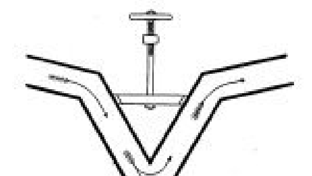

FIG. 9.

89. What variety of machine will with one operation collect the concentrates in salable value?

Conical separators receiving the pulverized tailings will separate the mineral quite effectively. A pair of cones are supported on stands in such manner that the distance between them may be regulated. A hopper or sluice empties the wet slimes and sands into the trough thence into the space between the 2 cones, as shown by the arrow. When they have arrived at the lowest point the coarsest grains separate and sink through the aperture at the bottom whence they are conveyed to the table or finishing concentrator. The finer sands which do not sink when they reach the bottom are carried up with the current as shown (very little of the mineral will fall out of its ascending current). This finer material is delivered to another larger conical separator when the current is not swift. Here the lighter and smaller mineral settles and from it escapes again the lightest of the slimes which are carried to the largest conical separator for final deposition. Each separator produces a very good concentrate which is at once salable, but if it is desired to further improve upon it, the savings are delivered to other machines. The speed of the flowing current is easily regulated, and this form of box gives very great satisfaction. The only way of treating the concentrates of these separators is on tables, to be explained, where a *thin layer* of very diluted slimes effect the washings.

90. What are the forms of slime dressing machines?

They are, in the main, but three varieties.

A bumping table, called, sometimes, Rittinger table.

A revolving inclined table, called, sometimes, buddle.

A moving inclined belt like the Frue Vanner.

91. Do these give salable concentrates?

Yes, each one of these receive the accumulations from one of the V pointed boxes and separates the mineral from the gangue or waste. Sometimes the waste from one of these machines is delivered to one of the other variety of machines.

92. Is there any difference in their behavior with slimes?

Yes, for example, as experience has taught that round sandy particles are better treated on the bumping or revolving tables, while flaky mineral is best saved by the inclined belts, it is evident that such a mixture of material as the V boxes deliver will contain some flaky mineral that the Frue Vanner will save, and some sandy particles that will roll off from it. If these tailings should be delivered to a buddle or a Rittinger, the round mineral can thereon be recovered. If, however, a certain ore for which you are designing a mill should produce only flaky or only sandy slimes, then one should choose, in accordance with the above mentioned principles, a Frue Vanner or a Rittinger.

METHODS IN MINING.

Shaft Sinking—Tunneling—Systems of Working Coal and Metals—Timbering in Mines.

86. Why are return air-ways driven along with each coal gallery?

The return air-way is always carried parallel to and near the haulageway (which is the intake) for a long distance ahead of the mining work to keep in advance of the winning. As the two are connected every few hundred feet, the gallery can be safely driven. Besides it is never safe to try to get along without a return airway. Coal operators would like to, if they could, because this narrow work is expensive but they cannot

FIG. 19.

for two reasons, as will be explained in questions on Ventilation there must be two air-ways if a mine is to be ventilated (and I may say here that metal mines require ventilation just as much as do coal mines) one for incoming air and one for outgoing air. Now one might divide the gallery into two parts by running a partition down its full length and from floor to roof, but that is dangerous. If the partition, leaks or if an explosion breaks it down there is no ventilation at all and the miners must suffer proportionately. Again it is a much more difficult arrangement to connect the working faces with the two parts of the same gallery so that the fresh air can be taken from one while the other receives the bad air. Finally the law, recognizing these risks and difficulties, has passed such regulations as will prevent such parsimonious efforts that invite disaster.

While the gallery is driving a temporary partition is carried by the miner along with the face. Posts reaching from floor to roof have nailed to them heavy tarred canvas cloth (Fig. 19) so that, until the gallery has advanced far enough for another *break* being made *through* the coal to the return air-way, the air current can travel as shown by the arrow. The return air-ways are always driven up hill from the gangway (that is to the rise). In thick coal seams the air way may even be in an upper bench or on top of the haulage-way.

A Simple and Practical Sight Feed Lubricator.

Below is shown Lunkenheimer's "Senior" Sight Feed Lubricator, which is acknowledged by all users to be a very satisfactory and perfect working cup. It is guaranteed by the makers to give entire satisfaction.

THE "SENIOR."

Description: B, oil reservoir; C, upper valve; E, filling plug; F, drain valve; H, union to connect condenser pipe and valve; K, discharge valve; L, valve for regulating flow of oil; N, indicator glass; P, sight-feed glass valve to drain or blow out sight-feed glass P.

Among its many and superior advantages are these: First, it is simple in construction. Second, it has no condensing bulb to freeze and burst. Third, the plugs S facilitate the replacing and cleansing of glasses. Fourth, it has a vent to blow out the sight-feed glass P. Fifth, the shanks on the one third and one-half pint sizes are threaded for $\frac{1}{4}''$ pipe instead of $\frac{1}{2}''$, consequently they are easily attached to small steam pipes. Sixth, every cup is tested and warranted.

These advantages combined with neat design and superior workmanship and finish make the "Senior" the most modern and efficient sight-feed lubricator in the market. It is made in eight sizes from one-half pint to one-gallon inclusive, and can be supplied by any dealer in brass goods. Complete directions are sent with every cup.

The "Senior" is manufactured only by The Lunkenheimer Brass Mfg. Co., of Cincinnati, Ohio, U. S. A., who manufacture a complete line of Superior Steam Specialties, Regrinding valves, Sight-Feed Lubricators, Glass Oil Cups, Grease Cups, etc. It will pay every steam user to send for their new 1892 catalogue.

The United States Mineral Wool Co., of No. 2 Cortlandt St., New York City, have lately added to their line of specialties an improved Sectional Mineral Wool Covering. Having added to their factory improved machinery, they can guarantee satisfaction in the execution of orders for their products.

THE ANTHRACITE COAL SUPPLY AND THE READING LEASES.

Abridged From an Article by A. A. McLeod, Esq., in the July "Forum"

There could—and let me say this at the outset—be no graver misuse of terms than to call the Reading leases an "Anthracite trust." This is the creation of a phrase to attract toward the Reading Railway the unfriendly criticisms which trade combinations called "trusts" have awakened in certain circles. Nothing has been created by these leases. Under the Reading charter, the railway has simply continued its policy of extension and enlargement, which it has systematically pursued in recent years, not only without adverse criticism, but with the hearty and sincere commendation of the public and the press; and I think it cannot be successfully denied that the many additions and extensions acquired by the Reading company under the auspices of the present management prior to those now under consideration, whenever sufficient time has elapsed to warrant a just conclusion concerning them, have resulted in every instance quite as much to the benefit of the communities affected by them as to the advantage of the company. The "Reading leases" mean simply that corporations, each with elements of strength and usefulness to the public which the others did not possess, come into close relations, the one taking what the others gave and each giving what it could with advantage bestow. The result has been a gain all around, not only to those concerned in the Reading management, but to the public, in whose service alone a profit can be found. The Reading has only followed the policy of other corporations, a policy made necessary by the stupendous growth of the country, and distinctly authorized and encouraged by the statutes of every State in the Union, though long neglected by this company from causes which seemed to be beyond the control of its management.

To criticise the Reading system as a commercial monopoly seeking artificial and oppressive gains at the expense of a single article of commerce is either the misrepresentation of ignorance or the libel of a wanton spirit. The Reading has followed the example of others who have developed the agencies of civilization. By precisely such combinations America grows in greatness. We had this example in the consolidation of the New York Central and the Pennsylvania systems. What, in a word, the Reading leases mean is that comparatively small and dependent lines are gathered into one and made strong, useful, and independent.

The Reading system proposes to itself a twofold duty. It will bring the products of its territory—coal among the rest—home to the consumer upon surer and better terms, and to the manifold industries along its various lines the raw material and supplies which enter into their products. It will assure to the thousands of investers in the Reading securities their undoubted right to some return for the money invested. In this will be found a complete explanation of the motives of the management in negotiating the leases. It is a mistake to suppose that there is or has been recently any material or substantial competition between the transportation lines as to the carriage of Anthracite coal; the carrying of the coal from the various mines and from the various regions is mainly determined by the ownership or control of the lands or by the necessities imposed by geographical location. Corporations have been formed acquiring the coal lands. These corporations, acting under existing laws, obtained their properties and hold them by the tenure of law. They are as much the possession of their owners as Government bonds or the homestead deed. The corporations as coal-mine owners are in close relations with the Reading and other companies. As a consequence, the competition about which so much is written is between individuals and corporations producing and selling coal, and not between the transportation companies carrying the coal to the market. This condition is in no wise altered by the Reading leases. The same mines are tributary to the same railroads as before; each line serves the same markets, and neither line gains nor loses a ton of Anthracite traffic as a consequence of our transportation arrangements.

In considering the Anthracite coal question we must remember that the supply is exhaustable. We are taking from a fixed quantity, the accretion of ages, which, when used, can never be recreated by any agency known to man.

If squandered as other resources quite as valuable have been, we come to the real oppression of prices, for the cost would advance as the supply grew less, until coal became an article of luxury. Economy in production must be observed by improved methods; and in the unification and strengthening of industrial processes we have a more prudent, practical, and economical system of mining, enhancing the security of the investors in coal properties, promoting the comfort and assuring the more regular employment of the laborer, and all ultimately inuring to the benefit of the consumer of coal, if not in the lowering of prices when they are already too low, considering the cost of production, at least in the way of continuing the supply at moderate prices.

The allegation that the prices of coal have been advanced to extortionate rates under the recent arrangements is the burden of many articles of the press. I read of "the untold millions" which are to be taken out of the meagre earnings of the poor as a consequence of the alliances and the proposed economies in the coal business. There can be no better reply than to study prices during the past four years. Here are the commercial circulars giving prices in May, 1892, at the tidewater points of Weehawken, Hoboken, and Perth Amboy. Grate coal is quoted at \$3.75 a ton. This is 30 cents higher than in 1888, 25 cents higher than in 1890 and 1891, and the same as it was in 1889. These figures show how little in four years prices have varied from the average. In egg coal the circulars quote the May rate as \$3.90. This was the quotation in 1889 while in 1888 it was \$4.00, showing a fall in four years of 10 cents a ton. Stove coal quoted at \$4.15 was the same price in 1889 and \$4.25 in 1888; in that also a decline from 1888 of 10 cents a ton. Chestnut coal is quoted at \$3.90, as against \$4 in 1889 and \$4.25 in 1888, a decline of 35 cents a ton. Compare the May quotations of grate, egg, stove, and chestnut coal in 1892 with the May quotations of 1888, and we see that in grate alone has been an advance. There has been a fall of 10 cents a ton in egg and stove and of 35 cents a ton in chestnut.

These latest reports are cited to show that there has been no advance over that which ruled five years ago. As a matter of fact, they show that coal in its various forms has kept an even pace, in some years a trifle more and in others a trifle less, the average about the same, subject to fluctuations of trade and those mutations in the supply and demand from which no business, commercial, financial, or railway, is free. While it is true that the Anthracite coal traffic is an element of great importance, it must be remembered that it is only an incident in the problems of the Reading road. The company has other interests than Anthracite coal. If its policy contemplates a permanent system, the becoming a part of the structure of our national welfare, it must accept the fact that Anthracite coal is a temporary and diminishing value, that it will last our time and, perhaps two or three generations more, but that other agencies must be cultivated for the fulfillment of its work. A large proportion of its tonnage is Anthracite coal and will be for a long time. It is by no means the major part, and the proportion in the general volume of its business will lessen from year to year. The Reading Railway will carry coal as it carries wheat and sugar and oil, but it is not upon the coal traffic that the future of the system depends.

There are many discussions as to the mistakes made in the capitalization of the various companies in the Reading system, the wisdom of purchases of what might be called dormant properties in past years and the financial burdens involved in the necessity of holding them for development. These discussions do not apply to the present Reading management. It is in the presence of conditions which it did not create and which it is striving to strengthen and amend by every agency known to a prudent business direction of affairs. The Reading management is charged so to govern its properties that obligations shall be met and the rights of investors assured. This, as experience shows, cannot be done by abandoning one interest to suit the whim of another. It can only be continued with due regard to the rights of all. In the management of the coal supply it is done first by terminating the squandering methods under which such a large percentage of mining has been sheer waste. It will be done by the prevention of spasmodic production and the ignoring of the laws of supply and demand, which in coal, as in everything else, is sure to bring improvidence. This will prevent the inadequacy of prices, and, while maintaining the investors' rights, assure steady and well paid work.

Over-production has ever been the bane of all industry. The recurring periods of ruin and depression which have swept over the country have been invariably accompanied by the continued production of some important article of commerce beyond the requirements of the market, whether of cotton and corn, the products of the soil, or of the iron and copper and silver from our mines. The same inexorable law applies to Anthracite coal. Nature has imposed peculiar and unusual limitations upon the production and consumption of Anthracite. These limitations govern and control both supply and demand, and must be recognized, either willingly or unwillingly, by all concerned. For a brief season in each year the requirements of the markets of the country absorb for consumption upwards of four millions of tons per month for a few months, or at the aggregate rate of about fifty millions of tons per annum; whereas the aggregate consumption scarcely exceeds the rate of forty millions of tons per year. To supply the extraordinary demands of the fall season the great producing companies have developed a capacity for production equal to the supply required at times of the greatest activity; but it is obvious that if the production should be continued, regardless of the demand, at the rate of the full capacity of all the mines, it would not be long before all the evils of disastrous over-production which I have pointed out would be upon us.

The enormous development of the mining capacity of the Anthracite regions and the millions of capital invested in the mines to enable them to produce coal at the highest rate required by the market forbid that they should lie idle for a moment at any time when the product can be sold at a moderate profit. The interest account accumulates too rapidly upon these enormous investments to allow the producers to wait, even if they were so inclined, for an unnatural market stimulated by a short supply. There always has been and must continue to be a supply of mined coal in excess of the immediate demand, except perhaps occasionally for very short periods of particular sizes. I have not alluded to the competition of Bituminous coal, which is present everywhere, but, if there were no other reasons, its presence in every market operates as a prohibition upon any unreasonable advance in the price of Anthracite coal, even if the power and disposition to make such an advance existed, which is impossible under any condition of things.

Upon one other point I think a word may be profitably added. In the development and augmentation of local industries along its lines lies the path of prosperity for the future railway system. The concentration of the industries of the country in and about the large centers of population has been largely brought about by the establishment of inadequate rates for transportation at competitive points and the maintenance of proportionately high rates at local interior points which became necessary to preserve a sufficient average revenue to support the transportation system of the country. The time has now arrived when the material reduction of what are called through competitive rates has reached its limit, and the competition of the future will be, not the competition of the railroads among themselves for the same traffic, but the competition of the communities along the several lines of railroad with other communities along other lines for the markets of the country; and that community which, not served by lines of railroad reaching all parts of the country, at rates commensurate with those enjoyed by other communities on other lines, must fall behind in the race for progress, and the railroad which serves it must follow in their wake. Perceiving its duty to the communities upon whose prosperity its own depends, the management of the Reading Railway has sought to equip it with all the means for entering upon the broader field of competition which the future is sure to open; and in doing so it has not overlooked the necessity of acquiring access to all the sources of supply which enter into the industries along its lines and to the markets to which their products must be carried.

Finally, to rescue the Reading management from complications which we have accepted but not created; to give the Reading system its standing among the natural necessary transportation systems of the Middle States; to make the road an element of strength to every national and local interest, industrial as well as financial, is the underlying thought of those who consummated the Reading leases. Experience thus far confirms the wisdom and equity of that transaction; and when it is understood in all its relations and ramifications and seen likewise in the light of experience, there is no apprehension as to the reasonable and discerning judgment of the country.

A Month's Record.

Business generally is considered quiet and many complaints are made by machinery men. However, as a notable exception to this, we find that the Lidgerwood Manufacturing Co., of New York, makers of Hoisting Engines and Cableways, have broken all previous sales records during the month of May, just passed, having shipped 127 engines and 45 boilers; an average of five engines per day. This speaks volumes for the character of the hoisting machinery as manufactured by this well known company.

MECHANICAL NOTES

Tool Sharpening by Acids.

It has long been known that instruments and tools, such as knives, shears, scythes, and files which have become blunt by use may again have a keen edge imparted to them by means of acids, as well as by the common methods of sharpening and whetting. But so far the less usual process does not appear to have met with the favor which its merits deserve. All dilute mineral acids are adapted for tool sharpening: for example, 10 parts of sulphuric acid hydrate to 100 parts of water. The desired end is more quickly attained if a portion of the sulphuric acid be replaced by nitric acid. A suitable mixture is: 1 litre of water, 50 grammes of Chili saltpetre, and 60 cubic centimetres of concentrated sulphuric acid. This compound dissolves 1½ grammes of metal within ten minutes from an iron surface of one square centimetre; dissolution is slower where sulphuric acid alone is used. Steel is acted upon in the same manner as iron, with the exception that the process is not so rapid because of the polished surface becoming covered with a thin deposit of separated carbon. It has been sought to strengthen the action of the acids, or, in other words, to shorten their period of action, by attracting the electric resistance of the iron with gas-retort coal or with other metals; but up to the present no substantial advantage has accrued from this method. In order to secure as uniform an acid action as possible, preliminary cleaning of the metallic surfaces, preferably with a soda solution, is recommended.—*The Age of Steel.*

Use Good Graphite.

A correspondent in the *American Machinist* says: If engineers, machinists, and millwrights in general, and pipe-fitters in particular, knew of the good qualities of graphite, I dare say there would be ten times the demand for it. Its lubricating qualities are questioned only by the impractical and it is this quality alone that sounds its key note, so to speak. Let me describe a few of what I consider its most important uses. As above stated its primary object is lubrication and it is to this fact we must credit good pipe joints and cool bearings. In making pipe cement (or as I would term it, pipe smear), it is not necessary to use the best oil or grease, as it is the graphite and not the body in which it is suspended, that makes the mixture valuable and the joint perfect. I use the drippings from line shaft bearings, caught in the ordinary way and mix it with the best Ticonderoga flake graphite so that it can be applied with an ordinary sash tool.

During the past three years I have used about fifteen or twenty pounds of dry Ticonderoga flake graphite for pipe joints, cylinder heads, piston rod packing, etc.

Bolts, smeared with graphite mixed as above, I have unscrewed after having been in the dampest places for upward of two years, or more, proving the antirusting qualities of graphite. To cool hot bearings put in on as thick as it will mix with oil.

Almost any oil or grease will answer, but don't use poor graphite.

Magnetic Iron Rust.

The London *Journal* notes that at the recent meeting at Hobart, Tasmania, of the Australasian Association for the Advancement of Science, Professor Liversidge, F. R. S., of the University of Sidney, read a suggestive paper on the rusting of iron. The author remarked that in books upon chemistry it is usually stated that iron rust is composed of the hydrated sesquioxide of iron; but on examining a very large number of specimens of rust from many different places, and from iron articles of various kinds, and formed under very varied conditions, Professor Liversidge has found that in almost every instance the rust contained more or less magnetic oxide. Indeed, in some cases the rust, although presenting the usual rust-brown color and appearance, was, when powdered, practically altogether attracted by the magnet. The specimens of rust which first drew the author's attention to this subject were large rust scales obtained from some old tramway metals, which he was led to collect and examine on account of their resemblance to the crust so often present upon metallic meteorites. On crushing these scales in a porcelain mortar, and testing the dust with a magnet, it was found to be wholly susceptible to magnetism, owing to the small quantity of magnetic oxide present being mechanically inclosed in the rust particles. The production of this magnetic oxide does not seem to have been due to the presence of mill scale, because, when bright iron wire, plates, rods, nails, etc., were artificially rusted in many ways with free access of oxygen, in almost every instance a large amount of magnetic oxide was formed. These observations have some practical bearing upon the problem of the preservation of wrought iron structures from rust

Training the Eye.

A good mechanic must have a good eye, must be able to detect inaccuracies and imperfections at a glance. This is one of the important characteristics to be acquired, and must be a part of the education which makes a good mechanic. The following from one of our exchanges is so pertinent to the subject that it is worthy of a repetition, and is recommended, especially to the young mechanic, who should make it useful to himself and a part of his study:

A good authority said some time ago: "Every man who is engaged in any kind of mechanical labor should cultivate studious and observant habits. There is scarcely any description of knowledge but which he will at some time have use for, especially if he ever hopes to rise above the position of ordinary mechanical labor. No man can ever hope to attain distinction as a mechanic unless he educates his mind as well as his hands."

One of the most important requirements of a mechanic is that he should be able to readily and lucidly convey ideas to another. There are many men who, while otherwise competent to direct others, have failed from lack of this faculty, or have refused good positions because they knew their weakness in this respect. Perhaps as many foremen fail from this cause as from any other. Undoubtedly, this faculty is one to be acquired; it is not one, if there are such, that is born with a man. Every man who works at a mechanical business should labor in the direction of acquiring the habit of concisely expressing his ideas, making this a part of his mechanical education. Talking of such subjects will help a man; writing of them is excellent practice.

A good mechanical eye is also an almost essential requisite in a good mechanic. No one can ever attain distinction as a mechanic unless he is able to detect ordinary imperfections at sight, so that he can see if things are out of plumb, out of level, out of square, and out of proper shape, and unless he can also detect disproportioned or ill-shaped patterns. This is a great mechanical attainment, and one which can be readily attained by an ordinary person. Of course there are defective eyes as there are other defective organs; the speech, for instance, is sometimes defective, but the eye is susceptible of the same training as any other organ. The muscles, the voice, the sense of hearing, all require training. Consider how the artist must train the organ of sight in order to detect the slightest imperfection in shade, color, proportion, shape, expression, etc. Not one blacksmith in five ever attains the art of hammering square, yet it is very essential in his occupation. It is simply because he allows himself to get into careless habits; a little training and care is all that is necessary for success.

But in these cases the fact is that the eye is not half as much at fault as the heedless mind. Some carpenters acquire the careless habit of trying the tri-square every time they plane off a shaving, in place of giving their minds right to their business and properly training their eyes, and unless they cultivate this power of the eye they will always be at journey work.

Look at the well-trained blacksmith; he goes across the shop, picks up the horse's foot, takes a squint, returns to his anvil, forges the shoe, and it exactly fits the foot. Contrast him with the bungler who looks at the shoe, then fits the foot to it, often to the ruin of a fine horse. Now, the fault lies in ever allowing himself to put a shoe on that is not in proper shape for the foot; he should determine to make the shoe fit the foot in place of the foot fitting the shoe, and he should follow it up until the object is accomplished.

A very good way to discipline the mechanical eye is to first measure an inch with the eye, then prove it with the rule, then measure a half-inch, then an eighth, and so on, and you will soon be able to discover at a glance the difference between a twelfth and a sixteenth of an inch; then go to 3 in., 6, 12, and so on. Some call this guessing; there is no guesswork about it. It is measuring with the eye and mind. Acquire the habit of criticising for imperfections every piece of work that you see; do everything as nearly as you can without measuring (or spoiling it), or as nearly as you can trust the eye at the present training. If you cannot see things mechanically, do not blame the eye for it; it is no more to blame than the mouth is because we cannot read, or the finger because we cannot write. A person may write a very good hand with his eyes closed, the mind, of course, directing the fingers The eye is necessary, however, to detect imperfections. Every occupation in life requires a mechanically-trained eye, and we should realize more than we do the great importance of properly training that organ.—*Metal and Iron Journal.*

HOW TO LIVE

Exercise Better Than Medicine.

Much of the food actually digested and assimilated is not used to the fullest extent for want of sufficient oxidation to make it yield the greatest amount of vitalizing power to the tissues of the body. Such partially unoxidized products have an irritating effect on the organs and tissues, and predisposes them to disease if they do not directly affect them with it.

Exercise has a stimulating effect on all parts of the body by inducing further oxidation in all the tissues and organs. This increased oxidation is attended by a greater demand on the part of the system for oxygen—as indicated by the greater number, force, and frequency of the respirations.

During exercise the heart beats faster, and forces more blood through the lungs to all parts of the body, bearing in its little blood cells the precious life-giving factor, oxygen. These little cells—one constituent of which, hæmoglobin, has the wonderful facility of quickly loading and unloading itself with oxygen—thus act as direct aids to the process of oxidation in the tissues and organs.

It is the combining of oxygen with unoxidized products in the blood that gives to each individual cell its possibility of sustaining life. Any process which increases the oxygen supplied to all parts of the body tends to strengthen the life in each individual cell, and to give it more power to resist disease.

Exercise of all factors does this most effectively; and besides actually producing in each individual cell a greater vitality, it gives a favorable opportunity for the waste products of the tissues to be thrown off rapidly. By thus causing a further oxidizing of certain matters in the blood, it conduces in a double sense to life and health.

Habitual out-door exercise, with suitable protection from extremes of weather, is the most effective means of prolonging life to old age.—*Youth's Companion.*

The Aroma of Coffee.

The aroma of coffee develops especially during the process of roasting; its fatty oil oxidizes, is burned, and is changed into essential oil, or caffeine, a species of ether that can be isolated by distillation, and which we can sometimes see with the naked eye on the surface of the ordinary infusion. But coffee, like many other natural products, such as wine, tobacco, and cacao, requires a certain length of time after being gathered before it reaches its full maturity. Experience has shown that the development of its aromatic principle is acquired by keeping it in a green state from one crop to another. But it well known that for about the last half century the caffeine seems to be lacking in the infusion of coffee, which has no longer the exquisite qualities due to its aroma.

If now, on the one hand, we consider that the production of coffee is necessarily limited by the conditions of climate requisite for its growth, and that, on the other hand, the planter, in order to supply the demand which is constantly on the increase, is now obliged to deliver the crop as soon as it is gathered, we can do nothing but infer that the cause of the degeneration of coffee lies in the fact that it is supplied to trade too soon, while it has not yet developed its constituent principles, and particularly its caffeine.

The inference from this is evident. If we wish that our coffee should regain the quality through which formerly it was considered such an exquisite beverage, we shall have to go back to the traditional process of only supplying it to trade when the caffeine has acquired its full development, which can only be given to it by time, and by being kept in a green condition from one crop to the next.

We must not, however, expect that dealers are going to follow this rule, but, at any rate, consumers can do it for themselves, by only roasting and using coffee which they have kept in a green condition for at least a year.

Bicycle Riding.

Among the main reasons which bicycle riders give for their choice of locomotion are the following:

Bicycling, is a popular, clean, healthful sport, and a wheel is good company.

The wheel is a time-saving machine, and in this busy age time is money.

Exercise on the wheel is better than walking, because the weight of the body is principally supported by the saddle. Strength is economized, and the exertion of force distributed more generally throughout the muscles of the legs, arms, and body, and equal results in progress reached by far less exertion, or proportionately greater results by the same exertion. In other words, the wheelman rides ten miles in an hour with less fatigue than he would walk four in the same time, because in walking almost all the muscular exertion is thrown on the legs.

Few people breathe properly. They use only the upper portion of the lungs, and leave a large residuum of impure air. Bicycle riding causes thorough respiration, and tones up the general circulation. It is particularly beneficial to men and women of sedentary habits, and gives them such exhilarating pleasure that they do not feel the labor involved.—*New York Ledger.*

Nutritive Value of Various Foods.

In the committee which organized the Workingman's Congress d'Hygiene that has just been held in Paris, was conceived the idea of having the seances of this congress preceded by a series of preparatory lectures destined to enlighten the members on the present condition of science as regards the hygiene of food, dwellings, and workshops.

One evening, M. Dujardin-Beaumetz, of the Academie de Medecine, treated the general question of food, one of the most important in the entire branch of hygiene, and at the same time one of the most difficult to solve. There is no one who is not concerned in this subject, which forms one of the leading preoccupations of all rulers and economists.

The taking of food is done with a view to restoring the losses undergone by an organism in the course of the continual destruction of the constituent elements of our tissues and to keep up to the heat of our bodies. My readers are undoubtedly aware of the fact that our frame is constantly consuming a portion of itself, that each day it loses a certain quantity of nitrogen, carbon, water, and salts. It is, of course, necessary that the food we take should be sufficient in quantity and quality to make good these losses, otherwise we must of necessity grow weak, dwindle away, and die.

COMPOSITION OF FOOD.

This amount of nitrogen and carbon has been accurately estimated: in twenty-four hours a man consumes 20 grammes of nitrogen, 310 grammes of carbon, and gives off by the breath and by the different secreting organs two or three litres of water and about 30 grammes of salts. Our food, therefore, must be of such a nature as to allow the organism to repair its losses, a food-stuff being a substance of many different origins, which when introduced into the living body may be used for nutrition.

The inorganic kingdom supplies us, either directly or through the intermediary of the animals and plants with which we nourish ourselves, with water, chloride of sodium, which is found in the blood and muscles, salts of lime and particularly the phosphate and carbonate which constitute more than half of the framework of the body, and salts of sodium, potassium, magnesium, and iron, which are useful in different degrees for tissue formation.

The vegetable kingdom gives to man substances composed of oxygen, carbon, and hydrogen, ternary substances, which are starch, sugar, and fat, and, in addition, compound materials made up of the three foregoing elements, to which a fourth—nitrogen—is added, such as gluten, which we find in many seeds, but particularly in cereals and the soft portion of plants.

The food which we derive from the animal kingdom consists of a variety of forms of albuminoid or nitrogenous substances, such as albumen, fibrine, caseine, as well as non-nitrogenous substances, such as fat and sugar of milk.

A complete form of food, such as milk or eggs, contains all the elements necessary for our body.

RELATIVE VALUE.

Ternary forms of food, such as fat, which keep up the combustion that takes place in the depth of our tissues, sometimes go by the name of respiratory forms of food; whereas the nitrogenous or quarternary substances are often called plastic food elements, as they are specially destined to replace lost tissue. The importance of the latter is shown by the fact that the nitrogenous substances predominate in the blood and muscles.

Our food contains greater or less quantities of oxygen, hydrogen, carbon, and nitrogen, and those substances which contain them all in the exact proportion necessary for the restoration of organic tissues are, as I have already said, complete forms of food. At the head of this class we must place milk and eggs, and meat is the most nutritive element after them; it contains the most nitrogenous substance, and its composition is about the same, no matter from what species it is taken. Fish is very similar to many forms of meats, and its nutritive value is very nearly identical. Just as is the case with meat, fish with fatty flesh is the most nourishing variety.

Dried vegetables, such as peas and beans, contain more nitrogenous matter than cereals, and even than the flesh of animals; but as regards their nutritive value, it should not be thought that it is a matter of indifference to use either one or two forms of food which contain about the same amount of nitrogen and carbon. Thus, although 100 grammes of beans contain more nitrogen and carbon than a similar amount of meat, still they could not replace 100 grammes of this substance. That they are chemically equivalent is not sufficient, as the one is not so easily assimilated as the other.

CEREALS AND VEGETABLES.

The cereals supply us with flour, which is used every day in making bread. This form of food has a high nutritive value. The finer kinds of bread contain more nitrogen, but less saline matter, which is found in larger quantities in common bread, of which the flour has been less carefully bolted.

Certain vegetables, such as peas, beans, and lentils, contain a very high proportion of nitrogen and starch, and are so nourishing on this account that they have been called the poor man's meat. Potatoes, rich in starch, but lacking in nitrogen, are not so nutritive, but go very well combined with meat. Cheese, which is very rich in nitrogen has a highly alimentary value.

I shall not carry this study of detail any further, but there is one point to which I should like to draw attention—namely, the necessity of seeking the elements of nutrition in both of the kingdoms, both animal and vegetable, man being an omnivorous creature. To obtain 310 grammes of carbon it would be necessary to absorb 1,183 grammes of meat, which, in addition to the cost, would require the organism to do such an amount of work that it might suffer in consequence. In the same way a purely vegetable diet would require us to absorb such an enormous weight of food that our digestive tube would not be able to stand it, as the intestines of men have neither the form nor dimensions of those of animals.

ALIMENTARY RATIONS.

The exact knowledge of the losses incurred by an organism lead us to an estimate of the amount of alimentary substances necessary for the support of each individual. It is necessary to replace regularly the daily loss, but, in addition to this, when a person works—that is, to say, produces heat and movements, and, in consequence, consumes his tissues—it is necessary, in order that the equilibrium indispensable to health and even to existence may be upheld, that the organism should receive an amount of alimentary substances proportional to the expenditure due to the labor. In other words, we have to distinguish between the amount sufficient for every day needs and the amount required by a working organism.

The alimentary regimen must be modified in its quantity according to whether a person works a little or a great deal, and in its quality according to climates. The inhabitant of warm climates eats little meat, but relies chiefly on vegetables and sweet and slightly acid fruit; he should be very careful about the effect of alcoholic drinks. On the other hand, the inhabitant of cold climates prefers nitrogenous food and fats. The tonic action of the cold gives greater activity in the digestive functions, and enables the organism to accumulate the materials necessary for the production of heat, which places the body in the position to resist the action of any low degree of temperature.—*New York Herald.*

USEFUL INFORMATION

Disciplining the Mind.

If for a moment we could lay aside the thought of the established routine which we have become accustomed to calling education we should, I think, easily see that facts about things which we do not come in contact with are not helpful; while they usurp the place of those things which are needed for every-day life. Do you say they discipline the mind and strengthen the memory? This is the reason given for many of the arbitrary rules and studies in the schools, but this is assuming that what is uninteresting and dry is better for development and as a preparation for life than are those things which are gratifying and agreeable. The body can only be fully nourished by eating such food as is pleasant to the taste. The nerves of sensation must be pleasantly excited to secure perfect digestion and assimilation, and it is a serious mistake in our ideas of education that we fail to recognize this beautiful law in intellectual processes.

There is a deal of nonsense about discipline of the mind, of the will, and of the body. Life is, or ought to be, for all normal human beings a continual discipline of brain, body, and will, and the means for this discipline are furnished in the needs and processes of life. Our failures come from not recognizing these processes, or from being out of place. In either case we are out of harmony with the "inflowing universe," and so fail to get our discipline in God's own way. Then we formulate our arbitrary methods to supply the place of the natural order, very much in the same way as artificial limbs, teeth, and other organs are supplied by science when the natural ones have failed us from carelessness, accident, or disease.

This false and exaggerated idea of our responsibility in furnishing discipline first grew out of the belief that the human being is all wrong till we set him right, and though total depravity is practically a thing of the past, yet the opposite theory—that the child is right till we lead him wrong by our false estimates of values— has failed to find its way very generally into old avenues of thought. Still less have we learned to follow and obey nature, and thereby transform our educational system from arbitrary and unattractive methods to those which meet glad acceptance—glad, because the brain in its natural condition enjoys its supply of knowledge as the body enjoys its food. The flowers bloom and fruits ripen when we make the conditions right for them, and then let them alone to revel in the operations of unerring and beneficent law.—*From Harper's Bazar.*

Mob Law is Lawlessness.

There are many excuses for lynching, but no justification. The crime of the victim may be horrible in the extreme, the process of the law's administration may be exasperatingly tedious, but wherever law exists, by law should all abide.

The men who usurp its sacred functions by taking punishment into their own hands are doing the same thing in a lesser degree for which they inflict the awful penalty of death. The negro who was recently burned at the stake in this country broke a sacred law, but so did the men who burned him. For all good laws are sacred, and, to be kept so, must be executed by their proper authorities.

Another point deserves mention:

Every lynching makes more murderers. This is an absolute fact of observation, however accounted for, and it has always been so.

In past ages men were crucified, boiled in oil, and consigned by the theology in which they all devoutly believed to eternal torment in a literal hell.

But none of these things prevented them from committing the most horrible crimes. Only as far back as the eighteenth century men were hung by the hundred every year in England for trifling offenses; and despite the gallows, black deeds were never more rampant. Jack Shepard and Dick Turpin were the admired captains of a great multitude, who murdered with a red hand and died glorying in their shame.

The truth is, *no punishment, in and of itself, can make a lawbreaker a good citizen.* And least of all can that punishment do so which is itself a breaking of law.

Nor can its terrors withhold scamps from lawlessness nearly so much as some people imagine.

The brave man and the good citizen respect the majesty of government. The coward and the ignorant, brutalized criminal, lack that education of the mind which induces such respect, and so they exalt the criminal spirit. "*Outwit* the law, and it can not reach me," says the lynched one. "*Leave alone* the law; it is not speedy enough for our hatred," says the lyncher. And between the two, law is left—entirely out of the tragedy, which then goes on to repeat itself in increasing ratio. Educate men to abide by law, and control their passions, and both lynched and lyncher will soon be a thing of the past.—*New York Ledger.*

The Care of One's Clothes.

One's apparel will last much longer, and also much replenishing be saved, if everything is well taken care of. Nothing pays better than this watchfulness, which only takes a little extra time and patience. Always, if possible, look over every article of wearing apparel each time it is taken off. Shake dresses, brush them thoroughly and carefully; hang them away in the closet, and be sure that the loops are placed in the right places; a dress should never be hung up without loops. Many prefer to fold handsome dresses, wrap them in an old sheet and lay them in a drawer. I hang all of mine up in closets, always keeping a sheet pinned across evening or light dresses. Never throw dresses over a chair, or hang other articles over them in the closet, as it makes them badly wrinkled and injures them badly. Cloaks and wraps, after being well brushed, should be hung up by a loop at the back of the neck, or they may be carefully laid in a drawer. Fold shawls in their original creases, and either lay them in a drawer or on the shelf, but never hang them up. Hats and bonnets should also have as good care putting them in boxes; or if laid on the shelf they should be wrapped in a piece of white cloth to keep them from the dust. When taking bonnets off, straighten and smooth the ribbons and flowers before laying away. One large drawer in the dresser should be kept and especially dedicated to one's ribbons, laces, handkerchiefs, gloves, etc., also having separate boxes in the drawer for articles of a kind—laces by themselves, ribbons, etc. Always, when taking off gloves, pull them out lengthwise, smooth them and lay carefully in a box set apart for them; never roll them up together and toss them aside like a bit of rubbish; and, if possible, do not fold them over in the center. Laces should be well looked after, and kept fresh, neat, and smoothly folded. Do not allow any of these smaller articles of the toilet to be thrown altogether in a drawer in a mass of confusion; it will take the freshness and neatness from them.

Shoes should never be thrown about, left to lie on the floor under the bed, to collect the dust, which surely injures them; smooth them out, brush them, and if no buttons are off, no rips found, place them in the shoe bag or box. Never allow a button to stay off a shoe, as it shows great negligence, besides hurting the appearance of the shoe.

Always have a brush broom, a bonnet brush, a sponge and pieces of soft flannel, bottles containing ammonia, benzine and alcohol, and some cleansing fluid, to aid in removing spots of dust and dirt, stains, etc., from the clothing. Keep every article carefully mended, as by that means it can be made to last much longer. Verily, a stitch in time does save more than nine. And by all means never wear a stocking with even a very small hole in it, but change it as quickly as possible and darn it very neatly; so with all articles of wearing apparel.—*Good Housekeeping.*

Scientific Advancement

Photographing in Colors.

A little more than a year ago we reported, in some detail, the experiments in photography of colors that had been made by Mr. Lippmann, in Paris, and their results. The process employed by him, it will be remembered, consisted in placing a reflecting surface behind the sensitized plate, so that the rays of light, after penetrating the film, would be turned back through it again. Thus Mr. Lippmann succeeded in producing several negatives in which the colors of a stained glass window were pretty faithfully introduced. The chief difficulty with which he had to contend was the character of the sensitive film, which was too course in quality and too slow in action. His operations since that time have been largely directed toward an improvement of the film, and the success attained by him is now made known in the last number of the "Comptes Rendus."

By the use of albumen-bromide of silver films, made orthochromatic with azalin and cyanin, Mr. Lippman has obtained very brilliant photographs of the solar spectrum. All the colors, secondary as well as primary, even including the red, appear in all their natural vividness, and that without the use of any color-screen. The exposures of these plates varied from five to thirty seconds. On the same theory he also proceeded to photograph various objects of blended and complex colors, such as a stained glass window, some draperies, a plate of oranges surmounted by a red poppy, and a many-hued parrot. The draperies and the parrot required exposures of the plate of from five to ten minutes, in sunlight, and the window and the oranges of several hours in a comparatively dim light; but the results obtained were altogether satisfactory. On other negatives he accurately fixed the blue of the sky, the green of foliage, and the pale grey of a stone wall.

Mr. Lippmann is confident, therefore, that this interesting problem is practically solved. It remains only to intensify the orthochromatic quality of the film, and to increase its sensitiveness to light. How much the sensitiveness must be increased may be judged by any one who is accustomed to practical photography. A plate that receives a vivid impression on exposure to white light for a fraction of a second may be exposed for some time to a red light without being affected in the least. But in color photography it must respond instantaneously to the red rays, and the yellow, as well as to the white and the blue. In handling such plates, the "dark room" will have to be really dark, and not, as at present, illuminated by the radiation of a ruby lantern.

It seems to us entirely within the bounds of reason to expect that perfect and practicable orthochromatic photography will presently be attained; perhaps on the lines indicated by Mr. Lippmann, perhaps by some other method. Such an achievement requires no greater advance upon the photography of to-day than the instantaneous dry-plate system of to-day marks upon the slow wet-plates of a few years ago.—*New York Tribune.*

Notes of Recent Inventions.

The man who observed that he would not go abroad until he could cross the ocean in a car may not have to wait so very long after all for the realization of his hopes. There comes from Sweden news of the construction at Christianstad of what is called a locomotive steamboat. It was built for use on a chain of small lakes in Sweden which are separated by waterfalls, and to get around these the steamboat has been fitted with wheels like those of a locomotive, and on leaving the water runs smoothly along on the land on trucks built for its accommodation. A canoe built on this same principle for use in the Adirondack lakes would be delightful. It could be paddled on the water and propelled after the fashion of the bicycle on the land, so saving the tourist a great deal of time and many wearisome "carries."

An ingenious resident of Bridgeport has worked out an invention which should become a great boon to unfortunates afflicted with deafness. It is briefly a device which makes the deaf hear. It is the same to the ears as glasses are to the eyes, and consists of a soft rubber disk and spring, so shaped that when inserted in the ear it will focus the waves of sound on the natural drum of the ear with such intensity, that the afflicted person receives impressions from the outside that nature had seemingly desired to withhold.

A patent bowling machine has just been tested in England for the use of cricketers in practice. It is found to be more unerring in its aim than most mortal bowlers, and takes the middle stump of expert batsmen as easily as though the batsman used a feather instead of his bat. The machine is sighted just as a gun is sighted, and the revolving iron hand from which the ball is thrown can bowl overhand or under-hand, according to the desires of the manipulator. It is not entirely beyond the possibilities that a mechanical batsman will soon be devised, so that in the next century boys and girls, and we ourselves, who will probably be the grandfathers of those boys and girls, may expect to be invited to witness a cricket game played entirely by automatons.

Some remarkably clever person in St. Petersburg has arranged and placed on exhibition a clock with a phonograph attachment that will repeat at an hour set, according to the possessor's desire, any orders or announcements as may be committed to it. This the New York *Tribune* rightly calls a great boon to the tired house mother, and adds that in the nursery the solemn time piece could be made to say, "Children, it is time to get up; dress quickly, and do not dawdle." In the kitchen, at an early hour, it would be ready with," Breakfast at eight sharp, Mary; don't forget"; and in the breakfast-room," You must start in ten minutes, or you will lose your train." The dial of this clock of the future is, we are told, a human face, from whose uncanny mouth comes the announcement of the hours as well as any directions that may be left with it.—*From Harper's Young People.*

Tobacco and Depopulation.

Thoughtful Frenchmen are coming to regard with some uneasiness the signs of stagnation, if not of actual decrease, in the population of their country. Under the heading of "*Le Tabac et la Depopulation de la France,*" M. Decroix, who is the founder of a society intended to check the abuse of tobacco, maintains that among the causes of such stagnation a prominent place must be assigned to the influence of tobacco. The arguments by which he seeks to fortify this opinion are ingenious, and he supports them by information contributed by various medical men, and by the vital statistics afforded by different departments of the country. Among the former there seems to be a consensus of opinion that tobacco consumed in excess exhibits in various degrees a constant weakening influence; and experiments by Dr. Depierras are quoted in order to show that the same rule holds good among the lower animals. In this case, the offspring of cocks and male rabbits exposed to the fumes of tobacco are said to have proved feebler and shorter-lived than those born under natural conditions. After comparing ten departments in which a greater, with ten others in which a less, amount of tobacco is consumed, M. Decroix, by summing up their collected disparities, has no difficulty in showing that in the former there is a marked excess of deaths, still-births, of divorces, and falling-off in the size of families. When, however, we compare the departments with each other separately, we frequently miss that evident connection between cause and effect which the author would wish us to expect, and it is clear that we must, in many cases, allow for the action of other influences in producing the result for which it is blamed. Under the circumstances all persons cannot agree with all the propositions advanced by M. Decroix. At the same time, it cannot be denied that the continued use of "the weed" is to be numbered among the forces opposed to a continuance of healthy life.—*New York Ledger.*

Artificial Production of Rain.

At the close of a paper read before the Electrical Section of the Franklin Institute, Professor Edwin Houston said that the following general conclusions might, in view of the present state of meteorological science, be properly drawn concerning the artificial production of rain: 1. That rain can never be made to fall at will by mid-air explosions on any part of the earth's surface, irrespective of the climatic conditions there existing. 2. That during certain meteorological conditions mid-air explosions may result in rainfall over extended areas. 3. That the liberation of energy necessary for such rainfalls is due not to mid air explosions, but to the energy stored up in the moist air from which the rain is derived. 4. That the meteorological conditions which must exist for the successful action of mid-air explosions would probably, in most, though not in all cases, themselves result in a natural production of rain. 5. That a comparatively high difference of electric potential between different parts of the air, or between the air and the earth, is possibly favorable when taken in connection with other meteorological conditions for artificial rain-making. 6. That an undirected mid-air explosion is not as likely to produce rain as an explosion in which the main tendency of the energy liberated is to cause a general up-rush of the air.

HOT-BLAST STOVE.

No. 469,830. George W. McClure and Carl Amsler, Pittsburgh, Pa. *Patented March 1st, 1892.* Fig. 1 shows in vertical central section the upper part, or dome, and the lower part of our improved hot-blast stove. The part of this figure at the lower right-hand corner is in section on the line *x x* of Fig. 2. Fig. 2 is a horizontal sectional view in four different section planes—viz., on the planes shown by the lines A A, B B, C C, and D D, respectively.

The stove as shown is divided into a number of concentric flues, of which 3 is the central flue of the stove, the base of which serves as the combustion-chamber, while the upper part terminates below the stove-crown 4 and communicates with an annular flue 5, formed by an outer cylindrical wall 6, which extends from the crown to the stove's base.

7 is an outer flue constituted by the annular space intervening between the walls 6 and 2. The flue 5 is divided into a number of parts by radial partition-walls 8, which serve to increase the heating-surface of the stove, and the flue 7 is also divided by an annular wall 9 and cross-partitions 10. The flues 5 and 7 are connected by ports 11 at the lower part of the stove. These ports 11 enter the middle of the flues, and in addition thereto there are other connecting-ports 11[1] at the sides of the ports 11, which insure even flow of the gas to all parts of the flue and prevent unequal distribution of the gas. All the radial walls in the outer flue 7 terminate above the level of the ports, so as to afford an open continuous flue chamber at the base of said flue.

12 is a gas-inlet port opening into the base of the flue 3.

13 is a gas-burner pipe adapted to discharge gas thereinto, and 14 is an air-inlet port through which air is admitted to support combustion of the gas.

15 is the hot blast main provided with a suitable valve 16 and leading from the base of the flue 3. This main is also provided with an air-port 17 for the inlet of air to assist in combustion of the gas.

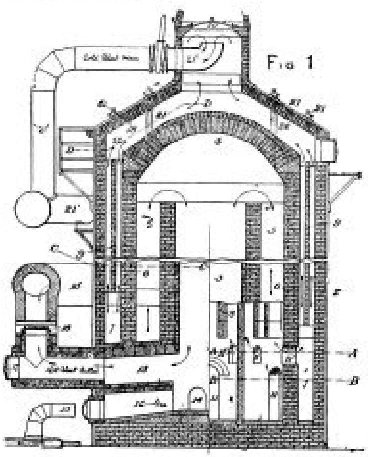

Fig 1

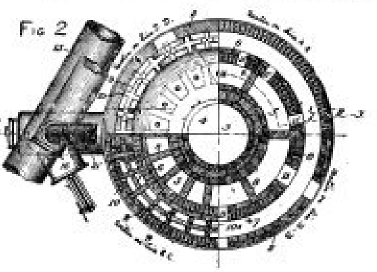

Fig 2

18 is a dome or arch which surmounts the outer wall 2 and is separate from the crown of the stove, so as to afford an intermediate flue or passage 22, connecting all the divisions of the outer flue 7 with a central stack-flue 19 for the exit of the products of combustion.

20 is a valve for closing the stack-flue, and 21[1] is the cold-blast-inlet pipe, which discharges into the stack-flue below said valve and is itself provided with a suitable controlling-valve by which the admission of air may be regulated.

21 21 are holes through which may be drawn chains attached to suitable brushes or scrapers in the flues.

The operation of the stove is as follows: To heat the flues the stack-flue valve 20 is opened, the valve of the hot-blast main is closed, and combustible gas is introduced into the gas-inlet 12. The gas, uniting with air admitted through the air-inlets, burns in the flue 3, ascends through this flue to the crown of the stove, then descends through the several divisions of the annular flue 5, and at the base thereof passes through the ports 11 and 11[1] into the outer flue 7, and ascends through the divisions of this flue, and finally passes through the flue 22 to the stack. When the flues have been heated in this manner to a sufficiently high degree, as in ordinary hot-blast stove practice, the gas and air inlets into the base of the flue 3 are closed, the stack-valve 20 is also closed, and the valves of the cold-blast pipe and hot-blast main are opened. The air then enters through the cold-blast main, descends through the flue 22, and passes in succession and in reverse direction to the movement of the burning gases (employed in heating) through all the flues, and passes off through the hot-blast valve 16 to the main 15.

GAS APPARATUS.

No. 472,077. Henry C. Rew, Chicago, Ill. *Patented April 5, 1892.* The coking chambers A are inclined so that the coal will feed downward toward the fire pot D by gravity. The chambers are made in pairs A and A[1]. Fig. 2 is a cross section, at right angles to Fig. 1 showing also two regenerators E, E[1]. Additional grates G G, are provided in the inclined floor of the coking-chambers to assist the coking of slow burning coal.

The operation of the apparatus is as follows: The fuel-chambers A, A[1], A[2], A[3], G, G, are first filled with coke or hard coal through the tight feeding apparatus H H, and the openings at the top are then tightly closed. The fuel is ignited in the base of chambers A A[1] and in the receptacles G G in the coking chambers. Air is supplied from a fan-blower through pipes and air-ports D, *d d*, to raise the fuel to incandescence. At the same time the exhauster is put in operation. The outlet-pipes being open, the primary products of combustion pass through flues L L[1] into the regenerators E E[1]. Heated air to burn the gases is supplied through pipes F, and the final burned products of combustion pass down through the regenerators E E[1] through outlet pipes and exhauster, and are discharged into the open air. This operation raises to incandescence the fuel in the steam-decomposing chambers A A[1] and in the combustion chambers G G located in the bases of the coking chambers. The heat generated by burning the primary products of combustion is stored in the regenerators. When the apparatus is properly heated, as seen through properly provided sight-holes, the air supply pipes are closed and steam is simultaneously admitted to the base of one of the regenerators, by opening the valve in pipe J, which is connected with outlet-pipe O. The valve *o* in outlet-pipe O is then closed, which directs the steam upward through regenerator E and through the flue L highly superheated, into and down through the incandescent fuel in chamber A, in which it is partially decomposed. The resulting water gas and undecomposed steam then pass through the flue C into and up through the incandescent fuel in chamber A[1] and the resulting water gas (the steam being thus completely decomposed) passes into the heated regenerator E[1]. At the same time the valve in pipe A[4] connecting the tops of the coking-chambers A[2] A[3] is wholly or partially opened to permit the passage of the coal-gas generated in the coking-chamber A[2] through said pipe into chamber A[3] and thence through space A[5] into the regenerator E[1] without passing through the incandescent fuel. A mixture of water-gas and volatile hydro-carbons distilled from soft coal are thus mingled and passed into the regenerator E[1], which are converted into a fixed illuminating gas, consisting of carbonic oxide and light carbureted hydrogen by passing down through the heated refractory material. The gas is drawn from the base of the chamber E through pipe O through the condenser, washer, and exhauster. The valve controlling the outlet-pipe for the final burned products is then closed and the valve to the gas-holder is simultaneously opened by a lever connected with both valves, thus directing the combustible gas into its proper holder. When the heat in the apparatus has been reduced by the super-heating and decomposition of the steam and by the fixing of the gases, the steam is shut off and the air is again admitted to the combustion and coking chambers for heating up and the valve in outlet-pipe O is opened. It is thus seen that the operations of heating up and of making gas are alternate, the exhauster being kept steadily in operation.

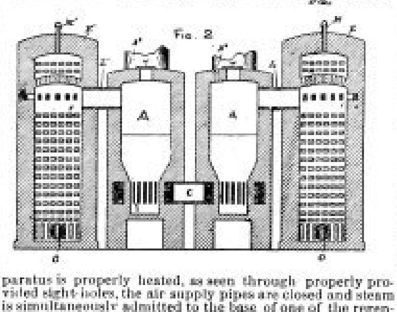

Fig. 2

ROTARY PUMP.

No. 471,280. Benjamin F. Taber, Buffalo, N. Y. *Patented March 22, 1892.* Fig. 1 is a vertical section parallel with the driving shaft, and Fig. 2 is a cross-section on the line *z z* of Fig. 1.

A represents the casing of the pump, having the usual suction chamber B and discharge chamber C.

D is the rotating cylinder or carrier, arranged eccentrically in the casing, and *e* is the abutment, against which the adjacent side of the cylinder runs.

F are the movable pistons, attached to the cylinder and arranged in pockets or recesses G, formed in the cylinder. These pistons each consist of a curved longitudinal plate *f*, pivoted at its inner edge to the front wall of its pocket and provided at its outer free edge with an outwardly extending bucket or receptacle f^2. These buckets are arranged on the front or advancing side of the pistons, and each bucket is composed of a longitudinal bottom plate f^2, arranged at an an angle to the piston plate *f* and curved concentric with the pivot of the piston, and plates f^3, and a longitudinal front plate f^4. The pistons with their buckets are free to recede inwardly into their pockets in passing the abutment *e* and to move outwardly, so that the outer edges of their buckets run in contact with the inner surface of the case. The pockets G are made of the proper form to receive the bucket pistons. The latter are provided at their inner edges with cylindrical knuckles f^5, which are seated in correspondingly shaped sockets *g*, formed in the front ends of the pockets. The interlocking hooks of the knuckles and sockets are so arranged relatively to each other that the knuckles will be confined in the sockets in all positions of the pistons, so that the pistons must be attached to the cylinder before inserting the latter in the casing by swinging the pistons outwardly beyond their normal position.

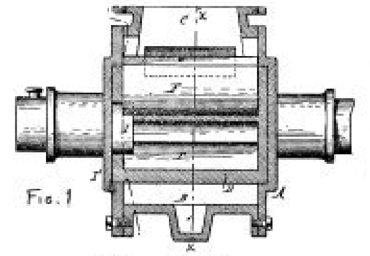

Fig. 1

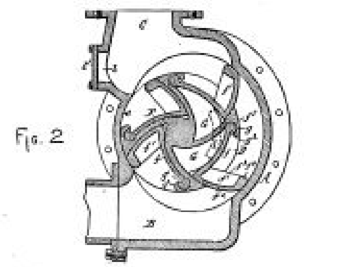

Fig. 2

I represents a stationary cam or projection arranged on one of the heads I[1] of the pump casing on the side of the cylinder opposite the abutment *e*, and whereby the swinging pistons are positively moved outwardly against the inner wall of the case after passing the abutment and in descending on the opposite side of the cylinder. The arms or solid portions *k* of the cylinder, which separate the pockets G, are provided with notches or recesses k^1, arranged in the path of the cam I, whereby the cylinder clears the cam. The shaft of the cylinder extends through the heads of the casing and is provided with the usual pulley for driving the cylinder. The pistons upon reaching the upper side of the cylinder and clearing the cam I drop into their pockets by gravity, and they are retained therein by the abutment *e* until they have passed below the latter. They then gradually move outwardly by gravity and in ascending on the opposite side of the cylinder ride over the cam I, whereby they are positively moved outwardly until the outer edges of their buckets bear against the inner surface of the pump casing. In passing from the suction chamber to the discharge chamber the pistons elevate the liquid and expel the same through the discharge chamber in the usual manner. Foreign substances, such as sand, stones, nails, etc., which are too heavy to be carried out by the current of liquid, lodge in the cupshaped part of the buckets, and remain there until removed by hand. A hand hole *l* is provided for that purpose. Thus they are prevented from jamming in the working parts of the pump and damaging the machine. The pump is designed for pumping thick and dirty liquids or sludge.

PROSPECTING DRILL.

No. 473,549. William Gehring, San Diego, California. *Patented April 26, 1892.* This is a small portable machine intended for miscellaneous work such as prospecting, drilling, chiseling, or pulverizing test samples. The bit T is attached to the end of the piston rod P, by a suitable socket (not shown) and different tools are used for various purposes. A square-ended tool is used for crushing or pulverizing ores. The piston Q has its edges beveled as shown, and operates two small tappet valves *c*, located in the upper side of the cylinder, which open the ends of the steam chest 2 and 3, Fig. 2, to the exhaust alternately, through the ports *j* and N, shown clearly in Fig. 3. This figure is a top view of the joint or face between the steam chest and the main cylinder A. The valve piston a^1 moves a small D valve *f*, across the ports *d*, d^1 and *z*, of which *z* is the exhaust port. Steam or compressed air enters at C and is controlled by a throttle valve D. The back head of a cylinder is provided with an adjustable leg G, by which the machine may be inclined as desired. The cylinder has also a boss K and socket L, by which it may be attached to a socket or post.

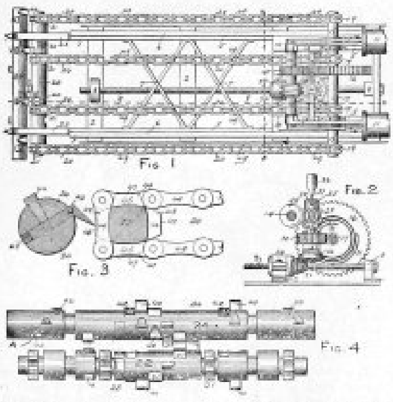
MINING MACHINE.

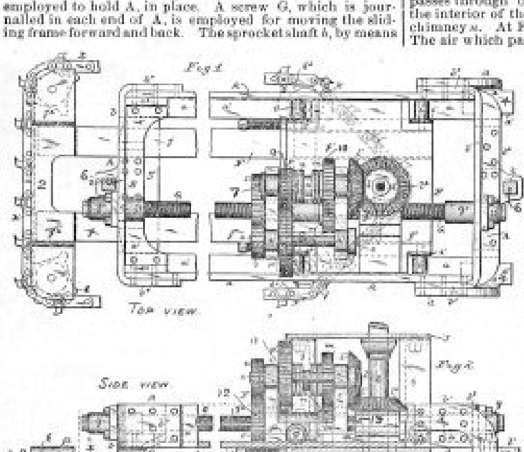
No. 473,604. Archibald Bailey, Philipsburgh, Pa. *Patented April 26, 1892.* This machine employs a rotary cutter bar 24 which is driven by a peculiar driving shaft 22 located close behind it. Fig. 1 is a top view of the machine; Fig. 2 is a partial elevation showing the feed works; Fig. 3 shows how the cutters pass by the driving chains, and Fig 4 shows the construction of the cutter shaft and driving shaft. The driving shaft 22 is driven by four chains 20, from the rear chain shaft 17. The sprocket wheels employed are shown in detail in Fig. 3. Power is supplied by the engines 11 which drive the crank shaft 14 and gears 15 and 16. The feed works are driven by a pair of bevel gears 32, 33, and a vertical shaft 25. The engine shaft carries a worm 29 which turns the worm wheel 28, and the gear-wheel 16 is provided with a spiral thread 31 on its side, which turns the worm wheel 30 in the opposite direction from 28. By means of



the clutch 35 either 28 or 30 may be coupled to the shaft 25, and so rotate the nut 34 in either direction. The screw 9 is stationary, and is fastened to the main frame. The engines and all the moving parts are attached to the sliding frame 5, 5, 7, and 23. The bars 5 slide in between the flanges of channel bars 6, which constitute the side bars of the main frame. The principal novelty is in the means used to drive the cutter bar. The cutters 42 are arranged in spiral order, as shown in Fig. 4. Behind each cutter is a single cog or gear tooth, and a corresponding set of cogs are formed on the driving shaft 22. Almost any number of teeth may be employed, thus making the motion very smooth. Clogging the teeth by dirt is impossible. As shown at A in Figs. 3 and 4, cutters may operate directly in front of the chains without touching them. The driving shaft is spotted or flattened off opposite each cutter to allow the cutter to project as much as possible from its shaft.

MINING MACHINE.

No. 472,363. Adam Kiel and Anton R. Westerdahl, Pittsburgh, Pa. *Patented April 5, 1892.* In its general features this machine resembles the one illustrated in the June number of The Colliery Engineer by the same inventors. The cutters are attached to a chain K which runs around the front cross-bar 2, around the guide pulley 3 and sprocket-wheel H. The sprocket-wheel is keyed on the lower end of a vertical shaft *h*, which is driven by a motor attached to the plate J. The chain is thus carried very close to the floor—as low in fact as may be desired. The main frame A stands above the sliding frame F, and rests on three feet—two, 4, 4, being at the rear, and one 5, at the front end. The bearing of 5, is as wide as the spread of the cutter chain will permit. The sides of frame A are made of angle bars, and the carriage which supports the motor and gearing is provided with rollers *i* which bear of the flanges of the side bars of A. Two jacks (shown in section at 6) are employed to hold A, in place. A screw G, which is journalled in each end of A, is employed for moving the sliding frame forward and back. The sprocket shaft *h*, by means



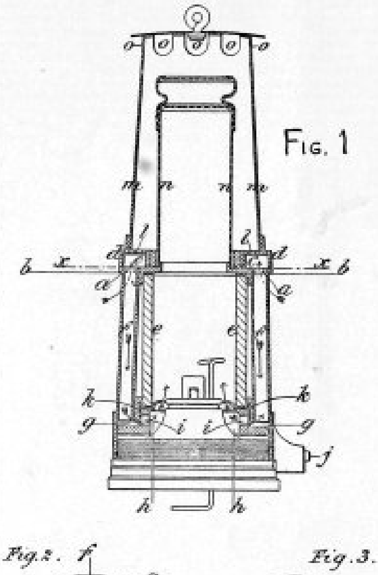
of bevel gears, drives a shaft 7, which carries a clutch *s*, and two loose pinions 9 and 10. Wheel 10 gears directly with a pinion 11, mounted on the screw G, and which has a feather engaging the slot in the screw. Wheel 9 meshes with an intermediate on the shaft 8 and drives a wheel 12 which also serves to drive the screw G in the opposite direction from 11, and at much lower speed. The slow speed is used for cutting and the fast speed for backing out.

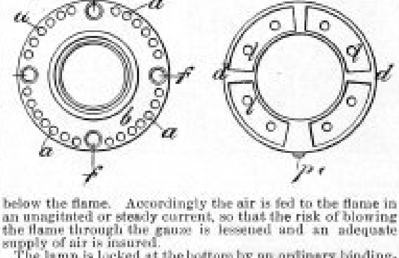
Either one is brought into use by coupling the clutch *s*, with pinion 9 or 10. The nut for the screw is formed in the boss 13, which also provides a bearing for the sprocket shaft.

SAFETY-LAMP.

No. 472,098. Lewis Noah Williams, Aberdare, England. *Patented April 5, 1892.* This invention consists of an improved method of supplying air to a miner's safety-lamp. In the accompanying drawings, Fig. 1 represents a part vertical section of a miner's safety-lamp constructed in accordance with this invention.

The air whereby the flame is fed with oxygen enters the lamp by orifices *a*, provided in the top ring *b* as seen more particularly at Fig. 2, which represents a plan of the top ring on and above the line *x x*, Fig. 1. The orifices *a* communicate with the annular space *c* in the ring *d* surmounting the glass *e*. Thence by the hollow pillars *f* the air is conducted to the space *g*, provided around the ring *h*, on which the glass *e* rests. From the space *g* the air is admitted by the orifices *i*, guarded by the band of gauze *k*, to the burner at a level





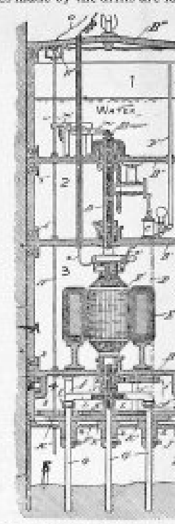
below the flame. Accordingly the air is fed to the flame in an unagitated or steady current, so that the risk of blowing the flame through the gauze is lessened and an adequate supply of air is insured.

The lamp is locked at the bottom by an ordinary binding-screw *j*, by which the outer shell is clamped to the oil-chamber.

Surplus air entering the annular space *c* in the ring *d* passes through orifices *l* into the space existing between the interior of the shield or bonnet *m* and the usual gauze chimney *n*. At Fig. 3 is shown a view of the ring *d* inverted. The air which passes by the orifices *l* into the space between the shield and the gauze chimney *n* escapes with the products of combustion through the apertures *o* at the top of the lamp.

SHAFT SINKING APPARATUS.

No. 473,570. Fulton Gardner, Chicago, Ill. *Patented April 26, 1892.* This apparatus is designed to cut a circular shaft of any desired diameter, having its walls smooth and straight. The drawing is a vertical section through the apparatus, in place in a shaft. The mechanism is encased in a circular shell A, which is divided into five sections. Section 1 is a water tank, section 2 contains a pump which takes up the water from the bottom of the hole, by a pipe P, and delivers it to the tank 1. Section 3 contains an electric motor which is employed to turn the pump in section 2, and to operate the drills. Sections 4 contains the gearing by which the motion is taken from the motor shaft D, and transmitted to the rotary drills G, and to the large circular cutter I. The head B is firmly attached to the lowest head F by several posts *f*. It is also made with a large groove 6 around its rim. The cutter shell I is attached to a ring 7, which runs between the heads F and B, and has internal gear teeth 8 around its interior; by which it is driven by one of the gang of gears K. The ring is also supported by rollers in the groove 6. The cutter I leaves the rock inside it standing as a core, and the drills G bore holes by which the core may be readily broken up by blasting. Water is supplied to the drills by a pipe running down through the shaft D and coupling by a swivel joint with the distributing pipe L. Each drill is hollow. The water is controlled by a valve M at the top of the shaft D. A "feeler" rod N extends into section 5, and when it touches the bottom of the hole it shuts the valve M, and touches an electric button N^1 on the top head, which rings a bell at the top of the shaft, and notifies the operator to hoist out the apparatus. The apparatus is lifted by a rope and ordinary derrick, and when it is removed from the shaft, the holes made by the drills are loaded and fired. The

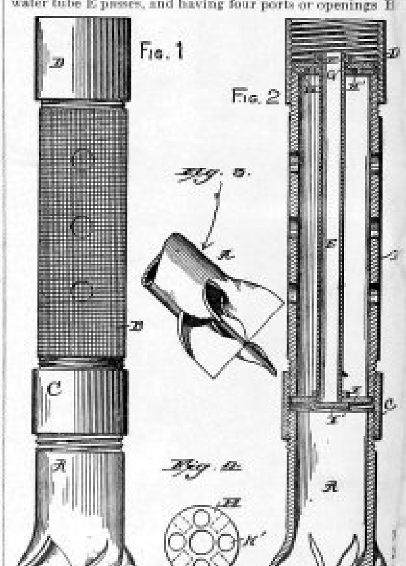


effect of the shots does not extend beyond the cut made by the cutter I, consequently the sides are left smooth, and the shaft is easily kept straight.

HYDRAULIC WELL DRILL.

No. 470,593. Charles H. Oxley, Norfolk, Nebraska. *Patented March 8, 1892.* This drill is intended for boring wells for water in earth, etc. The drill tube is provided with a hollow auger point A, constructed of the form shown, so that the water can pass through it, its upper tubular end being formed with a screw thread, while the lower end of this hollow cutting-point is enlarged and divided by equally distant slits, the sections thus formed being twisted so that their straight free lower ends meet in radial lines extending at right angles to each other, as clearly shown in the drawings. To the upper end of this auger is connected by a coupling C the screen tube B of the usual construction and the upper end of this screen is connected by a coupling D with the lower end of the well-tube when the well-point is to be used.

E indicates a water tube, on the lower end of which is secured a circular valve-plate I, the central opening of which is closed under upward pressure by a downwardly opening valve I^1. The valve plate I is of such size that it will fit against the lower end of the screen tube B, and upon the upper end of this tube fits a valve-plate H, having a central aperture through which the upper end of the water tube E passes, and having four ports or openings H^1



formed in it as shown. Upon the upper side of the valve plate H rests a leather valve G, and the water-tube and valves are all held firmly in position by a binding nut F. The valve-plates H and I are preferably formed of brass, so as to be non-corrosive.

In operation the motor liquid or water used in sinking the drill, is forced from the surface by a force-pump through the well-tube, when its downward pressure closes the valve G and forces it to descend through the central water-tube E, when it will open the valve I^1 at the lower end thereof and be forced out through the hollow auger point A, thus removing all dirt from the auger and passing up to the surface around the outside of the well-tube. When the desired water is reached by the boring-auger the force-pump is stopped and the pressure of the water from below will close the valve I^1, thereby preventing sand, &c., from passing up through the central tube E, the water entering the well passing up through the screen tube B, opening the valve G at the upper end thereof and rising up through the well tube, as will be clearly understood.
